Many conditions of a system do not correspond to any equilibrium thermodynamic state. Suppose a gas is confined by a piston in a cylinder with volume V_1 (thermodynamic state A). If the piston is abruptly pulled out to increase the volume to V_2 (Fig. 12.2), chaotic gas currents arise as the molecules begin to move into the larger volume. These intermediate stages are not thermodynamic states, because

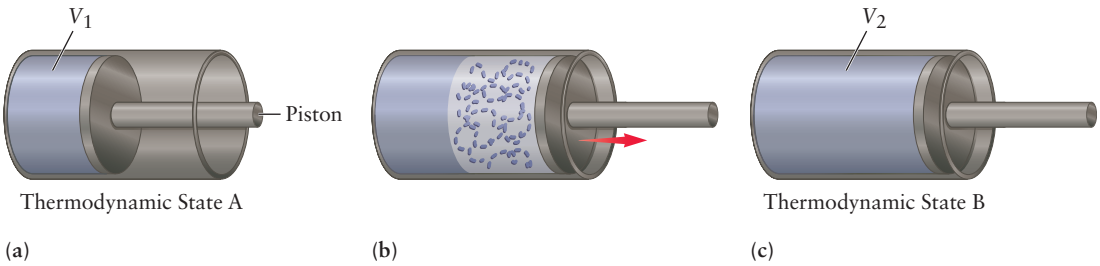

FIGURE 12.2 Stages in an irreversible expansion of a gas from an initial state (a) of volume V_1 to a final state (c) of volume V_2. In the intermediate stage shown (b), the gas is not in equilibrium; because of turbulence, pressure and temperature cannot be defined.

such properties as density and temperature are changing rapidly through space and in time. Eventually, the currents cease and the system approaches a new equilibrium thermodynamic state, B. States A and B are thermodynamic states, but the conditions in between cannot be described by only a few macroscopic variables, and therefore are not thermodynamic states. Such a process is called **irreversible.** An irreversible process cannot be represented as a path on a thermodynamic surface (as in Fig.12.1), because the intermediate stages are not thermodynamic equilibrium states and thus do not correspond to points on the equation-of-state surface.

In contrast, a **reversible process** proceeds through a continuous series of thermodynamic states, and thus can be shown as a path on the equation-of-state surface. The term reversible is used because an infinitesimal change in external conditions suffices to reverse the direction of motion of the system. For example, if a gas is expanded by slowly pulling out a piston, only a tiny change in the force exerted from the outside is required to change the direction of motion of the piston and begin to compress the gas. Such a process is an idealization, because the final equilibrium state would be reached only after an infinite length of time; therefore, such a process could never occur in a finite time. If a real process is conducted slowly enough and in sufficiently small steps, the real (irreversible) process can be approximated by an idealized limiting reversible process. A gas confined inside a piston–cylinder assembly will experience an irreversible compression when a kilogram of sand is suddenly dropped onto the piston. The same compression can be achieved (almost) reversibly by transferring the same kilogram of sand onto the piston one grain at the time.

An infinite number of reversible paths can be identified between any two thermodynamic states A and B. Two of them shown in Figure 12.1 could be realized by slowly changing the values of T and V in the proper sequence by manipulating the apparatus in the surroundings. We use such reversible paths throughout this textbook as a tool for calculating changes in properties caused by processes.

Certain properties of a system, called **state functions,** are uniquely determined by the thermodynamic state of the system. Volume, temperature, pressure, and the internal energy, U, are examples of state functions. The Greek letter delta (Δ) is used to indicate *changes* in the value of state functions in a thermodynamic process. Thus, $\Delta V = V_{\text{final}} - V_{\text{initial}}$ (or $V_f - V_i$) is the change in volume between initial and final states, and $\Delta U = U_{\text{final}} - U_{\text{initial}}$ is the corresponding change in internal energy. Because U, V, and T are all state functions, the value of ΔU (or ΔV or ΔT) depends only on the initial and final states in the process. The same change in any of these state functions will be measured no matter which path (reversible or irreversible) is followed between any given pair of thermodynamic states. *The change in any state function between two states is independent of path*. The converse statement is also true: If the change in a property of a system is independent of path, the property is a state function. Figure 12.3 illustrates two different paths that connect a given initial state and a common final state.

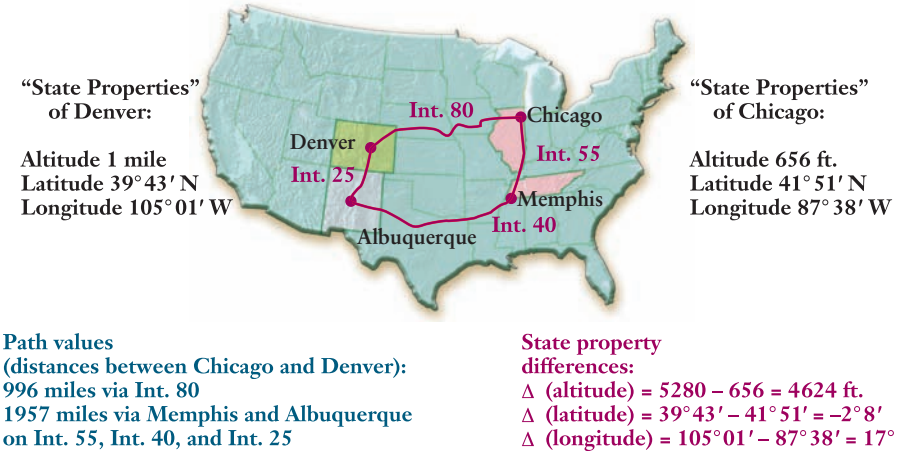

FIGURE 12.3 Differences in state properties (such as the difference in altitude between two points) are independent of the path followed. Other properties (such as the total distance traveled) depend on the particular path.

12.2 THE FIRST LAW OF THERMODYNAMICS: INTERNAL ENERGY, WORK, AND HEAT

The first law of thermodynamics (which is stated at the end of this section) relates the energy change in a thermodynamic process to the amount of work done on the system and the amount of heat transferred to the system. It is first necessary to examine the ways in which amounts of heat and work are measured to understand the significance of this law. You will see that heat and work are simply different means by which energy is transferred into or out of a system.

Work

The mechanical definition of **work** is the product of the external force on a body times the distance through which the force acts. If a body moves in a straight line from point r_i to r_f with a constant force, F, applied along the direction of the path, the work done on the body is

$$w = F(r_f - r_i) \qquad \text{(force along direction of path)}$$

To illustrate how work can change the energy of a system, we will examine the relation between work and energy in an ordinary mechanical system.

As the first example, consider a block of mass, M, moving with initial velocity v_i along a frictionless surface. We know that a force acting on an object increases the velocity, and therefore the kinetic energy of the object. In the following derivation, we show how the kinetic energy of an object changes when work is done on it. If a constant force, F, is exerted on it in the direction of its motion, it will experience a constant acceleration, $a = F/M$. After a time, t, the velocity of the block will have increased from v_i to v_f, and its position will have changed from r_i to r_f. The work done on the block is

$$w = F(r_f - r_i) = Ma(r_f - r_i)$$

The distance traveled, $r_f - r_i$, is given by the average velocity, in this case $(v_i + v_f)/2$, multiplied by the elapsed time, t:

$$r_f - r_i = \left(\frac{v_i + v_f}{2}\right)t$$

When the acceleration is constant, it is equal to the change in velocity, $v_f - v_i$, divided by the elapsed time:

$$a = (v_f - v_i)/t$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Substituting both of these results into the expression for the work done gives

$$w = M\left(\frac{v_f - v_i}{t}\right)\left(\frac{v_i + v_f}{2}\right)t$$

$$= \frac{M}{2}(v_f - v_i)(v_f + v_i)$$

$$= \frac{M}{2}v_f^2 - \frac{M}{2}v_i^2$$

$$= \Delta E_{kin}$$

The expression on the right side of the equations is the change in kinetic energy, $\frac{1}{2}Mv^2$, of the block. For this idealized example with a frictionless surface, the work done in moving the block from r_i to r_f is equal to the change in energy (in this case, kinetic) of the block.

As a second mechanical example, consider the work done in lifting an object in a gravitational field. To raise a mass, M, from an initial height, h_i, to a final height, h_f, an upward force sufficient to counteract the downward force of gravity, Mg, must be exerted. The work done on the object in this case is

$$w = Mg(h_f - h_i) = Mg\Delta h = \Delta E_{pot}$$

This is the change in *potential* energy, Mgh, of the object, showing once again that the mechanical work done in moving a body is equal to the change in energy of the body.

One important kind of mechanical work in chemistry is **pressure–volume work,** which results when a system is compressed or expanded under the influence of an outside pressure. Imagine that a gas has pressure P_i and is confined in a cylinder by a frictionless piston of cross-sectional area A and negligible mass (Fig. 12.4). The force exerted on the inside face of the piston by the gas is $F_i = P_iA$, because pressure is defined as force divided by area. If there is a gas on the outer side of the piston with pressure P_{ext} ("ext" for "external"), then if $P_{ext} = P_i$, the piston will experience no net force. If P_{ext} is increased, the gas will be compressed, and if it is decreased, the gas will expand. Consider first the case in which the external force is less than the initial force exerted by the gas, P_iA. Then the gas will expand and lift the piston from h_i to h_f. The work in this case is

$$w = -F_{ext}(h_f - h_i)$$

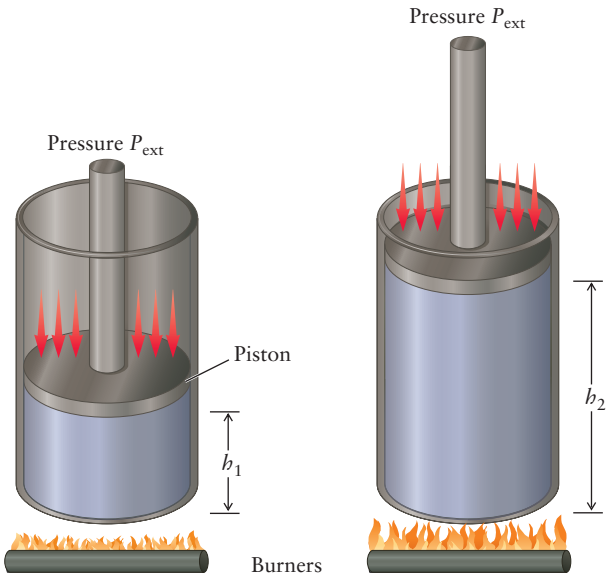

FIGURE 12.4 As the gas inside this cylinder is heated, it expands, pushing the piston against the pressure P_{ext} exerted by the gas outside. As the piston is displaced over a distance $h_f - \Delta h_i = \Delta h$, the volume of the cylinder increases by an amount $A\,\Delta h$, where A is the surface area of the piston.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The negative sign is inserted because the force from the gas outside opposes the direction of displacement of the piston during expansion of the gas inside the cylinder. This is rewritten as

$$w = -P_{ext}\, A\Delta h$$

The product $A\Delta h$ is the volume change of the system, ΔV, so the work is

$$w = -P_{ext}\, \Delta V \qquad [12.1]$$

For an expansion, $\Delta V > 0$, thus $w < 0$ and the system does work; it pushes back the surroundings. For a compression (by making $P_{ext} > P_i$), work is done *on* the system; it is pushed back by the surroundings. Again, $w = -P_{ext}\Delta V$, but now $\Delta V < 0$, so $w > 0$. If there is no volume change, $\Delta V = 0$, and no pressure–volume work is done. Finally, if there is no mechanical link to the surroundings (that is, if $P_{ext} = 0$), then once again no pressure–volume work can be performed because the volume is not changed.

If the pressure P_{ext} is expressed in pascals and the volume in cubic meters, their product is in joules (J). These are the International System of Units (SI) units for these quantities. For many purposes, it is more convenient to express pressures in atmospheres and volumes in liters; therefore, work has the unit liter-atmospheres (L atm). The two work units are related by

$$1 \text{ L atm} = (10^{-3} \text{ m}^3)(1.01325 \times 10^5 \text{ kg m}^{-1} \text{ s}^{-2}) = 101.325 \text{ J}$$

EXAMPLE 12.1

A cylinder confines 2.00 L gas under a pressure of 1.00 atm. The external pressure is also 1.00 atm. The gas is heated slowly, with the piston sliding freely outward to maintain the pressure of the gas close to 1.00 atm. Suppose the heating continues until a final volume of 3.50 L is reached. Calculate the work done on the gas and express it in joules.

Solution

This is an expansion of a system from 2.00 to 3.50 L against a constant external pressure of 1.00 atm. The work done on the system is then

$$w = -P_{ext}\,\Delta V = -\,(1.00 \text{ atm})(3.50 \text{ L} - 2.00 \text{ L}) = -1.50 \text{ L atm}$$

Conversion to joules gives

$$w = (-1.50 \text{ L atm})(101.325 \text{ J L}^{-1} \text{ atm}^{-1}) = -152 \text{ J}$$

Because w is negative, we see that -152 J of work was done *on* the gas. Put another way, $+152$ J of work was done *by* the gas as it expanded against atmospheric pressure.

Related Problems: 1, 2

Internal Energy

In the two simple mechanical cases discussed earlier, we saw how performing work on an object changes the amount of two types of energy: the kinetic energy of a moving object and the potential energy of an object in a gravitational field. In the same way, performing work can change the amount of energy in more complex cases. A third type of energy, less apparent but equally important, is **internal energy,** defined as the total energy content of a system arising from the potential energy between molecules, from the kinetic energy of molecular motions, and from chemical energy stored in chemical bonds. Potential energy between molecules includes the lattice energy of solids and the attractive and repulsive interactions between molecules in gases and liquids. Kinetic energy appears in the translation and

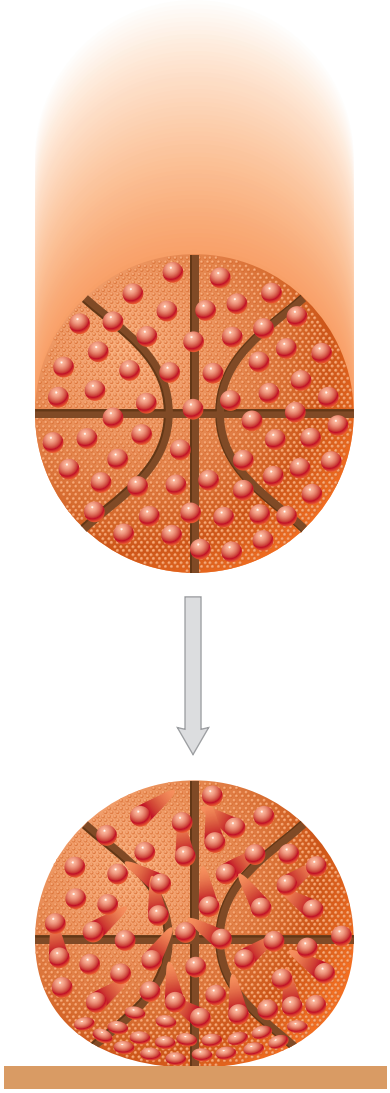

FIGURE 12.5 A ball dropped from a height increases its internal energy on impact with the ground. After impact, the molecules near the surface of the ball are pushed against one another, increasing the potential energy between the molecules. As the ball bounces, the molecules readjust their positions, after which they move a little faster. The kinetic energy of the molecules is higher than it was just before impact with the ground.

the internal motions of individual molecules (Fig. 12.5). Gas molecules are in a constant state of motion (see Section 9.5) even when no overall gas flow is taking place in the container; the same is true of molecules in liquids and solids. Example 12.1 illustrates how performing work can change the internal energy of a system. In this example, the system reduced its internal energy by performing +152 J of work against the surroundings. Had the gas been compressed instead of expanding, the internal energy of the system would have increased by the amount of work done on it. *We conclude that P–V work is a means of changing the internal energy of a macroscopic system through purely mechanical interaction between the system and its surroundings.*

Heat

Now, how do we describe the role of heat in the process in Example 12.1? After all, heating the gas caused it to expand, which enabled it to move the piston and do work on the surroundings. The heater in Figure 12.4 has no mechanical "moving parts," yet it set in motion a train of events that led to a mechanical result. To explain this result, we interpret *heat as a means of increasing the internal energy of a system without mechanical interaction.* Justification for this interpretation is provided later in this chapter.

The amount of energy transferred between two objects initially at different temperatures is called **heat,** or **thermal energy.** When a hot body is brought into contact with a colder body, the two temperatures change until they become equal. If a piece of hot metal is plunged into a container of water, the temperature of the water increases as its molecules begin to move faster, corresponding to an increase in the internal energy of the water. This process is sometimes described as the "flow" of heat from the hotter to the colder body. Although this picture is useful, it is based on the antiquated (and erroneous) notion that heat is a sort of fluid contained in matter.

The idea of heat flow has inspired methods for measuring the amount of energy transferred as heat; this branch of science is called **calorimetry.** One simple way is to use an **ice calorimeter** (Fig. 12.6), which consists of a bath containing ice and water, well insulated to prevent heat transfer to the surroundings. If heat is transferred to the bath from the system, some of the ice melts. Because a given mass of water has a smaller volume than the same mass of ice, the total volume of the ice–water mixture decreases as heat enters the bath. If twice as much heat is transferred, twice as much ice will melt and the volume change will be twice as great. The amount of heat transferred is determined from the change in volume of the contents of the calorimeter. Heat transferred from the ice bath *into* the system causes water to freeze and *increases* the total volume of the ice bath.

More contemporary versions of calorimetry use the fact that when heat is transferred to or removed from a substance in a single phase at constant pressure, the temperature changes in a reproducible way. The **specific heat capacity** of a material is the amount of heat required to increase the temperature of a 1-g mass by 1°C. If twice as much heat is transferred, the resulting temperature change will be twice as large (provided the specific heat capacity itself does not change appreciably with temperature). Thus, the temperature change of a fixed amount of a given substance is a measure of the thermal energy transferred to or from it. This is described by

$$q = Mc_s\Delta T \qquad [12.2]$$

where q is the heat transferred to a body of mass M with specific heat capacity c_s to cause a temperature change of ΔT.

Because heat, like work, is energy in the process of being transferred, the appropriate unit for it is also the joule. Historically, however, the connections among

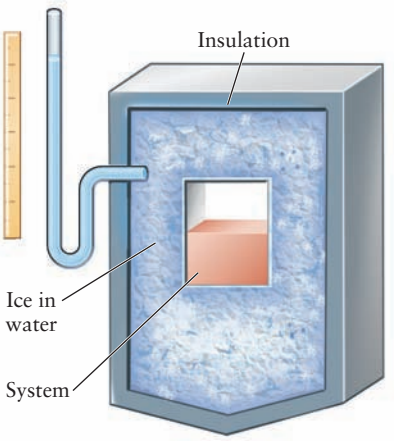

FIGURE 12.6 An ice calorimeter. As the ice melts, the volume of the ice–water mixture decreases, an effect that can be read off the scale on the left.

work, heat, and energy were not appreciated until the middle of the 19th century, by which time a separate unit for heat, the calorie, was already well established. One calorie was defined as the amount of heat required to increase the temperature of 1 g water from 14.5°C to 15.5°C (or, in other words, the specific heat capacity of water, c_s, at 15°C was *defined* as 1.00 cal K^{-1} g^{-1}).

The equivalence of heat and work as means of energy transfer was suggested in 1798 by Benjamin Thompson, Count Rumford. In the course of his work as military advisor to the King of Bavaria, Thompson observed that the quantity of heat produced in boring cannons was proportional to the amount of work done in the process. Moreover, the operation could be continued indefinitely, demonstrating that heat was not a "fluid" contained in the metal of the cannon. More quantitative measurements were conducted by the German physician Julius Mayer and by the English physicist James Joule. In the 1840s, these scientists showed that the temperature of a substance could be increased by doing work on the substance, as well as by adding heat to it. Figure 12.7 shows an apparatus in which a paddle, driven by a falling weight, churns the water in a tank. Work is performed on the water, and the temperature increases. The work done is $-Mg\,\Delta h$, where Δh is the (negative) change in the height of the weight and M is its mass. The experiment is conducted in an insulated container, so no heat enters the container or leaks out to the surroundings. Because all this work goes to increase the water temperature, the specific heat capacity of the water in *joules* per gram per degree is equal to the quantity of work done divided by the product of the mass of water and its temperature increase.

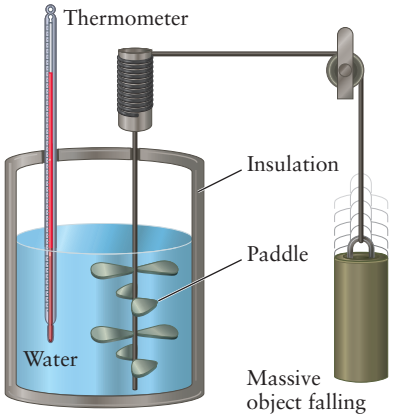

FIGURE 12.7 The falling weight turns a paddle that does work on the system (the water), causing an increase in its temperature.

EXAMPLE 12.2

Suppose a 10.00-kg mass drops through a height difference of 3.00 m, and the resulting work is used to turn a paddle in 200.0 g water, initially at 15.00°C. The final water temperature is found to be 15.35°C. Assuming that the work done is used entirely to increase the water temperature, calculate the conversion factor between joules and calories.

Solution

The total work done is

$$w = -Mg\Delta h = -(10.00\text{ kg})(9.807\text{ m s}^{-2})(-3.00\text{ m}) = 294\text{ J}$$

The heat (in calories) required to increase the water temperature by the same amount is

$$q = Mc_s\Delta T = (200.0\text{ g})(1.000\text{ cal K}^{-1}\text{ g}^{-1})(0.35\text{ K}) = 70\text{ cal}$$

Because the work done has the same effect on the water as direct transfer of heat, these two expressions can be set equal to each other, giving

$$70\text{ calories} = 294\text{ joules}$$

$$1\text{ calorie} \approx 4.2\text{ joules}$$

Related Problems: 3, 4

These and other experiments eliminated the need for the calorie as an independent unit, and the calorie is now *defined* as

$$1\text{ cal} = 4.184\text{ J} \quad \text{(exactly)}$$

This book uses the joule as the primary unit for heat and energy. Because much of the chemical literature continues to use the calorie as the unit of heat, it is important to be familiar with both units.

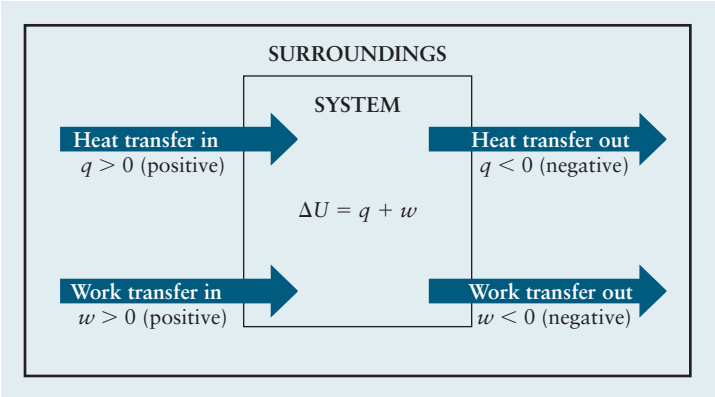
The First Law of Thermodynamics



Both heat and work are forms in which energy is transferred into and out of a system; they can be thought of as energy in transit. If the energy change is caused by *mechanical* contact of the system with its surroundings, work is done; if it is caused by *thermal* contact, heat is transferred. In many processes, both heat and work cross the boundary of a system, and the change in the internal energy, U, is the sum of the two contributions. We denote the internal energy by U to distinguish it from the sum of the potential and kinetic energy in a simple mechanical or electrical process, for which we use the symbol E throughout this book. This statement, called the **first law of thermodynamics,** takes the mathematical form[1]

$$\Delta U = q + w \qquad [12.3]$$

A system cannot be said to "contain" work or heat, because both "work" and "heat" refer not to states of the system but to *processes* that transform one state into another. In the Joule experiment shown in Figure 12.7, the work done on the water (the system) by the falling weight increased the temperature of the water. Work was performed on the system, and no heat was transferred; thus, the first law for this process takes the form $\Delta U = w$. The same change in state of the system can be achieved by transferring heat to the system without work being done; for this process, $\Delta U = q$. Because q and w depend on the particular process (or path) connecting the states, they are not state functions. But their sum, $\Delta U = q + w$, is independent of path; therefore, internal energy is a function of state. The fundamental physical content of the first law of thermodynamics is the following observation:

> *There exists a state function called internal energy represented by U whose changes* $\Delta U = q + w$ *are independent of path, although the values of q and w individually depend on the path of the process.*

We stated earlier that the laws of thermodynamics cannot be derived or proved; they are generalizations of the results of countless experiments on a tremendous

The first law of thermodynamics states that the change in internal energy in a process is the sum of the heat transfer and the work transfer. Both heat and work may be positive (energy gained by the system) or negative (energy lost by the system).

[1]Some books, especially engineering ones, define work as positive when it is done *by* the system. The reason is that many engineering applications focus on the work done by a particular heat engine; therefore, it is helpful to define that quantity as positive. Thus, the work is given by

$$w = P_{ext}\,\Delta V \text{ (engineering convention)}$$

and the first law reads

$$\Delta U = q - w \text{ (engineering convention)}$$

Although we do not use the engineering convention, you should check which convention is used when consulting other books.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

variety of substances. It is not possible even to "check" the first law by independently measuring ΔU, w, and q, because no "energy gauges" exist to determine energy changes ΔU. But what we *can* do is to measure w and q for a series of different processes connecting the same initial and final states. Every time, we find that their sum, $q + w$, is always the same.

In any process, the heat *added to* the system is *removed from* the surroundings; thus,

$$q_{sys} = -q_{surr}$$

In the same way, the work done *on* the system is done *by* the surroundings; thus,

$$w_{sys} = -w_{surr}$$

Adding these two and invoking the first law give

$$\Delta U_{sys} = -\Delta U_{surr}$$

Thus, the energy changes of system and surroundings have the same magnitude but opposite signs. The total energy change of the thermodynamic universe for a given process (system plus surroundings) is then

$$\Delta U_{univ} = \Delta U_{sys} + \Delta U_{surr} = 0 \qquad [12.4]$$

Our conclusion is that, in any process, the total energy of the thermodynamic universe remains unchanged; the total energy is conserved while it is exchanged between the system and the surroundings.

12.3 HEAT CAPACITY, CALORIMETRY, AND ENTHALPY

Section 12.2 defines specific heat capacity as the amount of heat required to increase the temperature of 1 g of material by 1 K. That definition is somewhat imprecise, because, in fact, the amount of heat required depends on whether the process is conducted at constant volume or at constant pressure. This section describes precise methods for measuring the amount of energy transferred as heat during a process and for relating this amount to the thermodynamic properties of the system under investigation.

Heat Capacity and Specific Heat Capacity

The **heat capacity, *C*,** is defined as the amount of energy that must be added to the system to increase its temperature by 1 K. The heat capacity is a property of the system as a whole and has units of J K^{-1}.

$$q = C\Delta T$$

Now consider a case in which two gaseous systems containing identical masses of the same substance are heated to produce identical changes in temperature. During the experiment, system 1 is held at constant volume, and system 2 at constant pressure. Which system absorbed more heat in these identical temperature changes? All the energy gained by system 1 contributed to increasing the temperature of the substance, and therefore the speed of the molecules, subject to the fixed volume. But in system 2, some of the energy gained was promptly lost as the system performed expansion work against the surroundings at constant pressure. Consequently, system 2 must absorb more thermal energy from the surroundings than

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

TABLE 12.1

Specific Heat Capacities at Constant Pressure (at 25°C)

Substance	Specific Heat Capacity ($J\ K^{-1}\ g^{-1}$)
$Hg(\ell)$	0.140
$Cu(s)$	0.385
$Fe(s)$	0.449
$SiO_2(s)$	0.739
$CaCO_3(s)$	0.818
$O_2(g)$	0.917
$H_2O(\ell)$	4.18

does system 1 to achieve the identical temperature change. Two independent heat capacity functions must be defined: C_P, the heat capacity at constant pressure, and C_V, the heat capacity at constant volume. For any system, C_P is greater than C_V. This difference can be quite large for gases. It is usually negligible for solids and liquids, because their only volume change at constant pressure is the small expansion or contraction on heating and cooling.

In thermodynamics, the *molar* heat capacities c_V and c_P (the system heat capacities C_V and C_P divided by the number of moles of substance in the system) are particularly useful: c_V is the amount of heat required to increase the temperature of 1 mol of substance by 1 K at constant volume, and c_P is the corresponding amount required at constant pressure. If the total heat transferred to n moles at constant volume is q_V, then

$$q_V = nc_V(T_2 - T_1) = nc_V\Delta T \qquad [12.5]$$

If an amount q_P is transferred at constant pressure, then

$$q_P = nc_P\Delta T \qquad [12.6]$$

provided that c_V and c_P do not change significantly between the initial and final temperatures. The *specific heat capacity* at constant V or constant P is the system heat capacity reported per gram of substance. Extensive tabulations of molar and specific heat capacities at constant volume and at constant pressure are available. The specific heat capacities of some common substances are listed in Table 12.1, and a more extensive tabulation of molar heat capacities at constant pressure is provided in Appendix D. We relate the heat capacity of a substance to its molecular structure in Section 12.5.

The importance of the heat capacity is illustrated by placing two objects initially at different temperatures into contact. Energy in the form of heat is exchanged between them until they reach a common temperature. If the two objects are insulated from the rest of the universe during the process, the amount of heat q_2 taken up by the cooler object is equal to $-q_1$, the amount of heat given up by the hotter object. As always, the convention followed is that energy transferred to an object has a positive sign; thus, q_2 is positive when q_1 is negative. This analysis is broadly applicable; a typical example follows.

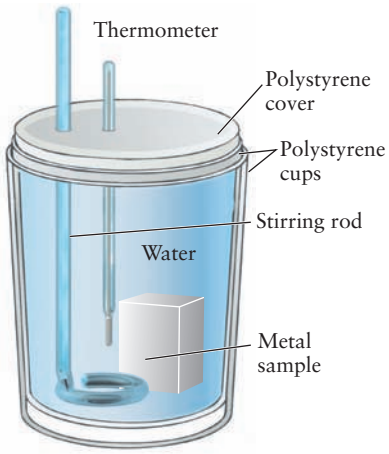

FIGURE 12.8 A Styrofoam cup calorimeter. As the piece of metal cools, it releases heat to the water. The amount of heat released can be determined from the temperature change of the water. The hot metal is the "system"; the water is the "surroundings." The Styrofoam cup wall prevents energy exchange with the remainder of the room and is the boundary of the "thermodynamic universe" for this problem.

EXAMPLE 12.3

A piece of iron weighing 72.4 g is heated to 100.0°C and plunged into 100.0 g water that is initially at 10.0°C in a Styrofoam cup calorimeter. Assume no heat is lost to the Styrofoam cup or to the environment (Fig. 12.8). Calculate the final temperature that is reached.

Solution

The "coffee cup calorimeter" operates at constant pressure determined by the atmosphere; therefore, we need specific heat data at constant pressure. Because the data involve masses, it is easier to work with specific heat capacities (see Table 12.1) than with molar heat capacities. If t_f is the final temperature (in degrees Celsius), then the equation for heat balance gives

$$M_1(c_{s1})\Delta T_1 = -M_2(c_{s2})\Delta T_2$$

$$(100.0\text{ g } H_2O)(4.18\text{ J °C}^{-1}\text{g}^{-1})(t_f - 10.0\text{°C}) =$$

$$-(72.4\text{ g Fe})(0.449\text{ J°C}^{-1}\text{g}^{-1})(t_f - 100.0\text{°C})$$

This is a linear equation for the unknown temperature t_f, and its solution is

$$418t_f - 4180 = -32.51t_f + 3251$$

$$t_f = 16.5°C$$

Note that specific heat capacities are numerically the same whether expressed in $J\ K^{-1}\ g^{-1}$ or $J\ (°C)^{-1}\ g^{-1}$ (because the degree Celsius and the kelvin have the same size). Converting 10.0°C and 100.0°C to kelvins and using specific heat capacities in units of $J\ K^{-1}\ g^{-1}$ gives $t_f = 289.7$ K, which is equivalent to the previous answer.

Heat Transfer at Constant Volume: Bomb Calorimeters

Suppose some reacting species are sealed in a small closed container (called a *bomb*) and the container is placed in a calorimeter like the one in Figure 12.9. The reaction is initiated by a heated wire inside the bomb. As the molecules react chemically, heat is given off or taken up, and the change in temperature of the calorimetric fluid is measured. Because the container is sealed tightly, its volume is constant and no pressure–volume work is done. Therefore, the change in internal energy is equal to the measured heat absorbed from the chemical reaction at constant volume:

$$\Delta U = q_V$$

Such experiments at constant volume are often inconvenient or difficult to perform. They require the use of a well-constructed reaction vessel that can resist the large pressure changes that occur in many chemical reactions.

Heat Transfer at Constant Pressure: Enthalpy

Most chemical reactions are carried out under constant (atmospheric) pressure conditions rather than at constant volume. It is desirable to identify a state function whose change in a process is equivalent to the heat transferred at constant pressure, q_P, just as is ΔU is equivalent to q_v.

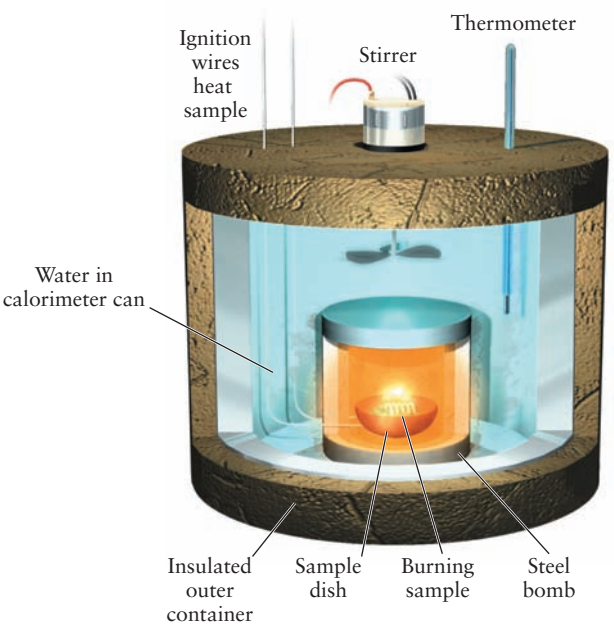

FIGURE 12.9 The combustion calorimeter is also called a "bomb calorimeter"; the combustion reaction in it is conducted at a fixed volume.

If the work done is entirely pressure–volume work, and if the external pressure is held constant, then

$$\Delta U = q_P + w = q_P - P_{ext}\Delta V$$

If the external pressure is now assumed to be equal to the internal pressure of the system P, then

$$\Delta U = q_P - P\Delta V$$

$$q_P = \Delta U + P\Delta V$$

Because P is constant, $P\Delta V = \Delta(PV)$, and this equation becomes

$$q_P = \Delta(U + PV)$$

The combination $U + PV$ appearing on the right side is now defined as the **enthalpy** H:

$$H = U + PV \qquad [12.7a]$$

thus,

$$q_P = \Delta(U + PV) = \Delta H \qquad [12.7b]$$

Because U, P, and V are state functions, H must also be a state function. Heat transfer in a process at constant pressure has therefore been related to the change in a state function.

It is important to remember that

$$\Delta H = q_P = \Delta U + P\Delta V \qquad \text{(constant pressure)}$$

holds only at constant pressure. If the pressure changes, the more general relationship

$$\Delta H = \Delta U + \Delta(PV)$$

must be used. Like the energy, the enthalpy change is determined by the initial and final states and is independent of the particular path along which the process is performed. This is always true for a state function.

Physical interpretation of the enthalpy function follows immediately from the equation $\Delta H = \Delta U + P\Delta V$ at constant pressure. Clearly, H has physical dimensions of energy and is, in effect, a "corrected" internal energy that reflects the consequences of changing V while thermal energy is being absorbed at constant pressure. The "correction term" $P\Delta V$ accounts precisely for the energy used by the system to do expansion work, rather than for increasing the temperature of the system. Thus, the value of q in constant pressure processes where only pressure–volume work is done is equivalent to the change in the state function enthalpy, ΔH.

12.4 THE FIRST LAW AND IDEAL GAS PROCESSES

We stated the first law of thermodynamics in a general form, applicable to any process that begins and ends in equilibrium states. We analyzed the heat and work terms separately and presented methods for calculating, measuring, and interpreting each. All the concepts are now in place for applying thermodynamics to the discussion of specific processes. Applications require data on certain properties of the substance being studied, such as its equation of state and its heat capacities. Thermodynamic arguments alone cannot provide the actual values of such properties; instead, thermodynamics establishes universal relations among such properties. The actual values must be obtained by methods other than thermodynamics, such as experimental measurements or theoretical calculations in statistical thermodynamics. To illustrate

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

these points, in the next few paragraphs we obtain data on the heat capacities of ideal gases by methods outside thermodynamics. Then we use these data to apply thermodynamics to analyze particular processes carried out on ideal gases.

Heat Capacities of Ideal Gases

The pair of molar heat capacities c_V and c_P for an ideal monatomic gas can be calculated from the results of the kinetic theory of gases and the ideal gas equation of state. From Section 9.5, the average translational kinetic energy of n moles of an ideal gas is

$$E_{kin} = \tfrac{3}{2} nRT$$

In a *monatomic* gas, changes in the total internal energy ΔU measured in thermodynamics can be equated to changes in the translational kinetic energy of the atoms. If n moles of a monatomic gas is taken from a temperature T_1 to a temperature T_2, the internal energy change is

$$\Delta U = \tfrac{3}{2} nR(T_2 - T_1) = \tfrac{3}{2} nR\Delta T$$

Note that the pressure and volume do not affect U explicitly (except through temperature changes), so this result is independent of the change in pressure or volume of the gas.

Now, consider changing the temperature of an ideal gas at constant volume from the point of view of thermodynamics. Because the volume is constant (the gas is confined in a vessel with rigid, diathermal walls), the pressure–volume work, w, must be zero; therefore,

$$\Delta U = q_V = nc_V\Delta T \qquad \text{(ideal gas)}$$

where q_V is the heat transferred at constant volume. Equating this thermodynamic relation with the previous expression for ΔU (from kinetic theory) shows that

$$c_V = \tfrac{3}{2}R \qquad \text{(monatomic ideal gas)} \qquad [12.8]$$

Similarly, the molar heat capacity at constant pressure, c_P, is calculated by examining the heating of a monatomic ideal gas at constant pressure from temperature T_1 to T_2. Experimentally, such a process can be performed by placing the gas in a cylinder with a piston that moves out as the gas is heated, keeping the gas pressure equal to the outside pressure. In this case,

$$\Delta U = \tfrac{3}{2} nR\Delta T = nc_V\Delta T$$

still holds (because the energy change depends only on the temperatures for an ideal gas), but we now have

$$\Delta U = q_P + w$$

because the work is no longer zero. The work for a constant-pressure process is easily calculated from

$$w = -P\Delta V = -P(V_2 - V_1)$$

and the heat transferred is

$$q_P = nc_P\Delta T$$

Because w is negative, q_P is larger than q_V by the amount of work done by the gas as it expands. This gives

$$\Delta U = q + w$$

$$nc_V\Delta T = nc_P\Delta T - P(V_2 - V_1)$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

From the ideal gas law, $PV_1 = nRT_1$ and $PV_2 = nRT_2$; thus,

$$nc_V\Delta T = nc_P\Delta T - nR\Delta T$$
$$c_V = c_P - R$$
$$c_P = c_V + R$$

For a monatomic ideal gas, this shows that $c_P = \frac{5}{2}R$. It is important to use the proper units for R in these expressions for c_V and c_P. If heat is to be measured in joules, R must be expressed as

$$R = 8.315 \text{ J K}^{-1} \text{ mol}^{-1}$$

For a diatomic or polyatomic ideal gas, c_V is greater than $\frac{3}{2}R$, because energy can be stored in rotational and vibrational motions of the molecules; a greater amount of heat must be transferred to achieve a given temperature change. (See Section 12.5.) Even so, it is still true that

$$c_P = c_V + R \text{ (any ideal gas)} \qquad [12.9]$$

and that internal energy changes depend only on the temperature change; therefore, for a small temperature change ΔT,

$$\Delta U = nc_V\Delta T \text{ (any ideal gas)} \qquad [12.10]$$

For an ideal gas process,

$$\Delta H = \Delta U + \Delta(PV) = nc_V\Delta T + nR\Delta T$$
$$\Delta H = nc_P\Delta T \text{ (any ideal gas)} \qquad [12.11]$$

because $c_P = c_V + R$. This result holds for any ideal gas process and shows that enthalpy changes, like internal energy changes, depend only on the temperature difference between initial and final states. These equations are not valid for systems other than ideal gases.

EXAMPLE 12.4

Suppose that 1.00 kJ of heat is transferred to 2.00 mol argon (at 298 K, 1 atm). What will the final temperature T_f be if the heat is transferred (**a**) at constant volume, or (**b**) at constant pressure? Calculate the energy change, ΔU, in each case.

Solution

Because argon is a monatomic, approximately ideal gas,

$$c_V = \tfrac{3}{2}R = 12.47 \text{ J K}^{-1} \text{ mol}^{-1}$$
$$c_P = \tfrac{5}{2}R = 20.79 \text{ J K}^{-1} \text{ mol}^{-1}$$

At constant volume,

$$q_V = nc_V\Delta T$$
$$1000 \text{ J} = (2.00 \text{ mol})(12.47 \text{ J K}^{-1} \text{ mol}^{-1})\Delta T$$
$$\Delta T = 40.1 \text{ K}; \; T_f = 298 + 40.1 = 338 \text{ K}$$
$$\Delta U = nc_V\Delta T = q_V = 1000 \text{ J}$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

At constant pressure,

$$q_P = nc_P\Delta T$$

$$1000\ \text{J} = (2.00\ \text{mol})(20.79\ \text{J K}^{-1}\ \text{mol}^{-1})\Delta T$$

$$\Delta T = 24.0\ \text{K};\ T_f = 298 + 24.0 = 322\ \text{K}$$

$$\Delta U = nc_V\Delta T = (2.00\ \text{mol})(12.47\ \text{J K}^{-1}\ \text{mol}^{-1})(24\ \text{K}) = 600\ \text{J}$$

Note that the expression for ΔU involves c_V even though the process is conducted at constant pressure. The difference of 400 J between the input q_P and ΔU is the work done by the gas as it expands.

Related Problems: 17, 18, 19, 20, 21, 22

Heat and Work for Ideal Gases

Now we have all the data needed to calculate heat and work for a variety of processes involving an ideal gas. To illustrate that q and w individually depend on the path followed, but their sum does not, consider the expansion of 1.00 mol of an ideal monatomic gas following two different paths. The system begins at state A ($P_A = 2.00$ atm, $V_A = 10.0$ L) and reaches a final state, B ($P_B = 1.00$ atm, $V_B = 30.0$ L), via either of two paths shown in Figure 12.10. Along path ACB (red arrows in Fig. 12.10), the system is first heated at constant pressure ($P_{ext} = P_A = 2$ atm) until the volume has tripled; then it is cooled at constant volume until the pressure is halved. Along path ADB (blue arrows in Fig. 12.10), the system is cooled at constant volume until the pressure is halved, and then heated at constant pressure ($P_{ext} = P_B = 1$ atm) until the volume has tripled.

The calculations of heat and work for each step are of the type already performed and are straightforward. Thus,

$$w_{AC} = -P_{ext}\Delta V = -P_A\,(V_B - V_A)$$

$$w_{CB} = 0 \text{ because } V_C = V_B$$

$$q_{AC} = q_P = nc_P\Delta T = \tfrac{5}{2}nR\,(T_C - T_A)$$

$$q_{CB} = q_V = nc_V\Delta T = \tfrac{3}{2}nR\,(T_B - T_C)$$

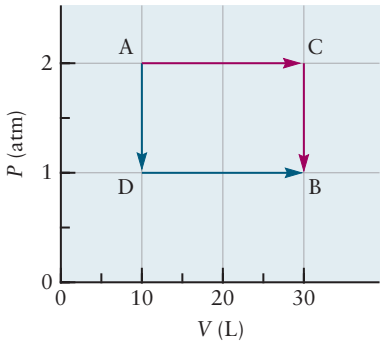

FIGURE 12.10 States A and B of a system are connected by two different ideal-gas processes, one passing through state C and the other through state D.

From the ideal gas law, $nRT_A = P_AV_A$, $nRT_B = P_BV_B$, and $nRT_C = P_CV_C = P_AV_B$ (because $P_A = P_C$ and $V_B = V_C$). Using these relations and summing over the two steps give

$$w_{ACB} = w_{AC} + w_{CB} = -P_A(V_B - V_A) = -40.0\ \text{L atm} = -4050\ \text{J}$$

$$q_{ACB} = q_{AC} + q_{CB} = \tfrac{5}{2}\,nR(T_C - T_A) + \tfrac{3}{2}\,nR(T_B - T_C)$$

$$= \tfrac{5}{2}\,P_A(V_B - V_A) + \tfrac{3}{2}\,V_B(P_B - P_A) = (100.0 - 45.0)\ \text{L atm} = 5570\ \text{J}$$

The sum of these is $\Delta U = w_{ACB} + q_{ACB} = 1520$ J. (This could also have been obtained by using the ideal gas law to calculate the initial and final temperatures T_A and T_B.)

The corresponding calculation for path ADB gives

$$w_{ADB} = -2030\ \text{J and } q_{ADB} = 3550\ \text{J}$$

Even though both the work and the heat have changed, their sum is still 1520 J, illustrating that U is a state function, whereas q and w are not.

12.5 MOLECULAR CONTRIBUTIONS TO INTERNAL ENERGY AND HEAT CAPACITY

The internal energy of a system is the total of the energy involved in the motions of its molecules and the interactions between them, and so must depend on the structures of the molecules. The heat capacity, defined as the rate of change of internal energy as temperature increases, measures the ability of these mechanical motions and interactions to accommodate thermal energy.

The bridge between thermodynamics and the mechanics of molecules is provided by the kinetic theory of matter. The kinetic theory of gases (see Section 9.5) views each molecule in an ideal gas as a point particle moving independently of the others, and describes the probability of molecular speeds by the Maxwell–Boltzmann distribution. From this, the average kinetic energy per molecule is calculated to be $\bar{\varepsilon} = \left(\frac{3}{2}\right) k_B T$, and multiplying by the total number of molecules, N, gives the total kinetic energy in n moles of an ideal gas as $E_{\text{kin}} = \left(\frac{3}{2}\right) nRT$. This model calculation interprets the internal energy of a monatomic ideal gas as consisting solely of the translational kinetic energy of the atoms. Calculating the change in this internal energy as T is increased predicts the molar heat capacity of a monatomic ideal gas to be (see Equations 12.8 and 12.9)

$$c_P = \tfrac{3}{2} R + R = \tfrac{5}{2} R = 20.785 \text{ J mol}^{-1}K^{-1}$$

independent of the temperature. Comparison with the experimental results in Table 12.2 shows that this model calculation accurately predicts the heat capacity for monatomic gases.

The measured heat capacity values for diatomic and polyatomic molecules are significantly larger than those for monatomic gases. The explanation must lie in the existence of molecular motions, or **degrees of freedom,** in addition to translation that can accommodate thermal energy.

Figure 12.11a shows the degrees of freedom for a diatomic molecule. The molecule as a whole can undergo translational motion of its center of mass, behaving as if it were a point particle with mass equal to the total mass of the molecule, in the x-, y-, or z-directions. The molecule has three translational degrees of freedom, and in each of them the kinetic energy takes the form $E_{\text{trans}} = \frac{1}{2} Mv^2$. The molecule can rotate about its center of mass with both atoms in a plane. (See Section 3.9.) It can also tumble end-over-end, which amounts to rotation about its center of mass in a different plane. It has two rotational degrees of freedom, in each of which the kinetic energy takes the form $E_{\text{rot}} = \frac{1}{2} I\omega^2$ where I is the moment of inertia and ω is the angular speed. The molecule can stretch, or vibrate, about its equilibrium bond length R_e along the internuclear axis. (See Sections 3.9.) The potential energy of vibration is $PE_{\text{vib}} = \frac{1}{2} k(R_{AB} - R_e)^2$, and the kinetic energy is $KE_{\text{vib}} = \frac{1}{2}\left(\frac{dR_{AB}}{dt}\right)^2$. In total, the diatomic molecule has three degrees of freedom for translational motion (kinetic energy only), two degrees of rotational freedom (kinetic energy only), and one degree of vibrational freedom (both kinetic and potential energy).

Figure 12.11b shows a similar description of the degrees of freedom of a nonlinear polyatomic molecule. Translational motion of the center of mass requires three degrees of freedom. Rotational motion can be visualized as an oblong object (such as an American football or a rugby ball) tumbling end-over-end in two separate planes, and also spiraling about its long axis. These motions require three degrees of freedom. The two planes are the same as described for the diatomic molecule. Because the spiraling motion does not occur for the diatomic molecule—it would be analogous to rotating a wire about its long axis—the diatomic molecule has one fewer degree of rotational freedom. To count the vibrational degrees of freedom, we start with the maximum total degrees of freedom that would be

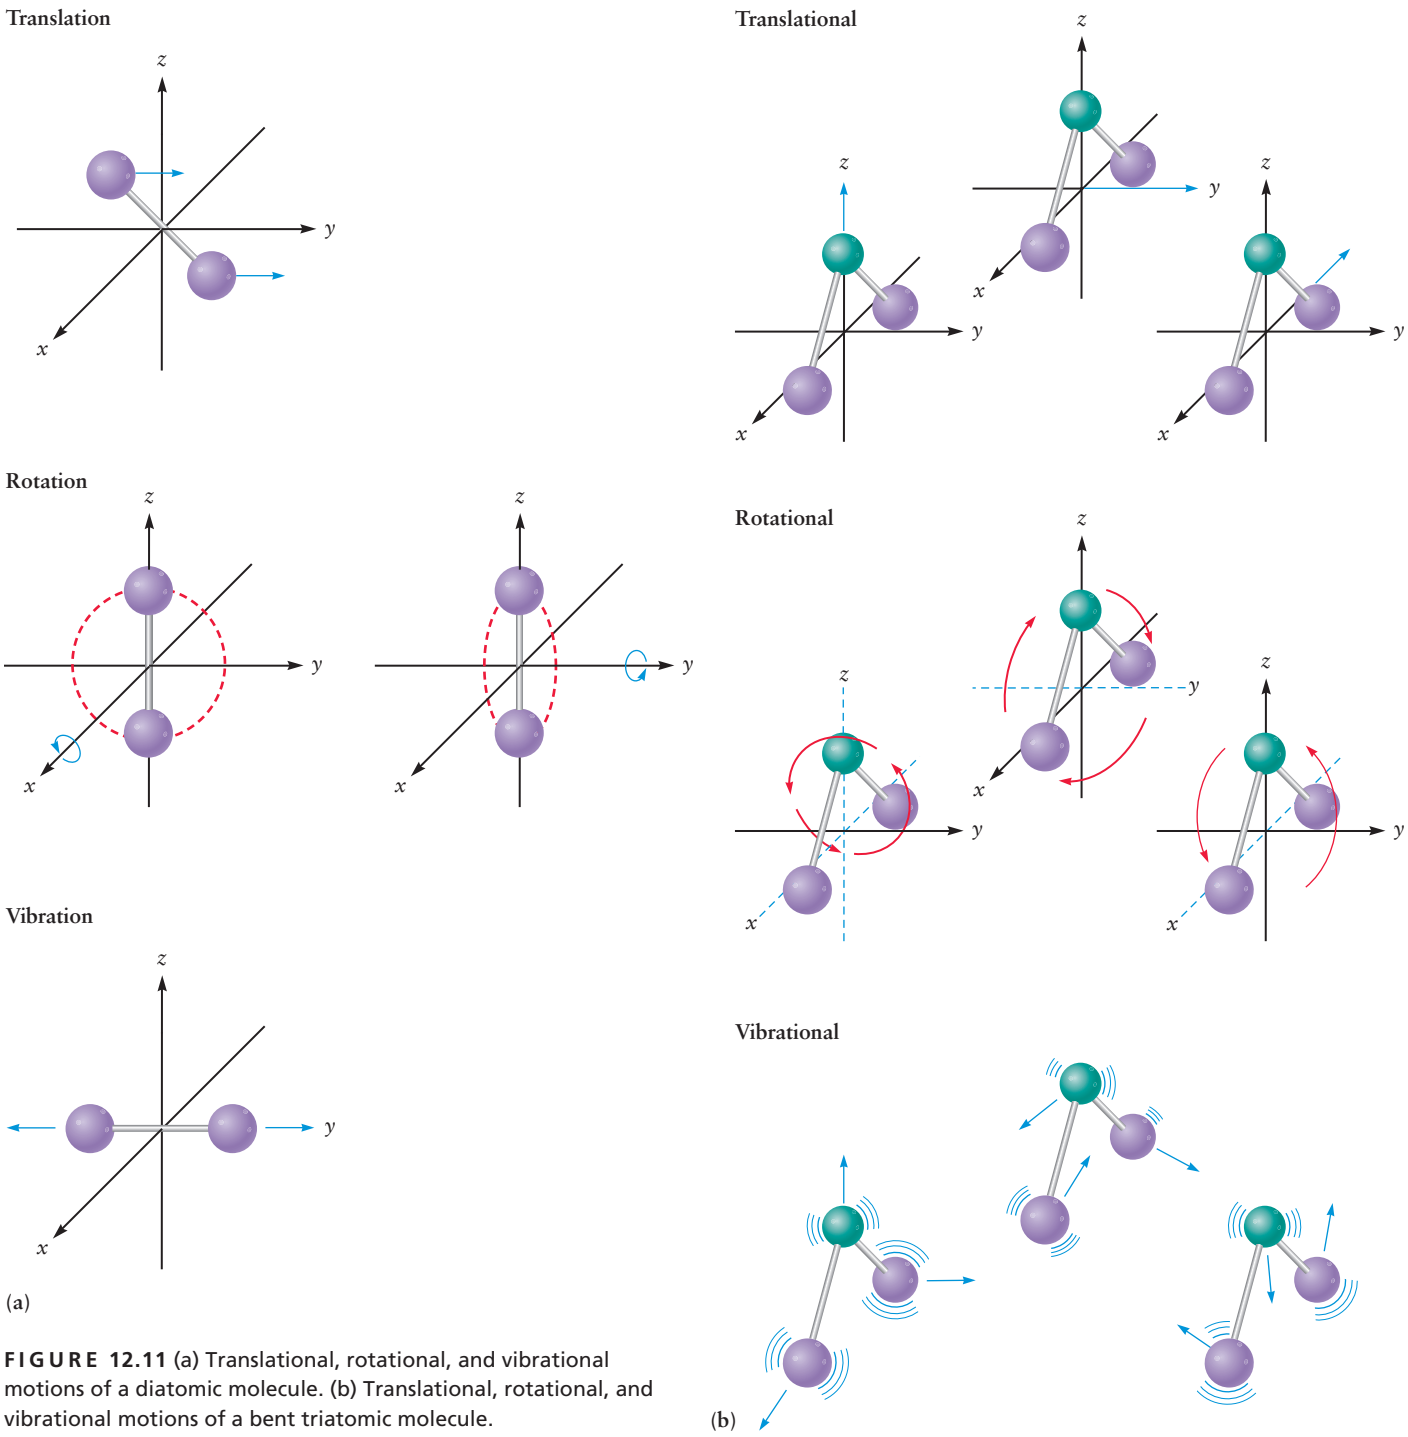

FIGURE 12.11 (a) Translational, rotational, and vibrational motions of a diatomic molecule. (b) Translational, rotational, and vibrational motions of a bent triatomic molecule.

needed to describe the motions of all the atoms in a molecule of N atoms ($3N$), subtract away those already assigned to the center of mass (3), and those assigned to rotation (2 for a linear molecule, 3 for a molecule of general shape), and obtain $3N$-5 vibrational degrees of motion for a linear molecule and $3N$-6 for a nonlinear molecule.

To see how these modes contribute to the internal energy, let's return to the calculation of the average kinetic energy per molecule in Equations 9.12–9.14. The kinetic energy of a molecule is proportional to the square of its speed, and the second power of its speed also appears in the statistical weighting factor of the Maxwell–Boltzmann equation in Equation 9.17. Averaging the kinetic energy over this distribution produces the result $RT/2$ for each translational degree of freedom.

Si	3	0	0	3	6/2	~6/2	24.94	20.0
Al	3	0	0	3	6/2	~6/2	24.94	24.35

The same result is obtained for each degree of freedom whose energy has a quadratic dependence on the speeds or coordinates, when its average is calculated over the Maxwell–Boltzmann distribution. This general conclusion is a result of the **equipartition theorem** of classical kinetic theory which depends on the mathematical form of the Maxwell–Boltzmann distribution. The result is that each translational degree of freedom contributes $RT/2$, and each rotational degree of freedom contributes $RT/2$ to the internal energy. Each vibrational degree of freedom contributes RT to the internal energy because it has one quadratic term for the kinetic energy and another for the potential energy.

We can determine the contribution of each mode to the heat capacity c_V by calculating the ratio $\Delta U/\Delta T$ as the temperature is increased from T_1 to T_2, sum these contributions to find the total value of c_V, and then calculate c_P as in Equation 12.8. The results are summarized in Table 12.3 for several gases. The last two columns in Table 12.3 show that the results predicted for c_P by equipartition are significantly larger than the experimental values of c_P measured at 298 K. Figure 12.12 shows that the measured results depend on temperature, and how each mode contributes to the total heat capacity, for several gases. The translational motions contribute $(5/2)R$ at all temperatures above 0 K. The rotational contribution for H_2 begins at low T, and by room temperature has reached its equipartition value of R; the total heat capacity for H_2 due to translational and rotational motion is $(7/2)R$ at room temperature. Heavier diatomics reach this equipartition value at even lower temperatures. Vibrational motions in H_2, N_2, and O_2 contribute to the heat capacity only above room temperature. At any temperature the difference between the measured values for these diatomics and $(7/2)R$ is essentially the magnitude of the vibrational contribution. At sufficiently high temperature the measured heat capacities for these diatomic gases approach the equipartition value of $(9/2)R = 37.41$ J mol^{-1} K^{-1}. Similarly the measured heat capacities for H_2O and CO_2 approach their equipartition values of $(14/2)R = 58.18$ J mol^{-1} K^{-1} and $(15/2)R = 62.37$ J mol^{-1} K^{-1} respectively.

The fact that predictions of the equipartition theorem agree with experiment at high temperature but not at low temperature is explained by quantum mechanics. The equipartition theorem is a consequence of classical mechanics, and it assumes that each mode of energy accommodation is always active. The quantum analysis starts by calculating the energy levels for each mode of motion and setting up probability for finding the molecules in excited energy states when the system is at temperature T. The probability function contains the factor

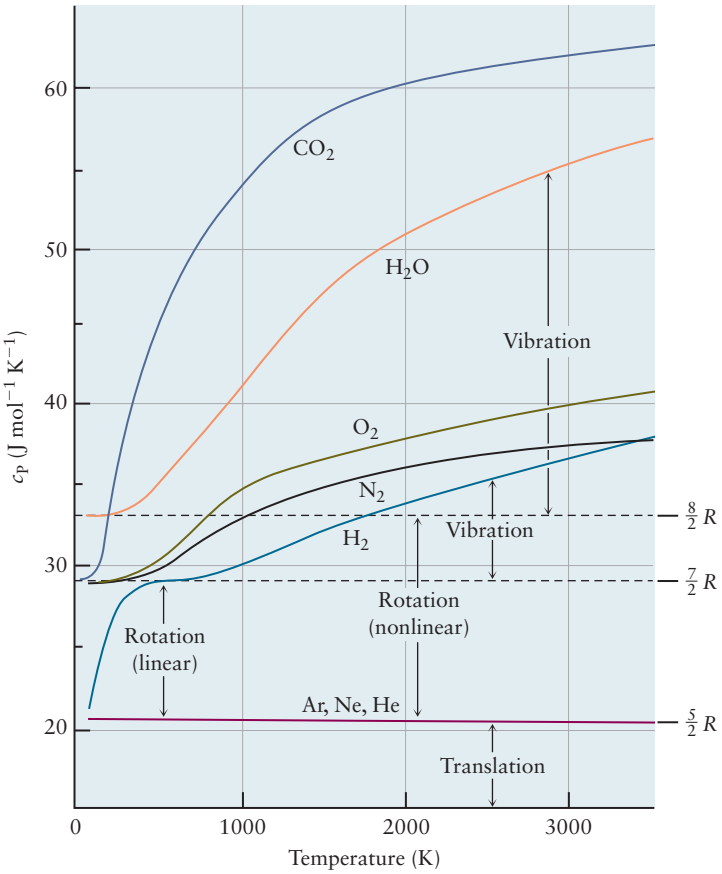

FIGURE 12.12 The temperature dependence of c_P for selected gases. Condensation to liquid and solid states at low temperatures is not included. Comparison with Table 12.3 shows that the diatomic molecules and the linear triatomic molecule CO_2 have contributions from two rotational degrees of freedom, and the non-linear triatomic H_2O has contributions from three. Vertical arrows represent the vibrational contributions for H_2 and for H_2O at specific temperatures.

$\exp(-\Delta\varepsilon/k_BT)$, where $\Delta\varepsilon$ is the gap between the ground state and a typical energy level. The dominant physical question is whether the temperature is sufficiently high to make $k_BT \gg \Delta\varepsilon$. If T is high enough, the quantum states will be populated and the system will behave essentially as predicted by classical mechanics. This analysis is illustrated in Example 4.7 by showing that the energy levels of He atoms confined in a three-dimensional box of macroscopic size are so closely spaced in energy that they are always populated at room temperature. We show in Chapter 20 that rotational motions are populated at room temperature for the same reason. The spacing between vibrational energy levels is larger, and each case must be examined to determine whether a significant number of molecules are vibrationally excited at a particular T. The detailed procedures are demonstrated in Section 12.8, *A Deeper Look . . .* Distribution of Energy among Molecules.

EXAMPLE 12.5

Calculate the value of c_P at 298 K and 1 atm pressure predicted for CO and Br_2 by the classical equipartition theorem. Compare the predicted results with the experimental results and calculate the per cent of the measured value that arises from vibrational motions.

Solution

Table 12.3 summarizes the predicted results for CO and Br_2. The total value of $c_P = (9R/2)$ because a diatomic molecule has 3 degrees of translational motion (each contributing $(R/2)$), 2 degrees of rotational motion (each contributing $(R/2)$), and 1 degree of vibrational motion contributing R for a total $(7R/2)$ to c_V. One additional term of R must be added to obtain $c_P = (9R/2)$. The numerical value is $c_P = 37.41$ J mol^{-1} K^{-1}.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Neglecting the vibrational motion predicts $c_P = (7R/2) = 29.10$ J mol^{-1} K^{-1}.

For CO:
The measured value is $c_P = 29.12$ J mol^{-1} K^{-1}.
The vibrational contribution = $29.12 - 29.10 = 0.02$ J mol^{-1} K^{-1}.
Per cent of c_P due to vibration = $(0.02/29.12) \times 100 = 0.1\%$

For Br_2:
The measured value is $c_P = 36.02$ J mol^{-1} K^{-1}.
The vibrational contribution = $36.02 = 29.10 = 6.92$ J mol^{-1} K^{-1}.
Per cent of c_P due to vibration = $(6.92/36.02) \times 100 = 19.2$ %

Additional insight into the different behavior of these two molecules is provided by the Boltzmann distribution for CO and Br_2 over vibrational states at room temperature in Figure 12.21 and Example 12.12 in Section 12.8.

Related Problems: 23, 24, 25, 26

The heat capacity values for solids also display quantum effects. The law of Dulong and Petit, known since about 1820, states that at room temperature the molar heat capacities of elemental solids have the value $3R$, which is 24.9 J K^{-1}. Research has shown that the values are substantially lower at low temperatures, approaching the value 0 as T approaches absolute 0, and increasing to the Dulong and Petit value at room temperature. See Figure 12.13a. The physical basis of the Dulong and Petit value is explained by modeling the solid as a three-dimensional stack of oscillators, in which each atom is located between a pair of "springs" along the x-axis, another pair along the y-axis, and a third pair along the z-axis. The three degrees of freedom for each atom are therefore tied up in three vibrational modes, each having a quadratic term in its potential energy and its kinetic energy. By the equipartition theorem, these modes contribute $6R/2 = 3R$ to c_V for the solid, as shown in Table 12.3. Einstein explained the behavior at low T in 1907 as an early application of Planck's quantum hypothesis which was introduced to explain blackbody radiation (see Section 4.2). He assumed each atom in the solid

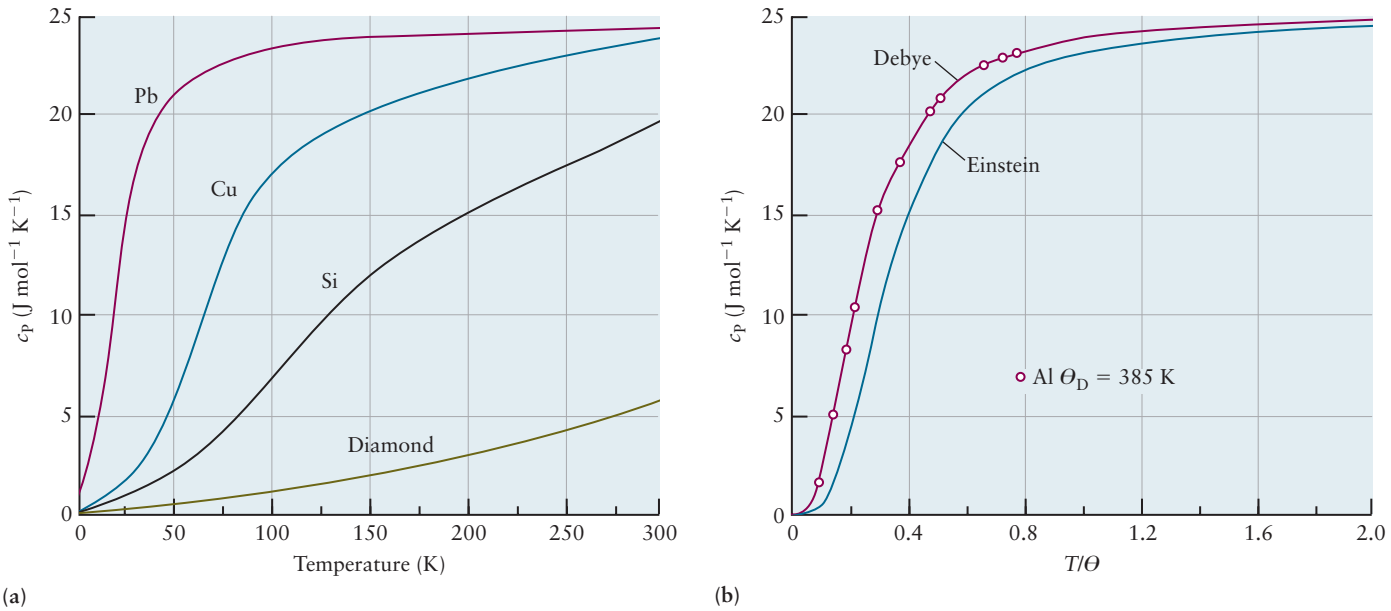

FIGURE 12.13 The temperature dependence of c_V for solids. (a) Measured values for selected elemental solids. (b) Debye and Einstein models for c_V for aluminum. (Adapted from D.R. Gaskell, *Introduction to the Thermodynamics of Materials* (5th ed), New York, Taylor and Francis, 2008, Figure 6.1, 6.2)

behaved as a harmonic oscillator, all moving with the same frequency ν. He calculated the average vibrational energy for these oscillators as a function of T, multiplied the result by Avogadro's number to obtain the internal energy per mole, and calculated c_V by taking the derivative with respect to T. This model leads to a characteristic temperature called the Einstein temperature $\Theta_E = h\nu/k_B$ at which the vibrational energies are excited. Einstein's calculated curve for c_V is plotted as a function of T/Θ_E in Figure 12.13b. As T increases $c_V \longrightarrow 3R$ in accord with the law of Dulong and Petit, and as $T \longrightarrow 0$, $c_V \longrightarrow 0$ in accord with experiment. Debye refined Einstein's model by allowing the atoms in the solid to vibrate about their equilibrium positions with a range of frequencies up to a maximum frequency $\nu_{max} = \nu_D$ called the Debye frequency. The Debye frequency corresponds to the shortest possible wavelength at which neighboring atoms would vibrate in opposition to each other; this is equal to twice the distance between atoms. Debye summed up Einstein's c_V contributions up to the Debye frequency, and plotted the result against the Debye temperature $\Theta_D = h\nu_D/k_B$ at which the maximum vibrational frequency becomes active. The result shown in Figure 12.13(b) reproduced the experimental data almost exactly.

We started this section with the statement that the heat capacity measures the ability of molecular motions and interactions to accommodate thermal energy. We now understand that accommodating thermal energy is fundamentally a quantum mechanical process. It is straightforward to identify modes of molecular motion and the corresponding degrees of freedom, but we must have a quantum description of the allowed energy levels for each mode in order to identify the temperature range in which each mode becomes active. If the temperature is not high enough, the modes are ineffective and might as well be absent. Figure 12.12 shows that the heat capacity of a gas is a series of individual "jumps" from one type of quantum state to another, and clearly illustrates how each successive mode becomes active and therefore contributes to the total heat capacity as the temperature is increased.

12.6 THERMOCHEMISTRY

Up to this point, all the energy changes we have considered are simple physical processes that involve direct mechanical work on a system (as in the paddle wheel driven by a falling weight) or direct thermal contact between two systems at different temperatures. The same methods apply to the heat given off or taken up in the course of a chemical reaction. The study of these heat transfers during chemical reactions is referred to as **thermochemistry.** Because chemical reactions are usually studied at constant pressure, heat transfers in reactions are measured at constant pressure. We obtain these numbers by conducting the chemical reaction in a constant-pressure calorimeter and measuring the heat transferred as q_P. This number is the enthalpy change of the reaction, viewed as a thermodynamic process:

$$q_P = \Delta H = H_f - H_i = H_{products} - H_{reactants} = \Delta H_{reaction}$$

The tabulated values are called **reaction enthalpies.**

Enthalpies of Reaction

When carbon monoxide is burned in oxygen to produce carbon dioxide,

$$CO(g) + \tfrac{1}{2}\ O_2(g) \longrightarrow CO_2(g)$$

heat is given off. Because this energy is transferred out of the reaction vessel (the system) and into the surroundings, it has a *negative* sign. Careful calorimetric measurements show that 1.000 mol CO reacted completely with 0.500 mol O_2, at 25°C and a constant pressure of 1 atm, leads to an enthalpy change of

$$\Delta H = q_P = -2.830 \times 10^5\ J = -283.0\ kJ$$

FIGURE 12.14 The thermite reaction, 2 Al(*s*) + Fe_2O_3(*s*) ⟶ 2 Fe(*s*) + Al_2O_3(*s*), is among the most exothermic of all reactions, liberating 16 kJ of heat for every gram of aluminum that reacts. (a) A piece of burning magnesium acts as a source of ignition when inserted into a pot containing a finely divided mixture of aluminum powder and iron(III) oxide. (b) After the ignition, the reaction continues on its own. (c) Enough heat is generated to produce molten iron, which can be seen flowing out of the broken pot onto the protective mat and the bottom of the stand.

The kilojoule (kJ), equal to 10^3 J, is used because most enthalpy changes for chemical reactions lie in the range of thousands of joules per mole.

When heat is given off by a reaction (ΔH is negative), the reaction is said to be **exothermic** (Fig. 12.14). Reactions in which heat is taken up (ΔH positive) are called **endothermic** (Fig. 12.15). One example of an endothermic reaction is the preceding reaction written in the opposite direction:

$$CO_2(g) \longrightarrow CO(g) + \tfrac{1}{2}\ O_2(g) \qquad \Delta H = +283.0 \text{ kJ}$$

If the direction of a chemical reaction is reversed, the enthalpy change reverses sign. Heat is required to convert CO_2 to CO and O_2 at constant pressure. The decomposition of CO_2 into CO and O_2 is difficult to perform in the laboratory, whereas the reverse reaction is straightforward. Thermodynamics allows us to predict ΔH of the decomposition reaction with complete confidence, even if a calorimetric experiment is never actually performed for it.

FIGURE 12.15 (a) When mixed in a flask, the two solids $Ba(OH)_2 \cdot 8H_2O$(*s*) and NH_4NO_3(*s*) undergo an acid–base reaction: $Ba(OH)_2 \cdot 8\,H_2O$(*s*) + 2 NH_4NO_3(*s*) ⟶ $Ba(NO_3)_2$ (*aq*) + 2 NH_3(*aq*) + 10 $H_2O(\ell)$. (b) The water produced dissolves excess ammonium nitrate in an endothermic reaction. The dissolution absorbs so much heat that the water on the surface of the wet wooden block freezes to the bottom of the flask, and the block can be lifted up with the flask.

Chemists have agreed on a convention for attaching reaction enthalpy values to balanced chemical equations. A reaction enthalpy written after a balanced chemical equation refers to the enthalpy change for the complete conversion of stoichiometric amounts of reactants to products; the numbers of moles of reactants and products are given by the coefficients in the equation. The preceding equation shows the enthalpy change when 1 mol CO_2 is converted to 1 mol CO and $\frac{1}{2}$ mol O_2. If this equation is multiplied by a factor of 2, the enthalpy change must also be doubled because twice as many moles are then involved (enthalpy, like energy, is an *extensive* property).

$$2\ CO_2(g) \longrightarrow 2\ CO(g) + O_2(g) \qquad \Delta H = +566.0\ kJ$$

The molar amounts need not be integers, as the following example illustrates.

EXAMPLE 12.6

Red phosphorus reacts with liquid bromine in an exothermic reaction (Fig. 12.16):

$$2\ P(s) + 3\ Br_2(\ell) \longrightarrow 2\ PBr_3(g) \qquad \Delta H = -243\ kJ$$

Calculate the enthalpy change when 2.63 g phosphorus reacts with an excess of bromine in this way.

Solution

First, convert from grams of phosphorus to moles, using the molar mass of phosphorus, 30.97 g mol^{-1}:

$$\text{moles P} = \frac{2.63\ \text{g P}}{30.97\ \text{g mol}^{-1}} = 0.0849\ \text{mol}$$

Given that an enthalpy change of −243 kJ is associated with 2 mol P, it is readily seen that the enthalpy change associated with 0.0849 mol is

$$\Delta H = 0.0849\ \text{mol P} \times \left(\frac{-243\ \text{kJ}}{2\ \text{mol P}}\right) = -10.3\ \text{kJ}$$

Related Problems: 27, 28, 29, 30

Cengage Learning/Charles D. Winters

FIGURE 12.16 Red phosphorus reacts exothermically in liquid bromine. The rising gases are a mixture of the product PBr_3 and unreacted bromine that has boiled off.

The enthalpy change for the reaction of 1 mol carbon monoxide with oxygen was stated to be −283.0 kJ. In a second experiment, the heat evolved when 1 mol carbon (graphite) is burned in oxygen to carbon dioxide at 25°C is readily measured to be

$$C(s,\text{gr}) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta H = -393.5\ kJ$$

Now, suppose we need to know the enthalpy change for the reaction

$$C(s,\text{gr}) + \tfrac{1}{2}\ O_2(g) \longrightarrow CO(g) \qquad \Delta H = ?$$

This reaction cannot be performed simply in the laboratory. If 1 mol graphite is heated with $\frac{1}{2}$ mol oxygen, almost half the carbon burns to $CO_2(g)$, and the remainder is left as unreacted carbon. Nevertheless, thermodynamics allows us to predict the heat that *would* evolve if we could perform the reaction as written. This is possible because H is a state function, and thus ΔH for the reaction is independent of the path followed from reactants to products. We are free to select any path for which we have all the data needed for the calculation. In Figure 12.17, we illustrate the path in which 1 mol C is burned with O_2 to CO_2 (with $\Delta H = -393.5$ kJ), and to this is added the calculated enthalpy change for the (hypothetical) process in which CO_2 is converted to CO and O_2 ($\Delta H = +283.0$ kJ). The total ΔH is the sum

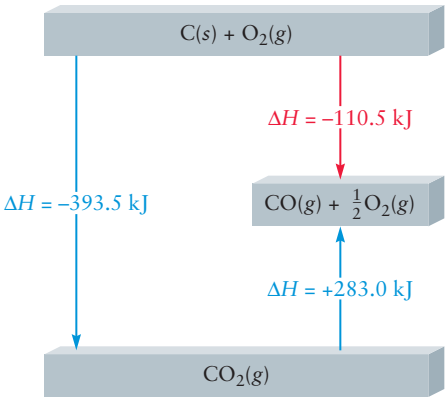

FIGURE 12.17 Because enthalpy is a state property, the enthalpy change for the reaction of carbon with oxygen to give carbon monoxide (red arrow) can be determined through measurements along a path that is less direct but easier to study (blue arrows). The enthalpy change sought is the sum of the enthalpy change to burn carbon to carbon dioxide and that to convert carbon dioxide to carbon monoxide and oxygen.

of the two known enthalpy changes, -393.5 kJ + 283.0 kJ = -110.5 kJ. To see this more clearly, the reactions are written out as follows:

$$\begin{aligned} \text{C}(s,\ \text{gr}) + \text{O}_2(g) &\longrightarrow \text{CO}_2(g) && \Delta H_1 = -393.5\ \text{kJ} \\ \text{CO}_2(g) &\longrightarrow \text{CO}(g) + \tfrac{1}{2}\,\text{O}_2(g) && \Delta H_2 = +283.0\ \text{kJ} \\ \hline \text{C}(s,\ \text{gr}) + \tfrac{1}{2}\,\text{O}_2(g) &\longrightarrow \text{CO}(g) && \Delta H = \Delta H_1 + \Delta H_2 = -110.5\ \text{kJ} \end{aligned}$$

If two or more chemical equations are added to give another chemical equation, the corresponding enthalpies of reaction must be added.

This statement is known as **Hess's law** and derives from the fact that enthalpy is a state function. It is proper to include in the pathway any convenient reaction for which the enthalpy change is known, even if that reaction is difficult to study directly and its enthalpy change is known only from studies of the reverse reaction. The step labeled (hypothetical) earlier is a good example.

The corresponding internal energy change ΔU might be desired for this reaction. The quantity ΔU is simple to calculate because of the relation

$$\Delta H = \Delta U + \Delta(PV)$$

or

$$\Delta U = \Delta H - \Delta(PV)$$

The gases can be assumed to obey the ideal gas law, so

$$\Delta(PV) = \Delta(nRT) = RT\,\Delta n_g$$

because the temperature is constant at 25°C. Here, Δn_g is the change in the number of moles of *gas* in the reaction as written:

$$\begin{aligned} \Delta n_g &= \text{total moles of product gases} - \text{total moles of reactant gases} \\ &= 1\ \text{mol} - \tfrac{1}{2}\ \text{mol} = \tfrac{1}{2}\ \text{mol} \end{aligned}$$

(Graphite is a solid, and its volume is negligible compared with the volumes of the gases.) Hence,

$$\Delta(PV) = RT\,\Delta n_g = (8.315\ \text{J K}^{-1}\ \text{mol}^{-1})(298\ \text{K})(\tfrac{1}{2}\ \text{mol}) = 1.24 \times 10^3\ \text{J} = 1.24\ \text{kJ}$$

Note that R must be expressed in J K^{-1} mol^{-1} to obtain the result in joules. Therefore,

$$\Delta U = -110.5\ \text{kJ} - 1.24\ \text{kJ} = -111.7\ \text{kJ}$$

For reactions in which only liquids and solids are involved, or those in which the number of moles of gas does not change, the enthalpy and energy changes are almost equal, and their difference can be neglected.

Phase changes are not chemical reactions, but their enthalpy changes can be analyzed in the same way. Heat must be absorbed by ice to transform to water, so the phase change is endothermic, with ΔH positive:

$$\text{H}_2\text{O}(s) \longrightarrow \text{H}_2\text{O}(\ell) \qquad \Delta H_{\text{fus}} = +6.007\ \text{kJ mol}^{-1}$$

Here, ΔH_{fus} is the **molar enthalpy of fusion,** the heat that must be transferred at constant pressure to melt 1 mole of substance. When a liquid freezes, the reaction is reversed and an equal amount of heat is given off to the surroundings; that is, $\Delta H_{\text{freez}} = -\Delta H_{\text{fus}}$. The vaporization of 1 mole of liquid at constant pressure and temperature requires an amount of heat called the **molar enthalpy of vaporization,** ΔH_{vap},

$$\text{H}_2\text{O}(\ell) \longrightarrow \text{H}_2\text{O}(g) \qquad \Delta H_{\text{vap}} = +40.66\ \text{kJ mol}^{-1}$$

whereas the condensation of a liquid from a vapor is an exothermic process, with $\Delta H_{\text{cond}} = -\Delta H_{\text{vap}}$. Table 12.4 lists enthalpies of fusion and vaporization.

TABLE 12.4

Enthalpy Changes of Fusion and Vaporization†

Substance	ΔH_{fus} (kJ mol^{-1})	ΔH_{vap} (kJ mol^{-1})
NH_3	5.650	23.35
HCl	1.992	16.15
CO	0.836	6.04
CCl_4	2.500	30.00
H_2O	6.007	40.66
NaCl	28.800	170.00

†The enthalpy changes are measured at the normal melting point and the normal boiling point, respectively.

EXAMPLE 12.7

To vaporize 100.0 g carbon tetrachloride at its normal boiling point, 349.9 K, and P = 1 atm, 19.5 kJ of heat is required. Calculate ΔH_{vap} for CCl_4 and compare it with ΔU for the same process.

Solution

The molar mass of CCl_4 is 153.8 g mol^{-1}; thus, the number of moles in 100.0 g is

$$\frac{100.0 \text{ g } CCl_4}{153.8 \text{ g mol}^{-1}} = 0.6502 \text{ mol } CCl_4$$

The enthalpy change for 1 mol CCl_4 is then

$$\left(\frac{19.5 \text{ kJ}}{0.6502 \text{ mol } CCl_4}\right) \times 1.00 \text{ mol } CCl_4 = 30.0 \text{ kJ} = \Delta H_{vap}$$

The internal energy change is then

$$\Delta U = \Delta H_{vap} - \Delta(PV) = \Delta H_{vap} - RT\,\Delta n_g$$

Inserting T = 349.9 K and Δn_g = 1 (because there is an increase of 1 mol of gaseous products for each mole of liquid that is vaporized) gives

$$\Delta U = 30.0 \text{ kJ} - (8.315 \text{ J K}^{-1} \text{ mol}^{-1})(349.9 \text{ K})(1.00 \text{ mol})(10^{-3} \text{ kJ J}^{-1})$$

$$= (30.0 - 2.9) \text{ kJ} = +27.1 \text{ kJ mol}^{-1}$$

Thus, of the 30.0 kJ of energy transferred from the surroundings in the form of heat, 27.1 kJ is used to increase the internal energy of the molecules (ΔU) and 2.9 kJ is used to expand the resulting vapor, $\Delta(PV)$.

Related Problems: 31, 32, 33, 34

Standard-State Enthalpies

Absolute values of the enthalpy of a substance, like absolute values of the internal energy, cannot be measured or calculated. Only *changes* in enthalpy can be measured. Just as altitudes are measured relative to a standard altitude (sea level), it is necessary to adopt a reference state for the enthalpies of substances. To cope with this problem, chemists define **standard states** for chemical substances as follows:

> For solids and liquids, the standard state is the thermodynamically stable state at a pressure of 1 atm and at a specified temperature.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

For gases, the standard state is the gaseous phase at a pressure of 1 atm, at a specified temperature and exhibiting ideal gas behavior.

For dissolved species, the standard state is a 1-M solution at a pressure of 1 atm, at a specified temperature and exhibiting ideal solution behavior.

Standard-state values of enthalpy and other quantities are designated by attaching a superscript ° (pronounced "naught") to the symbol for the quantity and writing the specified temperature as a subscript. Any temperature may be chosen as the "specified temperature." The most common choice is 298.15 K (25°C exactly); if the temperature of a standard state is not explicitly indicated, 298.15 K should be assumed to be the value.

Once standard states have been defined, the zero of the enthalpy scale is defined by arbitrarily setting the enthalpies of selected reference substances to zero in their standard states. This is completely analogous to assigning zero as the altitude at sea level. Chemists have agreed to the following: *The chemical elements in their standard states at 298.15 K have zero enthalpy.* A complication immediately arises because some elements exist in various allotropic forms that differ in structure and all physical properties, including enthalpy. For example, oxygen can be prepared as $O_2(g)$ or $O_3(g)$ (ozone), and carbon exists in numerous allotropic forms, including graphite, diamond, and the fullerenes (see Section 7.5). Chemists have agreed to assign zero enthalpy to the form that is most stable at 1 atm and 298.15 K. Thus, $O_2(g)$ is assigned zero enthalpy in its standard state at 298.15 K, whereas the standard-state enthalpy of $O_3(g)$ is not zero in its standard state at 298.15K. The most stable form of carbon at 1 atm and 298.15 K is graphite, which is assigned zero enthalpy; the standard state enthalpy values for diamond and all the fullerenes are not zero.[2]

The enthalpy change for a chemical reaction in which all reactants and products are in their standard states and at a specified temperature is called the **standard enthalpy** (written $\Delta H°$) for that reaction. The standard enthalpy is the central tool in thermochemistry because it provides a systematic means for comparing the energy changes due to bond rearrangements in different reactions. Standard enthalpies can be calculated from tables of reference data. For this purpose, we need one additional concept. The **standard enthalpy of formation** ΔH_f° of a compound is defined to be the enthalpy change for the reaction that produces 1 mol of the compound from its elements in their stable states, all at 25°C and 1 atm pressure. For example, the standard enthalpy of formation of liquid water is the enthalpy change for the reaction

$$H_2(g) + \tfrac{1}{2}\ O_2(g) \longrightarrow H_2O(\ell) \qquad \Delta H° = -285.83 \text{ kJ}$$
$$\Delta H_f^\circ(H_2O(\ell)) = -285.83 \text{ kJ mol}^{-1}$$

Here, the superscript ° indicates standard-state conditions, and the subscript f stands for *formation*.

The ΔH_f° for an *element* that is already in its standard state is clearly zero, because no further change is needed to bring it to standard-state conditions. But the standard enthalpy of formation of a mole of *atoms* of an element is often a large positive quantity. That is, the reaction to generate them is endothermic:

$$\tfrac{1}{2}\ H_2(g) \longrightarrow H(g) \qquad \Delta H° = +217.96 \text{ kJ}$$
$$\Delta H_f^\circ(H(g)) = 217.96 \text{ kJ mol}^{-1}$$

For dissolved species the standard state is defined as an ideal solution with a concentration of 1 M (this is obtained in practice by extrapolating the dilute solution

[2]There is one exception to this choice of standard state. The standard state of phosphorus is taken to be white phosphorus, rather than the more stable red or black form, because the latter are less well characterized.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

behavior up to this concentration). A special comment is in order on the standard enthalpies of formation of ions. When a strong electrolyte dissolves in water, both positive and negative ions form; it is impossible to produce one without the other. It is therefore also impossible to measure the enthalpy change of formation of ions of only one charge. Only the sum of the enthalpies of formation of the positive and negative ions is accessible to calorimetric experiments. Therefore, chemists have agreed that ΔH_f° of $H^+(aq)$ is set to zero to establish a reference point for the enthalpies of formation of cations and anions.

Tables of ΔH_f° for compounds are the most important data source for thermochemistry. From them it is easy to calculate $\Delta H°$ for reactions of the compounds, and thereby systematically compare the energy changes due to bond rearrangements in different reactions. Appendix D gives a short table of standard enthalpies of formation at 25°C. The following example shows how they can be used to determine enthalpy changes for reactions performed at 25°C and 1 atm pressure.

EXAMPLE 12.8

Using Appendix D, calculate $\Delta H°$ for the following reaction at 25°C and 1 atm pressure:

$$2\ NO(g) + O_2(g) \longrightarrow 2\ NO_2(g)$$

Solution

Because enthalpy is a function of state, ΔH can be calculated along any convenient path. In particular, two steps can be chosen for which ΔH is found easily. In step 1, the reactants are decomposed into the elements in their standard states:

$$2\ NO(g) \longrightarrow N_2(g) + O_2(g) \qquad \Delta H_1 = -2\ \Delta H_f^\circ(NO)$$

The minus sign appears because the process chosen is the reverse of the formation of NO; the factor of 2 is present because 2 mol NO is involved. Because oxygen is already an element in its standard state, it does not need to be changed [equivalently, $\Delta H_f^\circ(O_2(g))$ is 0].

In step 2, the elements are combined to form products:

$$N_2(g) + 2\ O_2(g) \longrightarrow 2\ NO_2(g) \qquad \Delta H_1 = 2\ \Delta H_f^\circ(NO_2)$$

The enthalpy change of the overall reaction is then the sum of these two enthalpies:

$$\Delta H° = \Delta H_1 + \Delta H_2 = -2\ \Delta H_f^\circ(NO) + 2\ \Delta H_f^\circ(NO_2)$$

$$= -(2\ \text{mol})(90.25\ \text{kJ mol}^{-1}) + (2\ \text{mol})(33.18\ \text{kJ mol}^{-1}) = -114.14\ \text{kJ}$$

Related Problems: 39. 40, 41, 42

The general pattern should be clear from this example. The change $\Delta H°$ for a reaction at atmospheric pressure and 25°C is the sum of the ΔH_f° for the *products* (multiplied by their coefficients in the balanced chemical equation) minus the sum of the ΔH_f° for the *reactants* (also multiplied by their coefficients). For a general reaction of the form

$$aA + bB \longrightarrow cC + dD$$

the standard enthalpy change is

$$\Delta H° = c\ \Delta H_f^\circ(C) + d\ \Delta H_f^\circ(D) - a\ \Delta H_f^\circ(A) - b\ \Delta H_f^\circ(B)$$

This equation can be extended to calculate the standard-state enthalpy change for any chemical reaction by adding up the standard-state enthalpy of formation for all

the products (each multiplied by its stoichiometric coefficient in the balanced chemical equation) and subtracting off the total for all the reactants (each multiplied by its stoichiometric coefficient in the balanced chemical equation). In mathematical form, this procedure is represented by the equation

$$\Delta H° = \sum_{i=1}^{prod} n_i \Delta H_i^\circ - \sum_{j=1}^{react} n_j \Delta H_j^\circ \qquad [12.12]$$

Bond Enthalpies

Chemical reactions between molecules require existing bonds to break and new ones to form in a new arrangement of the atoms. Chemists have developed methods to study highly reactive intermediate species in which one or more bonds have been broken, and to find the energy required to break a particular bond. For example, a hydrogen atom can be removed from a methane molecule,

$$CH_4(g) \longrightarrow CH_3(g) + H(g)$$

leaving two fragments, neither of which has a stable valence electron structure in the Lewis electron dot picture. Both will go on to react rapidly with other molecules or fragments and eventually form the stable products of that reaction. Nonetheless, we can measure many of the properties of these reactive species during the short time they are present.

One such important measurable quantity is the enthalpy change when a bond is broken in the gas phase, called the **bond enthalpy**. This change is invariably positive because atoms bonded together have lower energy than when separated (see Fig. 6.1). For example, the bond enthalpy of a C—H bond in methane is 438 kJ mol^{-1}, measured as the standard enthalpy change for the reaction

$$CH_4(g) \longrightarrow CH_3(g) + H(g) \qquad \Delta H° = +438 \text{ kJ}$$

in which 1 mol of C—H bonds is broken, one for each molecule of methane. Bond enthalpies are fairly constant from one compound to another. Each of the following gas-phase reactions involves the breaking of a C—H bond:

$$C_2H_6(g) \longrightarrow C_2H_5(g) + H(g) \qquad \Delta H° = +410 \text{ kJ}$$

$$CHF_3(g) \longrightarrow CF_3(g) + H(g) \qquad \Delta H° = +429 \text{ kJ}$$

$$CHCl_3(g) \longrightarrow CCl_3(g) + H(g) \qquad \Delta H° = +380 \text{ kJ}$$

$$CHBr_3(g) \longrightarrow CBr_3(g) + H(g) \qquad \Delta H° = +377 \text{ kJ}$$

The approximate constancy of the measured enthalpy changes (all lie within 8% of their average value) suggests that the C—H bonds in all five molecules are similar. Because such bond enthalpies are constant from one molecule to another, it is useful to tabulate *average* bond enthalpies from measurements on a series of compounds (Table 12.5). Any given bond enthalpy will differ somewhat from those shown, but in most cases, the deviations are small. The constant of bond energies in a series of molecules was introduced in Section 3.9, and representative values were listed in Table 3.4. Bond energy values are related to bond enthalpy values by the relation $\Delta H = \Delta U + \Delta(PV)$, described in the paragraphs following Example 12.6.

The bond enthalpies in Table 12.5 can be used, together with enthalpies of atomization of the elements from the same table, to estimate standard enthalpies of formation ΔH_f° for molecules in the gas phase and enthalpy changes $\Delta H°$ for gas-phase reactions. This is illustrated by the following example.

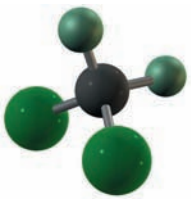

FIGURE 12.18 Dichlorodifluoromethane, CCl_2F_2, also known as Freon-12.

EXAMPLE 12.9

Estimate the standard enthalpy of formation of dichlorodifluoromethane, $CCl_2F_2(g)$ (Fig. 12.18). This compound is also known as Freon-12 and has been used as a refrigerant because of its low reactivity and high volatility. It and other related chlorofluorocarbons (CFCs) are being phased out because of their role in depleting the ozone layer in the outer atmosphere, as discussed in Section 20.6.

Solution

The standard enthalpy of formation of $CCl_2F_2(g)$ is the enthalpy change for the process in which it is formed from the elements in their standard states at 25°C:

$$C(s,\text{gr}) + Cl_2(g) + F_2(g) \longrightarrow CCl_2F_2(g)$$

This reaction can be replaced by a hypothetical two-step process: All the species appearing on the left are atomized, and then the atoms are combined to make CCl_2F_2.

$$C(s,\text{gr}) + Cl_2(g) + F_2(g) \longrightarrow C(g) + 2\ Cl(g) + 2\ F(g)$$

$$C(g) + 2\ Cl(g) + 2\ F(g) \longrightarrow CCl_2F_2(g)$$

The enthalpy change ΔH_1 for the first step is the sum of the atomization energies:

$$\Delta H_1 = \Delta H_f^\circ(C(g)) + 2\ \Delta H_f^\circ(Cl(g)) + 2\ \Delta H_f^\circ(F(g))$$

$$= 716.7 + 2(121.7) + 2(79.0) = 1118\ \text{kJ}$$

The enthalpy change ΔH_2 for the second step can be estimated from the bond enthalpies of Table 12.5. This step involves the formation (with release of heat and, therefore, negative enthalpy change) of two C—Cl and two C—F bonds per molecule. The net ΔH for this step is then

$$\Delta H_2 \approx -[2(328) + 2(441)] = -1538\ \text{kJ}$$

$$\Delta H_1 + \Delta H_2 = -1538 + 1118 = -420\ \text{kJ}$$

This ΔH_f°, -420 kJ mol^{-1}, compares fairly well with the experimental value, -477 kJ mol^{-1}. In general, much better agreement than this is not to be expected, because tabulated bond enthalpies are only average values.

12.7 REVERSIBLE PROCESSES IN IDEAL GASES

Most thermodynamic processes conducted in laboratory work are irreversible, in the sense of Section 12.1. Except in the initial and final states, the system is not at equilibrium, and the equation of state relationship between observable properties does not exist. Consequently, changes in thermodynamic quantities during an irreversible process cannot in general be calculated. Nonetheless, the changes in those quantities that are state functions are well defined, as long as the initial and final equilibrium states are known. Because these changes are independent of the detailed path of the process, they can be evaluated for any known process that connects these initial and final states. Changes can be directly calculated along *reversible* paths, during which the system proceeds through a sequence of equilibrium states in which observable properties are related by the equation of state.

This section demonstrates calculations of changes in macroscopic properties caused during several specific reversible processes in ideal gases. These will serve as auxiliary calculation pathways for evaluating changes in state functions during irreversible processes. We use this procedure extensively in Chapter 13 on spontaneous processes and the second law of thermodynamics.

Recall from Section 12.1 that a true reversible process is an idealization; it is a process in which the system proceeds with infinitesimal speed through a series of equilibrium states. The external pressure P_{ext}, therefore, can never differ by more than an infinitesimal amount from the pressure, P, of the gas itself. The heat, work, energy, and enthalpy changes for ideal gases at constant volume (called **isochoric processes**) and at constant pressure **(isobaric processes)** have already been considered. This section examines *isothermal* (constant temperature) and *adiabatic* ($q = 0$) processes.

Isothermal Processes

An **isothermal process** is one conducted at constant temperature. This is accomplished by placing the system in a large reservoir (bath) at fixed temperature and allowing heat to be transferred as required between system and reservoir. The reservoir is large enough that its temperature is almost unchanged by this heat transfer. In Section 12.4, U for an ideal gas was shown to depend only on temperature; therefore, $\Delta U = 0$ for any isothermal ideal gas process. From the first law it follows that

$$w = -q \text{ (isothermal process, ideal gas)}$$

In a *reversible* process, $P_{ext} = P_{gas} \equiv P$. But the relation $w = -P_{ext}\,\Delta V$ from Section 12.2 cannot be used to calculate the work, because that expression applies only if the external pressure remains constant as the volume changes. In the reversible isothermal expansion of an ideal gas,

$$P_{ext} = P = \frac{nRT}{V} \qquad [12.13]$$

By Boyle's law, the pressure falls as the volume is increased from V_1 to V_2, as shown by the solid line in Figure 12.19. In this case, the work is calculated by approximating the process as a *series* of expansions by small amounts ΔV, during each of which P_{ext} is held constant at P_i, with $i = 1, 2, 3$, and so on labeling the step. The work done in step i is $-P_i\delta V$, and thus the total work done is the sum of the work in all steps:

$$w = -P_1\delta V - P_2\delta V - \cdots$$

The work in the complete process is the sum of the areas of the rectangles in the figure. As the step size δV is made smaller, it approaches the infinitesimal volume change that is written dV, and the corresponding increment of work becomes

$$dw = -P_{ext}\,dV$$

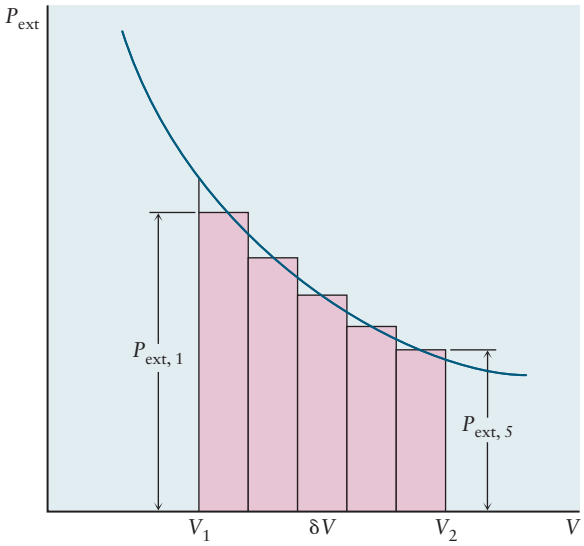

FIGURE 12.19 The area under the graph of external pressure against volume can be approximated as the sum of the areas of the rectangles shown.

In this limit the sum of the areas of the rectangles approaches the area under the graph of P versus V. This limiting sum is the *integral* of P_{ext} from V_1 to V_2 and is written symbolically using an integral sign:

$$w = -\int_{V_1}^{V_2} P\,dV \qquad \text{(reversible process)} \qquad \textbf{[12.14]}$$

Note that we used Equation 12.13 to replace P_{ext} with the internal pressure P in this reversible process. This is a compact way of saying that the work, w, for a reversible expansion process is (with a minus sign) the area under the graph of P plotted against V from V_1 to V_2.

The formal definition of an integral and procedures for evaluating integrals are covered in classes on calculus. For our purposes here it is sufficient that you interpret an integral as simply the area under a curve. Appendix C provides some useful background information and analytic expressions for a few common integrals that we use in this book.

In this case, the ideal gas law is used to write this area as

$$w = -nRT\int_{V_1}^{V_2} \frac{1}{V}\,dV \qquad \textbf{[12.15]}$$

This integral is the area under a curve of $1/V$ against V (a hyperbola) from V_1 to V_2. The integral of $1/x$ evaluated between the points x_1 and x_2 is equal to $\ln(x_2/x_1)$, where ln is the natural logarithm function (see Table C.2). Because we know that $\Delta U = 0$ for an isothermal process, we can find that $q = -w$ for such a process. Combining this relation with the result of evaluating the integral in Eqn. [12.15] leads us to conclude that $\Delta H = 0$ for isothermal processes involving ideal gases.

$$w = -nRT\ln\frac{V_2}{V_1}$$

$$q = -w = nRT\ln\frac{V_2}{V_1}$$

$$\Delta U = 0 \text{ because } \Delta T = 0$$

$$\Delta H = \Delta U + \Delta(PV) = \Delta U + \Delta(nRT) = 0 \qquad \textbf{[12.16]}$$

The enthalpy change, like the internal energy change, depends only on temperature for an ideal gas.

That V_2 is greater than V_1 implies that $w < 0$ and $q > 0$; in an isothermal expansion, the system does work against the surroundings and heat must be transferred into it to maintain T constant. In an isothermal compression, the reverse is true: The surroundings do work on the system, and the system must then lose heat to the bath to maintain T constant.

EXAMPLE 12.10

Calculate the heat and the work associated with a process in which 5.00 mol of gas expands reversibly at constant temperature $T = 298$ K from a pressure of 10.00 to 1.00 atm.

Solution

At constant T and n, q and w are given by the equations just above Equation 12.16. Inserting the data for this example gives

$$\frac{V_2}{V_1} = \frac{P_1}{P_2} = \frac{10.0 \text{ atm}}{1.00 \text{ atm}} = 10.0$$

Thus,

$$w = -(5.00 \text{ mol})(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K}) \ln 10.0$$

$$= -2.85 \times 10^4 \text{ J} = -28.5 \text{ kJ}$$

$$q = -w = 28.5 \text{ kJ}$$

Related Problems: 55, 56

Adiabatic Processes

An **adiabatic process** is one in which there is no transfer of heat into or out of the system. This is accomplished by placing an adiabatic wall (thermal insulation) around the system to prevent heat flow.

$$q = 0$$

$$\Delta U = w$$

Consider a small adiabatic change. The volume changes by an amount dV and the temperature by an amount dT. Now U depends only on temperature for an ideal gas, so

$$dU = nc_V \, dT$$

As always, the work is given by $-P_{ext} \, dV$. Setting these equal gives

$$nc_V \, dT = -P_{ext} \, dV$$

In other words, the temperature change dT is related to the volume change dV in such a process.

If the process is *reversible*, as well as adiabatic, so that $P_{ext} \approx P$, the ideal gas law can be used to write

$$nc_V \, dT = -P \, dV = -\frac{nRT}{V} \, dV$$

The equation is simplified by dividing both sides through by nT, making the left side depend only on T and the right side only on V:

$$\frac{c_V}{T} \, dT = -\frac{R}{V} \, dV$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Suppose now that the change is not infinitesimal but large. How are temperature and volume related in this case? If a series of such infinitesimal changes is added together, the result is an integral of both sides of the equation from the initial state (specified by T_1 and V_1) to the final state (specified by T_2 and V_2):

$$c_V \int_{T_1}^{T_2} \frac{1}{T}\ dT = -R \int_{V_1}^{V_2} \frac{1}{V}\ dV$$

Here, c_V has been assumed to be approximately independent of T over the range from T_1 to T_2. Evaluating the integrals gives

$$c_V \ln \frac{T_2}{T_1} = -R \ln \frac{V_2}{V_1} = R \ln \frac{V_1}{V_2}$$

A more useful form results from taking antilogarithms of both sides:

$$\left(\frac{T_2}{T_1}\right)^{c_V} = \left(\frac{V_1}{V_2}\right)^{R} = \left(\frac{V_1}{V_2}\right)^{c_P - c_V}$$

The last step used the fact that $R = c_P - c_V$. Thus,

$$\left(\frac{T_2}{T_1}\right) = \left(\frac{V_1}{V_2}\right)^{c_P/c_V - 1} = \left(\frac{V_1}{V_2}\right)^{\gamma - 1}$$

where $\gamma = c_P/c_V$ is the ratio of specific heats. This can be rearranged to give

$$T_1 V_1^{\gamma-1} = T_2 V_2^{\gamma-1} \qquad [12.17]$$

In many situations, the initial thermodynamic state and, therefore, T_1 and V_1 are known. If the final volume V_2 is known, T_2 can be calculated; if T_2 is known, V_2 can be calculated.

In some cases, only the final pressure, P_2, of an adiabatic process is known. In this case, the ideal gas law gives

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2}$$

Multiplying this by Equation 12.17 gives

$$P_1 V_1^{\gamma} = P_2 V_2^{\gamma} \qquad [12.18]$$

This can be used to calculate V_2 from a known P_2.

Once the pressure, temperature, and volume of the final state are known, the energy and enthalpy changes and the work done are straightforward to calculate:

$$\Delta U = nc_V(T_2 - T_1) = w \text{ (reversible adiabatic process for ideal gas)}$$

$$\Delta H = \Delta U + \Delta(PV) = \Delta U + (P_2V_2 - P_1V_1)$$

or more simply,

$$\Delta H = nc_P\Delta T$$

EXAMPLE 12.11

Suppose 5.00 mol of an ideal monatomic gas at an initial temperature of 298 K and pressure of 10.0 atm is expanded adiabatically and reversibly until the pressure has decreased to 1.00 atm. Calculate the final volume and temperature, the energy and enthalpy changes, and the work done.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

The initial volume is

$$V_1 = \frac{nRT_1}{P_1} = \frac{(5.00\text{ mol})(0.08206\text{ L atm K}^{-1}\text{ mol}^{-1})(298\text{ K})}{(10.0\text{ atm})} = 12.2\text{ L}$$

and the heat capacity ratio for a monatomic gas is

$$\gamma = \frac{c_P}{c_V} = \frac{\frac{5}{2}R}{\frac{3}{2}R} = \frac{5}{3}$$

For a reversible adiabatic process,

$$\frac{P_1}{P_2}\ V_1^{\gamma} = V_2^{\gamma}$$

$$(10.0)(12.2\text{ L})^{5/3} = V_2^{5/3}$$

$$V_2 = (12.2\text{ L})(10.0)^{3/5} = 48.7\text{ L}$$

The final temperature can now be calculated from the ideal gas law:

$$T_2 = \frac{P_2V_2}{nR} = 119\text{ K}$$

From this the work done and the energy change can be found,

$$w = \Delta U = nc_V\Delta T = (5.00\text{ mol})(\tfrac{3}{2} \times 8.315\text{ J K}^{-1}\text{ mol}^{-1})(119\text{ K} - 298\text{ K})$$

$$= -11,200\text{ J}$$

as well as the enthalpy change:

$$\Delta H = nc_P\Delta T = (5.00\text{ mol})(\tfrac{5}{2} \times 8.315\text{ J K}^{-1}\text{ mol}^{-1})(119\text{ K} - 298\text{ K}) = -18{,}600\text{ J}$$

Related Problems: 57, 58

Figure 12.20 compares the adiabatic expansion of this to the isothermal expansion of Example 12.11. Note that the initial states were the same in the two cases, as

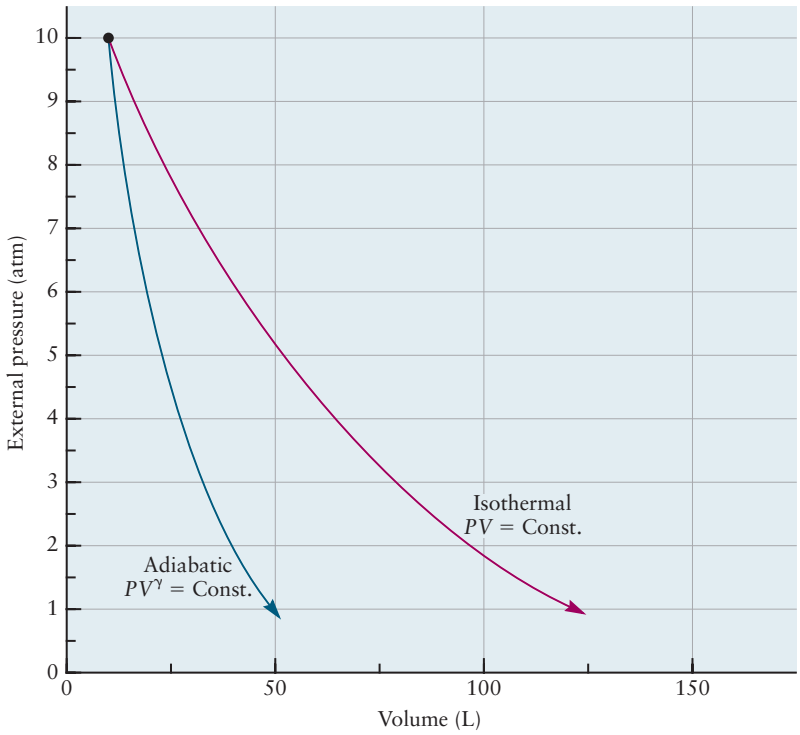

FIGURE 12.20 A comparison of reversible isothermal and adiabatic expansions. Using the technique shown in Figure 12.19, the adiabatic work is 40% of the isothermal work.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

were the final pressures. However, the final volume is larger by more than a factor of 2 for the isothermal expansion, and the work output for the adiabatic case is only 40% of the output from the isothermal expansion. Because $\gamma > 1$, the adiabatic line falls off more rapidly with increasing volume than the isothermal line. Because no heat is transferred in an adiabatic expansion, the work comes from the internal energy of the gas; thus, the temperature declines.

A DEEPER LOOK

12.8 DISTRIBUTION OF ENERGY AMONG MOLECULES

The kinetic molecular theory of gases (Section 9.5) relates the macroscopic properties of a gas to the structure of the constituent molecules, the forces between them, and their motions. Because the number of molecules in a sample of gas is so incredibly large—28 g nitrogen contains 6.02×10^{23} molecules—we give up the idea of following the detailed motions of any one molecule and rely on a statistical description that gives the *probability* of finding a molecule in the gas at a certain position, with a certain speed, with a certain value of energy, and so on. Treating the molecules as point masses obeying classical mechanics and using simple statistical arguments, the kinetic theory shows that the temperature of the gas is proportional to the average kinetic energy per molecule. This relation not only provides a microscopic interpretation of the concept of temperature, but it also indicates the typical values of molecular kinetic energy that occur in a gas at a particular temperature.

Now we want to determine the relation between temperature and the energy involved in other kinds of molecular motions that depend on molecular structure, not just the translation of the molecule. This relation is provided by the *Boltzmann energy distribution,* which relies on the quantum description of molecular motions. This section defines the Boltzmann distribution and uses it to describe the vibrational energy of diatomic molecules in a gas at temperature T.

The Boltzmann energy distribution is one of the most widely used relations in the natural sciences, because it provides a reliable way to interpret experimental results in terms of molecular behavior. You should become skilled in its applications.

The Boltzmann Energy Distribution

We start with a model system in which gaseous molecules move around inside a container held at temperature T. The molecules collide with the container walls, but not with one another. We can achieve this condition by setting up the experiment with sufficiently low pressure in the system. But this time we assume that the molecules have quantum states described by a quantum number n and represented on an energy level diagram where the energy of each state is labeled ε_n. After the system has settled down to equilibrium, how many of the molecules are in their ground state? To what extent are the excited states populated? The answers depend on the probability that a molecule in the gas is in the quantum state n, which is given by the **Boltzmann energy distribution:**

$$P(n) = C \exp(-\varepsilon_n / k_B T) \qquad [12.19]$$

where C is a normalization factor and k_B is Boltzmann's constant. This equation was derived for classical systems by Ludwig Boltzmann even before quantum

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

mechanics had been invented. Max Planck used a version of the Boltzmann distribution in formulating his theory of blackbody radiation (see Section 4.2) to obtain the probability that his quantized oscillators would radiate energy when the blackbody was at temperature T. We do not derive the distribution, but illustrate its application and interpretation.

Vibrational Energy Distribution

We apply the Boltzmann distribution to describe the probability of finding molecules in each of the vibrational states in a sample of CO held at temperature T. We describe the vibrational motions using the harmonic oscillator model, for which the allowed energy levels are

$$\varepsilon_n = \left(n + \frac{1}{2}\right)h\nu$$

where $n = 0, 1, 2, 3, \ldots$ and the vibrational frequency is related to the force constant by

$$\nu = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}}$$

and μ is the reduced mass. These equations define the energy level diagram, which has uniformly spaced levels separated by

$$h\nu = \frac{h}{2\pi}\sqrt{\frac{k}{\mu}} \qquad [12.20]$$

We calculate the reduced mass of $^{12}C^{16}O$ using the isotopic masses in Table 19.1 to be

$$\mu = \frac{m_C m_O}{m_C + m_O}$$

$$= \frac{(12.00)(15.99)\text{ amu}}{27.99}\left(\frac{1\text{ g}}{6.02\times10^{23}\text{ amu}}\right)\left(\frac{1\text{ kg}}{10^3\text{ g}}\right)$$

$$\mu = 1.14\times10^{-26}\,\text{kg}$$

The value of the force constant for CO is 1902 N m^{-1}, as measured in vibrational spectroscopy (see Section 20.3). The value of the energy level separation is then

$$h\nu = \left(\frac{6.63\times10^{-34}\text{ J s}}{2\pi}\right)\left(\frac{1.902\times10^{3}\text{N m}^{-1}}{1.14\times10^{-26}\text{ kg}}\right)^{1/2}$$

$$h\nu = 4.52\times10^{-20}\text{ J}$$

The relative probability of finding molecules in the excited state n and in the ground state $n = 0$ is given by

$$\frac{P(n)}{P(0)} = \frac{C\exp(-\varepsilon_n/k_BT)}{C\exp(-\varepsilon_0/k_BT)} = \exp(-[\varepsilon_n - \varepsilon_0]/k_BT) \qquad [12.21]$$

Inserting the energy level expression for the harmonic oscillator gives

$$\frac{P(n)}{P(0)} = \exp(-[(n+\tfrac{1}{2})h\nu - \tfrac{1}{2}h\nu]/k_BT) = \exp(-nh\nu/k_BT) \qquad [12.22]$$

The relative populations of the first excited state $n = 1$ and the ground state are determined by the ratio $h\nu/k_BT$. We know from Chapter 4 that $h\nu$ is the quantum of vibrational energy needed to put a CO molecule in its first excited state, and we

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

have calculated that value to be $h\nu = 4.52 \times 10^{-20}$ J. From Section 9.5 we know that the average kinetic energy of a molecule in the gas is $(3/2)k_BT$, which is $(1/2)k_BT$ for each of the x, y, and z directions of motion. Therefore, we interpret k_BT as a measure of the average energy available to each molecule in a gas at temperature T. So, the ratio $h\nu/k_BT$ determines whether there is sufficient energy in the gas to put the molecules into excited states. At 300 K, the value of k_BT is 4.14×10^{-21} J, which is a factor of 10 smaller than the vibrational quantum of CO. Inserting these numbers into Equation 12.22 gives the relative probability as 3.03×10^{-5}. This means that only 3 molecules in a group of 100,000 are in the first excited state at 300 K. At 1000 K, the value of k_BT is 1.38×10^{-20} J, which is closer to the value of the CO vibrational quantum and gives a relative population of 4.41×10^{-2}.

This case study shows that CO molecules do not have significant vibrational energy unless the temperature is quite high. This happens because CO has a triple bond and, therefore, a large force constant ($k = 1902$ N m^{-1}). The correlation between force constant and bond order in diatomic molecules is explained by molecular orbital theory, and is summarized in Figure 6.20. Other diatomic molecules will have quantitatively different distributions, as determined by their structure.

EXAMPLE 12.12

Calculate the population of the first and second vibrational excited states, relative to the ground state, for Br_2 at $T = 300$ K and 1000 K. For Br_2, the measured vibrational frequency is 9.68×10^{12} s^{-1}. Interpret your results in relation to the chemical bond in Br_2.

Solution

Use Equation 12.22 with $n = 1$ to obtain N_1/N_0 and $n = 2$ to obtain N_2/N_0. It is convenient to evaluate the important quantities before substituting into the equation.

Evaluate the vibrational energy of Br_2:

$$h\nu = (6.63 \times 10^{-34}\ \text{J s})(9.68 \times 10^{12}\ \text{s}^{-1}) = 6.42 \times 10^{-21}$$

Evaluate k_BT at 300 K and 1000 K:

$$k_BT = (300\ \text{K})(1.380 \times 10^{-23}\ \text{J K}^{-1}) = 4.14 \times 10^{-21}\ \text{J}$$

$$k_BT = (1000\ \text{K})(1.380 \times 10^{-23}\ \text{J K}^{-1}) = 1.38 \times 10^{-20}\ \text{J}$$

The population ratios at 300 K are:

$$\frac{P(1)}{P(0)} = \exp\left[-\frac{6.42 \times 10^{-21}\ \text{J}}{4.14 \times 10^{-21}\ \text{J}}\right] = 0.212$$

$$\frac{P(2)}{P(0)} = \exp\left[-\frac{2(6.42 \times 10^{-21}\ \text{J})}{4.14 \times 10^{-21}\ \text{J}}\right] = 0.045$$

The population ratios at 1000 K are:

$$\frac{P(1)}{P(0)} = \exp\left[-\frac{6.42 \times 10^{-21}\ \text{J}}{1.38 \times 10^{-20}\ \text{J}}\right] = 0.628$$

$$\frac{P(2)}{P(0)} = \exp\left[-\frac{2(6.42 \times 10^{-21}\ \text{J})}{1.38 \times 10^{-20}\ \text{J}}\right] = 0.395$$

The distribution for the first six states at 300 K and 1000 K is shown in Figure 12.21.

The quantized energy of vibration is much less for Br_2 than for CO for two reasons: the single bond in Br_2 has a much smaller force constant than the triple bond in CO, and the Br atoms are much more massive than C and O atoms.

CHAPTER SUMMARY

The central goal of this chapter is to define and measure the heat liberated or absorbed during a chemical reaction. We achieved that goal in Section 12.6 by introducing the enthalpy change of a reaction, which is measured by performing the reaction in a constant-pressure calorimeter. Tabulating data for reactions in which both products and reactants are in their standard states gives the standard enthalpy of reaction, which enables systematic comparison of the energy changes due to bond rearrangements in different reactions. The standard enthalpy change for a reaction is readily calculated from tables of the standard enthalpy of formation for the products and reactants. These basic tools of thermochemistry completely describe the energy transfers in chemical reactions.

The discussion of basic thermodynamics in Sections 12.1 through 12.4 can be viewed as background necessary for achieving the central goal. Sections 12.5 and 12.7 provide the molecular interpretation of these relations. Even so, this material is important in its own right and will be used repeatedly throughout the book. Similarly, the discussion of reversible isothermal and adiabatic processes in Section 12.6 provides background needed later in the book to calculate changes in state functions for irreversible processes.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 12.1 – Systems, States, and Processes

Give precise definitions for the terms thermodynamic system, open system, closed system, thermodynamic state, reversible process, irreversible process.

- The system is that part of the universe of interest, for example a chemical reaction, an engine, a human being.
- The surroundings are that part of the universe that exchanges matter and energy with the system during a process.
- The thermodynamic universe is the combination of the system and the surroundings for a particular process of interest; it is assumed to be closed and isolated.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- A closed system is one in which no exchange of matter between system and surroundings is permitted.
- An adiabatic system is one in which no exchange of heat between system and surroundings is permitted.
- A thermodynamic state is a condition in which all macroscopic properties of a system are determined by the external conditions imposed on the system (for example, n, T, and P).
- A thermodynamic system is in thermodynamic equilibrium if none of its macroscopic properties is changing over time. (**Note:** Some states that appear not to be changing may not be true equilibrium states because the changes are too slow to be observed, for example, diamond turning into graphite.)
- Properties of a system may either be independent of the amount of material present (intensive, like T and P) or proportional to the quantity of material present (extensive, like internal energy and heat capacity).
- Processes can be either irreversible (a small change in the external condition will not reverse the course of the process) or reversible (a small change in the external condition will reverse the course of the process). The latter are idealizations, often called quasi-static, and would take an infinite amount of time to occur in a real sense.

Define and give examples of properties that are state functions of a system.

- A state function is a property whose value depends only on the current state of the system and not on the path by which that state was reached (examples include T and P).
- A path-dependent function is one in which the value does depend on the details of the path taken, work and heat being the most common examples.

Section 12.2 – The First Law of Thermodynamics: Internal Energy, Work, and Heat

Calculate the work done on an ideal gas when it is compressed reversibly (Problems 1–2).

- Work (w) is force times displacement $w = Fd$. Perhaps the most important type of work in chemistry is pressure–volume work, in which a system either expands against or is compressed by the external pressure.
- We chose the sign convention so that $+w$ indicates work is done on the system.

Give a physical interpretation to the concept of heat, and calculate the change in temperature of a given quantity of a substance from its heat capacity and the amount of heat transferred to it (Problems 3–8).

- Heat transfer is measured by calorimetry. $q = Mc_s\Delta T$, where M is the mass of the heat-absorbing substance in the calorimeter (usually water) and c_s is the specific heat of the substance.
- We chose the sign convention so that $+q$ indicates heat is added to the system.

State the first law of thermodynamics and give a physical interpretation (Problems 9–10).

- $\Delta U = q + w$. The internal energy of a system is a state function. Although q and w are functions of the path, their sum is a state function. Heat transferred and work done must leave the energy of the thermodynamic universe unchanged.

$$q_{sys} = -q_{surr}$$

$$w_{sys} = -w_{surr}$$

$$\Delta U_{sys} = -\Delta U_{surr}$$

Section 12.3 – Heat Capacity, Calorimetry, and Enthalpy

Calculate the final temperature reached when two substances of different mass, heat capacity, and temperature are placed in thermal contact (Problems 11–16).

- The heat q_2 taken up by the cooler body is $-q_1$, the heat given up by the warmer body. This fact gives the equation

$$M_1 c_{s1}(T_f - T_1) = -M_2 c_{s2}(T_f - T_2)$$

  which is solved for T_f.

Section 12.4 – The First Law and Ideal Gas Processes

Calculate the amounts of heat and work and the change in the internal energy of an ideal gas during expansion and compression (Problems 17–22).

- Heat capacities of ideal monatomic gases

$$c_V \text{ (ideal gas)} = (3/2)\,R$$
$$c_P = c_V + R = (5/2)R$$

- Heat and work for ideal gases: The calculations on page 536 associated with Figure 12.10 demonstrate that the values of q and w depend on the path over which a process occurs.

Section 12.5 – Molecular Contributions to Internal Energy and Heat Capacity

Estimate the heat capacity for a gas based on its molecular structure (Problems 23–26).

- From the known structure of the gaseous molecule, we determine the number of degrees of freedom for rotational and vibrational motions, and add these to the three degrees of freedom for translation of the molecule. Assuming ideal gas behavior, we calculate c_V by adding up the contributions from all these degrees of freedom using the classical equipartition theorem. Each translation degree of freedom contributes $R/2$, each rotational degree of freedom contributes $R/2$, and each vibrational degree of freedom contributes R. We add one additional term R to convert c_V to c_P. The results are summarized and illustrated in Table 12.3.

Section 12.6 – Thermochemistry

Calculate the energy and enthalpy changes for chemical reactions from the standard molar enthalpies of formation of reactants and products (Problems 39–46).

- The most useful thermochemical data are tables of the standard enthalpy of formation ΔH_f° for compounds, defined as the enthalpy of formation of a compound in its standard state from the elements in their standard states at 1 atm and 298.15 K.
- The change in standard state enthalpy for any reaction can be calculated from the standard state enthalpy of formation of its products and reactants as

$$\Delta H^\circ = \sum_{i-1}^{prod} n_i \Delta H_i^\circ - \sum_{j-1}^{react} n_j \Delta H_j^\circ$$

Use bond enthalpies to estimate enthalpies of formation of gaseous compounds (Problems 49–52).

- Bond enthalpy is the enthalpy change associated with making or breaking a chemical bond. It is based on the idea that bond enthalpy, like bond energy (see Chapter 3), is approximately independent of the rest of the molecule. Average bond enthalpies are tabulated from measurements over a broad range of molecules in which the same bond appears.

Section 12.7 – Reversible Processes in Ideal Gases

Calculate the heat absorbed and work done by an ideal gas when it expands reversibly and either isothermally or adiabatically (Problems 55–58).

- **Isothermal processes:** In this case, heat will flow (in either direction) to offset the cost of PV work, whereas T remains constant.

$$dw = -PdV$$

$$w = -\int_{V_1}^{V_2} P\,dV$$

- For an ideal gas, $P = nRT/V$. Because T is constant it comes outside the integral to give

$$w = -nRT\int_{V_1}^{V_2} (1/V)\,dV$$

$$w = -nRT\ln(V_2/V_1)$$

$$q = +nRT\ln(V_2/V_1)$$

$$\Delta U = 0$$

$$\Delta H = 0$$

- **Adiabatic processes:** No heat flows, so all of the energy comes from or goes into the internal energy of the system. The key steps are:

$$q = 0, \text{ so } \Delta U = w$$

$nc_V dT = -PdV = nRTdV$ rearranging, integrating, and "simplifying" gives $P_1 V_1^{\gamma} = P_2 V_2^{\gamma}$, where $\gamma = c_P/c_V = 5/3$ for ideal gases.

- The important result is that the pressure decreases faster in an adiabatic expansion than in an isothermal expansion because there is no heat to enable the expansion work and keep the pressure higher.

Section 12.8 – A Deeper Look . . . Distribution of Energy among Molecules

Use the Boltzmann distribution to determine the relative population of two quantum states in a gas at temperature T (Problems 59–64).

- The relative probability of finding molecules in the excited state n and in the ground state $n = 0$ is given by

$$\frac{P(n)}{P(0)} = \frac{C\exp(-\varepsilon_n/k_B T)}{C\exp(-\varepsilon_0/k_B T)} = \exp(-[\varepsilon_n - \varepsilon_0]/k_B T$$

CUMULATIVE EXERCISES

Vanessa Vick/Photo Researchers, Inc.

A methanol-powered bus.

Methanol as a Gasoline Substitute

Methanol (CH_3OH) is used as a substitute for gasoline in certain high-performance vehicles. To design engines that will run on methanol, we must understand its thermochemistry.

(a) The methanol in an automobile engine must be in the gas phase before it can react. Calculate the heat (in kilojoules) that must be added to 1.00 kg liquid methanol to increase its temperature from 25.0°C to its normal boiling point, 65.0°C. The molar heat capacity of liquid methanol is 81.6 J K^{-1} mol^{-1}.

(b) Once the methanol has reached its boiling point, it must be vaporized. The molar enthalpy of vaporization for methanol is 38 kJ mol^{-1}. How much heat must be added to vaporize 1.00 kg methanol?

Methanol, CH_3OH.

(c) Once it is in the vapor phase, the methanol can react with oxygen in the air according to

$$CH_3OH(g) + \tfrac{3}{2}\,O_2(g) \longrightarrow CO_2(g) + 2\,H_2O(g)$$

Use average bond enthalpies to estimate the enthalpy change in this reaction, for 1 mol of methanol reacting.

(d) Use data from Appendix D to calculate the actual enthalpy change in this reaction, assuming it to be the same at 65°C as at 25°C.

(e) Calculate the heat released when 1.00 kg gaseous methanol is burned in air at constant pressure. Use the more accurate result of part (d), rather than that of part (c).

(f) Calculate the *difference* between the change in enthalpy and the change in internal energy when 1.00 kg gaseous methanol is oxidized to gaseous CO_2 and H_2O at 65°C.

(g) Suppose now that the methanol is burned inside the cylinder of an automobile. Taking the radius of the cylinder to be 4.0 cm and the distance moved by the piston during one stroke to be 12 cm, calculate the work done on the gas per stroke as it expands against an external pressure of 1.00 atm. Express your answer in liter-atmospheres and in joules.

Answers

(a) 102 kJ

(b) 1.2×10^3 kJ

(c) −508 kJ

(d) −676.49 kJ

(e) 2.11×10^4 kJ

(f) $\Delta H - \Delta U = 43.9$ kJ

(g) −0.60 L atm = −61 J

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

The First Law of Thermodynamics: Internal Energy, Work, and Heat

1. Some nitrogen for use in synthesizing ammonia is heated slowly, maintaining the external pressure close to the internal pressure of 50.0 atm, until its volume has increased from 542 to 974 L. Calculate the work done on the nitrogen as it is heated, and express it in joules.

2. The gas mixture inside one of the cylinders of an automobile engine expands against a constant external pressure of 0.98 atm, from an initial volume of 150 mL (at the end of the compression stroke) to a final volume of 800 mL. Calculate the work done on the gas mixture during this process, and express it in joules.

3. When a ball of mass m is dropped through a height difference Δh, its potential energy changes by the amount $mg\,\Delta h$, where g is the acceleration of gravity, equal to 9.81 m s^{-2}. Suppose that when the ball hits the ground, all that energy is converted to heat, increasing the temperature of the ball. If the specific heat capacity of the material in the ball is 0.850 J K^{-1} g^{-1}, calculate the height from which the ball must be dropped to increase the temperature of the ball by 1.00°C.

4. During his honeymoon in Switzerland, James Joule is said to have used a thermometer to measure the temperature difference between the water at the top and at the bottom of a waterfall. Take the height of the waterfall to be Δh and the acceleration of gravity, g, to be 9.81 m s^{-2}. Assuming that all the potential energy change $mg\,\Delta h$ of a mass m of water is used to heat that water by the time it reaches the bottom, calculate the temperature difference between the top and the bottom of a waterfall 100 meters high. Take the specific heat capacity of water to be 4.18 J K^{-1} g^{-1}.

5. The specific heat capacities of Li(s), Na(s), K(s), Rb(s), and Cs(s) at 25°C are 3.57, 1.23, 0.756, 0.363, and 0.242 J K^{-1} g^{-1}, respectively. Compute the molar heat capacities of these elements and identify any periodic trend. If there is a trend, use it to predict the molar heat capacity of francium, Fr(s).

6. The specific heat capacities of $F_2(g)$, $Cl_2(g)$, $Br_2(g)$, and $I_2(g)$ are 0.824, 0.478, 0.225, and 0.145 J K^{-1} g^{-1}, respectively. Compute the molar heat capacities of these elements and identify any periodic trend. If there is a trend, use it to predict the molar heat capacity of astatine, $At_2(g)$.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

7. The specific heat capacities of the metals nickel, zinc, rhodium, tungsten, gold, and uranium at 25°C are 0.444, 0.388, 0.243, 0.132, 0.129, and 0.116 J K^{-1} g^{-1}, respectively. Calculate the molar heat capacities of these six metals. Note how closely the molar heat capacities for these metals, which were selected at random, cluster about a value of 25 J K^{-1} mol^{-1}. The rule of Dulong and Petit states that the molar heat capacities of the metallic elements are approximately 25 J K^{-1} mol^{-1}.

8. Use the empirical rule of Dulong and Petit stated in Problem 7 to estimate the specific heat capacities of vanadium, gallium, and silver.

9. A chemical system is sealed in a strong, rigid container at room temperature, and then heated vigorously.
- (a) State whether ΔU, q, and w of the system are positive, negative, or zero during the heating process.
- (b) Next, the container is cooled to its original temperature. Determine the signs of ΔU, q, and w for the cooling process.
- (c) Designate heating as step 1 and cooling as step 2. Determine the signs of $(\Delta U_1 + \Delta U_2)$, $(q_1 + q_2)$, and $(w_1 + w_2)$, if possible.

10. A battery harnesses a chemical reaction to extract energy in the form of useful electrical work.
- (a) A certain battery runs a toy truck and becomes partially discharged. In the process, it performs a total of 117.0 J of work on its immediate surroundings. It also gives off 3.0 J of heat, which the surroundings absorb. No other work or heat is exchanged with the surroundings. Compute q, w, and ΔU of the battery, making sure each quantity has the proper sign.
- (b) The same battery is now recharged exactly to its original condition. This requires 210.0 J of electrical work from an outside generator. Determine q for the battery in this process. Explain why q has the sign that it does.

Heat Capacity, Calorimetry, and Enthalpy

11. Suppose 61.0 g hot metal, which is initially at 120.0°C, is plunged into 100.0 g water that is initially at 20.00°C. The metal cools down and the water heats up until they reach a common temperature of 26.39°C. Calculate the specific heat capacity of the metal, using 4.18 J K^{-1} g^{-1} as the specific heat capacity of the water.

12. A piece of zinc at 20.0°C that weighs 60.0 g is dropped into 200.0 g water at 100.0°C. The specific heat capacity of zinc is 0.389 J K^{-1} g^{-1}, and that of water near 100°C is 4.22 J K^{-1} g^{-1}. Calculate the final temperature reached by the zinc and the water.

13. Very early in the study of the nature of heat it was observed that if two bodies of equal mass but different temperatures are placed in thermal contact, their specific heat capacities depend inversely on the change in temperature each undergoes on reaching its final temperature. Write a mathematical equation in modern notation to express this fact.

14. Iron pellets with total mass 17.0 g at a temperature of 92.0°C are mixed in an insulated container with 17.0 g water at a temperature of 20.0°C. The specific heat capacity of water is 10 times greater than that of iron. What is the final temperature inside the container?

15. In their *Memoir on Heat,* published in 1783, Lavoisier and Laplace reported, "The heat necessary to melt ice is equal to three quarters of the heat that can raise the same mass of water from the temperature of the melting ice to that of boiling water" (English translation). Use this 18th-century observation to compute the amount of heat (in joules) needed to melt 1.00 g ice. Assume that heating 1.00 g water requires 4.18 J of heat for each 1.00°C throughout the range from 0°C to 100°C.

16. Galen, the great physician of antiquity, suggested scaling temperature from a reference point defined by mixing equal masses of ice and boiling water in an insulated container. Imagine that this is done with the ice at 0.00°C and the water at 100.0°C. Assume that the heat capacity of the container is negligible, and that it takes 333.4 J of heat to melt 1.000 g ice at 0.00°C to water at 0.00°C. Compute Galen's reference temperature in degrees Celsius.

The First Law and Ideal Gas Processes

17. If 0.500 mol neon at 1.00 atm and 273 K expands against a constant external pressure of 0.100 atm until the gas pressure reaches 0.200 atm and the temperature reaches 210 K, calculate the work done on the gas, the internal energy change, and the heat absorbed by the gas.

18. Hydrogen behaves as an ideal gas at temperatures greater than 200 K and at pressures less than 50 atm. Suppose 6.00 mol hydrogen is initially contained in a 100-L vessel at a pressure of 2.00 atm. The average molar heat capacity of hydrogen at constant pressure, c_P, is 29.3 J K^{-1} mol^{-1} in the temperature range of this problem. The gas is cooled reversibly at constant pressure from its initial state to a volume of 50.0 L. Calculate the following quantities for this process.
- (a) Temperature of the gas in the final state, T_2
- (b) Work done on the gas, w, in joules
- (c) Internal energy change of the gas, ΔU, in joules
- (d) Heat absorbed by the gas, q, in joules

19. Suppose 2.00 mol of an ideal, monatomic gas is initially at a pressure of 3.00 atm and a temperature $T = 350$ K. It is expanded *irreversibly* and *adiabatically* ($q = 0$) against a constant external pressure of 1.00 atm until the volume has doubled.
- (a) Calculate the final volume.
- (b) Calculate w, q, and ΔU for this process, in joules.
- (c) Calculate the final temperature of the gas.

20. Consider the free, isothermal (constant T) expansion of an ideal gas. "Free" means that the external force is zero, perhaps because a stopcock has been opened and the gas is allowed to expand into a vacuum. Calculate ΔU for this irreversible process. Show that $q = 0$, so that the expansion is also adiabatic ($q = 0$) for an ideal gas. This is analogous to a classic experiment first performed by Joule.

21. If 6.00 mol argon in a 100-L vessel initially at 300 K is compressed adiabatically ($q = 0$) and irreversibly until a final temperature of 450 K is reached, calculate the energy change of the gas, the heat added to the gas, and the work done on the gas.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

22. A gas expands against a constant external pressure of 2.00 atm until its volume has increased from 6.00 to 10.00 L. During this process, it absorbs 500 J of heat from the surroundings.
    (a) Calculate the energy change of the gas, ΔU.
    (b) Calculate the work, w, done on the gas in an irreversible adiabatic ($q = 0$) process connecting the same initial and final states.

Molecular Contributions to Internal Energy and Heat Capacity

23. Calculate the value of c_P at 298 K and 1 atm pressure predicted for $I_2(g)$ and $HI(g)$ by the classical equipartition theorem. Compare the predicted results with the experimental results (See Appendix D) and calculate the per cent of the measured value that arises from vibrational motions.

24. Calculate the value of c_P at 298 K and 1 atm pressure predicted for $CH_4(g)$ and $C_2H_4(g)$ by the classical equipartition theorem. Compare the predicted results with the experimental results (See Appendix D) and calculate the per cent of the measured value that arises from vibrational motions.

25. (a) Calculate the change in enthalpy when 2.00 moles of argon is heated from 298 K to 573 K at constant pressure of 1 atmosphere.
    (b) Calculate the change in enthalpy when 2.00 moles of ethylene C_2H_4 is taken through the same process. In both cases assume the heat capacity values predicted by equipartition are valid through the temperature range stated.

26. (a) Calculate the change in enthalpy when 20.0 grams of aluminum metal is heated from 298 K to 573 K at constant pressure of 1 atmosphere.
    (b) Calculate the change in enthalpy when 20.0 grams of metallic lead is taken through the same process. In both cases assume the heat capacity values predicted by equipartition are valid through the temperature range stated.

Thermochemistry

27. For each of the following reactions, the enthalpy change written is that measured when the numbers of moles of reactants and products taking part in the reaction are as given by their coefficients in the equation. Calculate the enthalpy change when 1.00 *gram* of the underlined substance is consumed or produced.
    (a) $4\ Na(s) + O_2(g) \longrightarrow \underline{2\ Na_2O(s)}$ $\quad \Delta H = -828$ kJ
    (b) $CaMg(CO_3)_2(s) \longrightarrow \underline{CaO(s)} + \underline{MgO(s)} + 2\ CO_2(g)$ $\quad \Delta H = +302$ kJ
    (c) $H_2(g) + 2\ \underline{CO(g)} \longrightarrow H_2O_2(\ell) + 2\ C(s)$ $\quad \Delta H = +33.3$ kJ

28. For each of the following reactions, the enthalpy change given is that measured when the numbers of moles of reactants and products taking part in the reaction are as given by their coefficients in the equation. Calculate the enthalpy change when 1.00 *gram* of the underlined substance is consumed or produced.
    (a) $Ca(s) + \underline{Br_2(\ell)} \longrightarrow CaBr_2(s)$ $\quad \Delta H = -683$ kJ
    (b) $6\ Fe_2O_3(s) \longrightarrow 4\ \underline{Fe_3O_4(s)} + O_2(g)$ $\quad \Delta H = +472$ kJ
    (c) $\underline{2\ NaHSO_4(s)} \longrightarrow 2\ NaOH(s) + 2\ SO_2(g) + O_2(g)$ $\quad \Delta H = +806$ kJ

29. Liquid bromine dissolves readily in aqueous NaOH:

$$Br_2(\ell) + 2\ NaOH(aq) \longrightarrow NaBr(aq) + NaOBr(aq) + H_2O(\ell)$$

Suppose 2.88×10^{-3} mol of $Br_2(\ell)$ is sealed in a glass capsule that is then immersed in a solution containing excess $NaOH(aq)$. The capsule is broken, the mixture is stirred, and a measured 121.3 J of heat evolves. In a separate experiment, simply breaking an empty capsule and stirring the solution in the same way evolves 2.34 J of heat. Compute the heat evolved as 1.00 mol $Br_2(\ell)$ dissolves in excess $NaOH(aq)$.

30. A chemist mixes 1.00 g $CuCl_2$ with an excess of $(NH_4)_2HPO_4$ in dilute aqueous solution. He measures the evolution of 670 J of heat as the two substances react to give $Cu_3(PO_4)_2(s)$. Compute the ΔH that would result from the reaction of 1.00 mol $CuCl_2$ with an excess of $(NH_4)_2HPO_4$.

31. Calculate the enthalpy change when 2.38 g carbon monoxide (CO) vaporizes at its normal boiling point. Use data from Table 12.2.

32. Molten sodium chloride is used for making elemental sodium and chlorine. Suppose the electrical power to a vat containing 56.2 kg molten sodium chloride is cut off and the salt crystallizes (without changing its temperature). Calculate the enthalpy change, using data from Table 12.2.

33. Suppose an ice cube weighing 36.0 g at a temperature of −10°C is placed in 360 g water at a temperature of 20°C. Calculate the temperature after thermal equilibrium is reached, assuming no heat loss to the surroundings. The enthalpy of fusion of ice is $\Delta H_{fus} = 6.007$ kJ mol^{-1}, and the molar heat capacities c_P of ice and water are 38 and 75 J K^{-1} mol^{-1}, respectively.

34. You have a supply of ice at 0.0°C and a glass containing 150 g water at 25°C. The enthalpy of fusion for ice is $\Delta H_{fus} = 333$ J g^{-1}, and the specific heat capacity of water is 4.18 J K^{-1} g^{-1}. How many grams of ice must be added to the glass (and melted) to reduce the temperature of the water to 0°C?

35. The measured enthalpy change for burning ketene (CH_2CO)

$$CH_2CO(g) + 2\ O_2(g) \longrightarrow 2\ CO_2(g) + H_2O(g)$$

is $\Delta H_1 = -981.1$ kJ at 25°C. The enthalpy change for burning methane

$$CH_4(g) + 2\ O_2(g) \longrightarrow CO_2(g) + 2\ H_2O(g)$$

is $\Delta H_2 = -802.3$ kJ at 25°C. Calculate the enthalpy change at 25°C for the reaction

$$2\ CH_4(g) + 2\ O_2(g) \longrightarrow CH_2CO(g) + 3\ H_2O(g)$$

36. Given the following two reactions and corresponding enthalpy changes,

$$CO(g) + SiO_2(s) \longrightarrow SiO(g) + CO_2(g) \qquad \Delta H = +520.9 \text{ kJ}$$

$$8\ CO_2(g) + Si_3N_4(s) \longrightarrow 3\ SiO_2(s) + 2\ N_2O(g) + 8\ CO(g) \qquad \Delta H = +461.05 \text{ kJ}$$

compute the ΔH of the reaction

$$5\ CO_2(g) + Si_3N_4(s) \longrightarrow 3\ SiO(g) + 2\ N_2O(g) + 5\ CO(g)$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

37. The enthalpy change to make diamond from graphite is 1.88 kJ mol^{-1}. Which gives off more heat when burned—a pound of diamonds or a pound of graphite? Explain.

38. The enthalpy change of combustion of monoclinic sulfur to $SO_2(g)$ is -9.376 kJ g^{-1}. Under the same conditions, the rhombic form of sulfur has an enthalpy change of combustion to $SO_2(g)$ of -9.293 kJ g^{-1}. Compute the ΔH of the reaction

$$\text{S(monoclinic)} \longrightarrow \text{S(rhombic)}$$

per gram of sulfur reacting.

39. Calculate the standard enthalpy change $\Delta H°$ at 25°C for the reaction

$$N_2H_4(\ell) + 3\ O_2(g) \longrightarrow 2\ NO_2(g) + 2\ H_2O(\ell)$$

using the standard enthalpies of formation (ΔH_f°) of reactants and products at 25°C from Appendix D.

40. Using the data in Appendix D, calculate $\Delta H°$ for each of the following processes:
(a) $2\ NO(g) + O_2(g) \longrightarrow 2\ NO_2(g)$
(b) $C(s) + CO_2(g) \longrightarrow 2\ CO(g)$
(c) $2\ NH_3(g) + \frac{7}{2}\ O_2(g) \longrightarrow 2\ NO_2(g) + 3\ H_2O(g)$
(d) $C(s) + H_2O(g) \longrightarrow CO(g) + H_2(g)$

41. Zinc is commonly found in nature in the form of the mineral sphalerite (ZnS). A step in the smelting of zinc is the roasting of sphalerite with oxygen to produce zinc oxide:

$$2\ ZnS(s) + 3\ O_2(g) \longrightarrow 2\ ZnO(s) + 2\ SO_2(g)$$

(a) Calculate the standard enthalpy change $\Delta H°$ for this reaction, using data from Appendix D.
(b) Calculate the heat absorbed when 3.00 metric tons (1 metric ton = 10^3 kg) of sphalerite is roasted under constant-pressure conditions.

42. The thermite process (see Fig. 12.14) is used for welding railway track together. In this reaction, aluminum reduces iron(III) oxide to metallic iron:

$$2\ Al(s) + Fe_2O_3(s) \longrightarrow 2\ Fe(s) + Al_2O_3(s)$$

Igniting a small charge of barium peroxide mixed with aluminum triggers the reaction of a mixture of aluminum powder and iron(III) oxide; the molten iron produced flows into the space between the steel rails that are to be joined.
(a) Calculate the standard enthalpy change $\Delta H°$ for this reaction, using data from Appendix D.
(b) Calculate the heat given off when 3.21 g iron(III) oxide is reduced by aluminum at constant pressure.

43. The dissolution of calcium chloride in water

$$CaCl_2(s) \longrightarrow Ca^{2+}(aq) + 2\ Cl^-(aq)$$

is used in first-aid hot packs. In these packs, an inner pouch containing the salt is broken, allowing the salt to dissolve in the surrounding water.
(a) Calculate the standard enthalpy change $\Delta H°$ for this reaction, using data from Appendix D.
(b) Suppose 20.0 g $CaCl_2$ is dissolved in 0.100 L water at 20.0°C. Calculate the temperature reached by the solution, assuming it to be an ideal solution with a heat capacity close to that of 100 g pure water (418 J K^{-1}).

44. Ammonium nitrate dissolves in water according to the reaction

$$NH_4NO_3(s) \longrightarrow NH_4^+(aq) + NO_3^-(aq)$$

(a) Calculate the standard enthalpy change $\Delta H°$ for this reaction, using data from Appendix D.
(b) Suppose 15.0 g NH_4NO_3 is dissolved in 0.100 L water at 20.0°C. Calculate the temperature reached by the solution, assuming it to be an ideal solution with a heat capacity close to that of 100 g pure water (418 J K^{-1}).
(c) From a comparison with the results of Problem 43, can you suggest a practical application of this dissolution reaction?

45. The standard enthalpy change of combustion [to $CO_2(g)$ and $H_2O(\ell)$] at 25°C of the organic liquid cyclohexane, $C_6H_{12}(\ell)$, is -3923.7 kJ mol^{-1}. Determine the ΔH_f° of $C_6H_{12}(\ell)$. Use data from Appendix D.

46. The standard enthalpy change of combustion [to $CO_2(g)$ and $H_2O(\ell)$] at 25°C of the organic liquid cyclohexane, $C_6H_{10}(\ell)$, is -3731.7 kJ mol^{-1}. Determine the ΔH_f° of $C_6H_{10}(\ell)$.

47. A sample of pure solid naphthalene ($C_{10}H_8$) weighing 0.6410 g is burned completely with oxygen to $CO_2(g)$ and $H_2O(\ell)$ in a constant-volume calorimeter at 25°C. The amount of heat evolved is observed to be 25.79 kJ.
(a) Write and balance the chemical equation for the combustion reaction.
(b) Calculate the standard change in internal energy ($\Delta U°$) for the combustion of 1.000 mol naphthalene to $CO_2(g)$ and $H_2O(\ell)$.
(c) Calculate the standard enthalpy change ($\Delta H°$) for the same reaction as in part (b).
(d) Calculate the standard enthalpy of formation per mole of naphthalene, using data for the standard enthalpies of formation of $CO_2(g)$ and $H_2O(\ell)$ from Appendix D.

48. A sample of solid benzoic acid (C_6H_5COOH) that weighs 0.800 g is burned in an excess of oxygen to $CO_2(g)$ and $H_2O(\ell)$ in a constant-volume calorimeter at 25°C. The temperature increase is observed to be 2.15°C. The heat capacity of the calorimeter and its contents is known to be 9382 J K^{-1}.
(a) Write and balance the equation for the combustion of benzoic acid.
(b) Calculate the standard change in internal energy ($\Delta U°$) for the combustion of 1.000 mol benzoic acid to $CO_2(g)$ and $H_2O(\ell)$ at 25°C.
(c) Calculate the standard enthalpy change ($\Delta H°$) for the same reaction as in part (b).
(d) Calculate the standard enthalpy of formation per mole of benzoic acid, using data for the standard enthalpies of formation of $CO_2(g)$ and $H_2O(\ell)$ from Appendix D.

49. A second CFC used as a refrigerant and in aerosols (besides that discussed in Example 12.9) is CCl_3F. Use the atomization enthalpies and average bond enthalpies from Table 12.5 to estimate the standard enthalpy of formation (ΔH_f°) of this compound in the gas phase.

50. The compound CF_3CHCl_2 (with a C—C bond) has been proposed as a substitute for CCl_3F and CCl_2F_2 because it decomposes more quickly in the atmosphere and is much less liable to reduce the concentration of ozone in the strato-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

sphere. Use the atomization enthalpies and average bond enthalpies from Table 12.5 to estimate the standard enthalpy of formation (ΔH_f°) of CF_3CHCl_2 in the gas phase.

51. Propane has the structure $H_3C{-}CH_2{-}CH_3$. Use average bond enthalpies from Table 12.5 to estimate the change in enthalpy $\Delta H°$ for the reaction

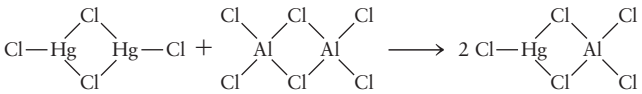
$$C_3H_8(g) + 5\ O_2(g) \longrightarrow 3\ CO_2(g) + 4\ H_2O(g)$$

52. Use average bond enthalpies from Table 12.5 to estimate the change in enthalpy $\Delta H°$ for the reaction

$$C_2H_4(g) + H_2(g) \longrightarrow C_2H_6(g)$$

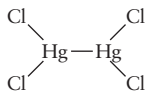
Refer to the molecular structures on page 109.

53. The following reaction



$$BBr_3(g) + BCl_3(g) \longrightarrow BBr_2Cl(g) + BCl_2Br(g)$$

has a ΔH close to zero. Sketch the Lewis structures of the four compounds, and explain why ΔH is so small.



54. At 381 K, the following reaction takes place:

$$Hg_2Cl_4(g) + Al_2Cl_6(g) \longrightarrow HgAlCl_5(g) \qquad \Delta H = +10\ kJ$$

(a) Offer an explanation for the very small ΔH for this reaction for the known structures of the compounds

(b) Explain why the small ΔH in this reaction is evidence against

as the structure of $Hg_2Cl_4(g)$.

Reversible Processes in Ideal Gases

55. If 2.00 mol of an ideal gas at 25°C expands isothermally and reversibly from 9.00 to 36.00 L, calculate the work done on the gas and the heat absorbed by the gas in the process. What are the changes in energy (ΔU) and in enthalpy (ΔH) of the gas in the process?

56. If 54.0 g argon at 400 K is compressed isothermally and reversibly from a pressure of 1.50 to 4.00 atm, calculate the work done on the gas and the heat absorbed by gas in the process. What are the changes in energy (ΔU) and in enthalpy (ΔH) of the gas?

57. Suppose 2.00 mol of a monatomic ideal gas ($c_V = \frac{3}{2} R$) is expanded adiabatically and reversibly from a temperature $T = 300$ K, where the volume of the system is 20.0 L, to a volume of 60.0 L. Calculate the final temperature of the gas, the work done on the gas, and the energy and enthalpy changes.

58. Suppose 2.00 mol of an ideal gas is contained in a heat-insulated cylinder with a moveable frictionless piston. Initially, the gas is at 1.00 atm and 0°C. The gas is compressed reversibly to 2.00 atm. The molar heat capacity at constant pressure, c_P, equals 29.3 J K^{-1} mol^{-1}. Calculate the final temperature of the gas, the change in its internal energy, ΔU, and the work done on the gas.

A Deeper Look . . . Distribution of Energy among Molecules

59. Calculate the relative populations of two energy levels separated by 0.4×10^{-21} J in a gas at temperature 25°C.

60. Calculate the relative populations of two energy levels separated by 40×10^{-21} J in a gas at temperature 25°C.

61. Estimate the ratio of the number of molecules in the first excited vibrational state of the molecule N_2 to the number in the ground state, at a temperature of 450 K. The vibrational frequency of N_2 is 7.07×10^{13} s^{-1}.

62. The vibrational frequency of the ICl molecule is 1.15×10^{13} s^{-1}. For every million (1.00×10^6) molecules in the ground vibrational state, how many will be in the first excited vibrational state at a temperature of 300 K?

63. The force constant for HF is 966 N m^{-1}. Using the harmonic oscillator model, calculate the relative population of the first excited state and the ground state at 300 K.

64. The force constant for HBr is 412 N m^{-1}. Using the harmonic oscillator model, calculate the relative population of the first excited state and the ground state at 300 K.

ADDITIONAL PROBLEMS

65. At one time it was thought that the molar mass of indium was near 76 g mol^{-1}. By referring to the law of Dulong and Petit (see Problem 7), show how the measured specific heat of metallic indium, 0.233 J K^{-1} g^{-1}, makes this value unlikely.

66. The following table shows how the specific heat at constant pressure of liquid helium changes with temperature. Note the sharp increase over this temperature range:

Temperature (K):							
1.80	1.85	1.90	1.95	2.00	2.05	2.10	2.15
c_s (J K^{-1} g^{-1}):							
2.81	3.26	3.79	4.42	5.18	6.16	7.51	9.35

Estimate how much heat it takes at constant pressure to increase the temperature of 1.00 g He(ℓ) from 1.8 to 2.15 K. (*Hint:* For each temperature interval of 0.05 K, take the average, c_s, as the sum of the values at the ends of the interval divided by 2.)

67. Imagine that 2.00 mol argon, confined by a moveable, frictionless piston in a cylinder at a pressure of 1.00 atm and a temperature of 398 K, is cooled to 298 K. Argon gas may be considered ideal, and its molar heat capacity at constant pressure is $c_P = (5/2)R$, where $R = 8.315\ \text{J K}^{-1}\ \text{mol}^{-1}$. Calculate:
(a) The work done on the system, w
(b) The heat absorbed by the system, q
(c) The energy change of the system, ΔU
(d) The enthalpy change of the system, ΔH

68. Suppose 1.00 mol ice at −30°C is heated at atmospheric pressure until it is converted to steam at 140°C. Calculate q, w, ΔH, and ΔU for this process. For ice, water, and steam, c_P is 38, 75, and 36 $\text{J K}^{-1}\ \text{mol}^{-1}$, respectively, and can be taken to be approximately independent of temperature. ΔH_{fus} for ice is 6.007 kJ mol^{-1}, and ΔH_{vap} for water is 40.66 kJ mol^{-1}. Use the ideal gas law for steam, and assume that the volume of 1 mol ice or water is negligible relative to that of 1 mol steam.

69. The gas inside a cylinder expands against a constant external pressure of 1.00 atm from a volume of 5.00 L to a volume of 13.00 L. In doing so, it turns a paddle immersed in 1.00 L water. Calculate the temperature increase of the water, assuming no loss of heat to the surroundings or frictional losses in the mechanism. Take the density of water to be 1.00 g cm^{-3} and its specific heat to be 4.18 $\text{J K}^{-1}\ \text{g}^{-1}$.

70. Suppose 1.000 mol argon (assumed to be an ideal gas) is confined in a strong, rigid container of volume 22.41 L at 273.15 K. The system is heated until 3.000 kJ (3000 J) of heat has been added. The molar heat capacity of the gas does not change during the heating and equals 12.47 $\text{J K}^{-1}\ \text{mol}^{-1}$.
(a) Calculate the original pressure inside the vessel (in atmospheres).
(b) Determine q for the system during the heating process.
(c) Determine w for the system during the heating process.
(d) Compute the temperature of the gas after the heating, in degrees Celsius. Assume the container has zero heat capacity.
(e) Compute the pressure (in atmospheres) inside the vessel after the heating.
(f) Compute ΔU of the gas during the heating process.
(g) Compute ΔH of the gas during the heating process.
(h) The correct answer to part (g) exceeds 3.000 kJ. The increase in enthalpy (which at one time was misleadingly called the "heat content") in this system exceeds the amount of heat actually added. Why is this not a violation of the law of conservation of energy?

71. When glucose, a sugar, reacts fully with oxygen, carbon dioxide and water are produced:

$$C_6H_{12}O_6(s) + 6\ O_2(g) \longrightarrow 6\ CO_2(g) + 6\ H_2O(\ell) \qquad \Delta H° = -2820\ \text{kJ}$$

Suppose a person weighing 50 kg (mostly water, with specific heat capacity 4.18 $\text{J K}^{-1}\ \text{g}^{-1}$) eats a candy bar containing 14.3 g glucose. If all the glucose reacted with oxygen and the heat produced were used entirely to increase the person's body temperature, what temperature increase would result? (In fact, most of the heat produced is lost to the surroundings before such a temperature increase occurs.)

72. In walking 1 km, you use about 100 kJ of energy. This energy comes from the oxidation of foods, which is about 30% efficient. How much energy do you save by walking 1 km instead of driving a car that gets 8.0 km L^{-1} gasoline (19 miles/gal)? The density of gasoline is 0.68 g cm^{-3} and its enthalpy of combustion is −48 kJ g^{-1}.

73. Liquid helium and liquid nitrogen are both used as coolants; $He(\ell)$ boils at 4.21 K, and $N_2(\ell)$ boils at 77.35 K. The specific heat of liquid helium near its boiling point is 4.25 $\text{J K}^{-1}\ \text{g}^{-1}$, and the specific heat of liquid nitrogen near *its* boiling point is 1.95 $\text{J K}^{-1}\ \text{g}^{-1}$. The enthalpy of vaporization of $He(\ell)$ is 25.1 J g^{-1}, and the enthalpy of vaporization of $N_2(\ell)$ is 200.3 J g^{-1} (these data are calculated from the values in Appendix F). Discuss which liquid is the better coolant (on a per-gram basis) *near* its boiling point and which is better *at* its boiling point.

74. When 1.00 g potassium chlorate ($KClO_3$) is dissolved in 50.0 g water in a Styrofoam calorimeter of negligible heat capacity, the temperature decreases from 25.00°C to 23.36°C. Calculate q for the water and $\Delta H°$ for the process.

$$KClO_3(s) \longrightarrow K^+(aq) + ClO_3^-(aq)$$

The specific heat of water is 4.184 $\text{J K}^{-1}\ \text{g}^{-1}$.

75. The enthalpy of combustion and the standard enthalpy of formation of a fuel can be determined by measuring the temperature change in a calorimeter when a weighed amount of the fuel is burned in oxygen.
(a) Write a balanced chemical equation for the combustion of isooctane, $C_8H_{18}(\ell)$, to $CO_2(g)$ and $H_2O(\ell)$. Isooctane is a component of gasoline and is used as a reference standard in determining the "octane rating" of a fuel mixture.
(b) Suppose 0.542 g isooctane is placed in a fixed-volume (bomb) calorimeter, which contains 750 g water, initially at 20.450°C, surrounding the reaction compartment. The heat capacity of the calorimeter itself (excluding the water) has been measured to be 48 J K^{-1} in a separate calibration. After the combustion of the isooctane is complete, the water temperature is measured to be 28.670°C. Taking the specific heat of water to be 4.184 $\text{J K}^{-1}\ \text{g}^{-1}$, calculate ΔU for the combustion of 0.542 g isooctane.
(c) Calculate ΔU for the combustion of 1 mol isooctane.
(d) Calculate ΔH for the combustion of 1 mol isooctane.
(e) Calculate ΔH_f° for the isooctane.

76. The enthalpy change to form 1 mol $Hg_2Br_2(s)$ from the elements at 25°C is $-206.77\ \text{kJ mol}^{-1}$, and that of $HgBr(g)$ is 96.23 kJ mol^{-1}. Compute the enthalpy change for the decomposition of 1 mol $Hg_2Br_2(s)$ to 2 mol $HgBr(g)$:

$$Hg_2Br_2(s) \longrightarrow 2\ HgBr(g)$$

* 77. The gas most commonly used in welding is acetylene, $C_2H_2(g)$. When acetylene is burned in oxygen, the reaction is

$$C_2H_2(g) + \tfrac{5}{2}\ O_2(g) \longrightarrow 2\ CO_2(g) + H_2O(g)$$

(a) Using data from Appendix D, calculate $\Delta H°$ for this reaction.
(b) Calculate the total heat capacity of 2.00 mol $CO_2(g)$ and 1.00 mol $H_2O(g)$, using $c_P(CO_2(g)) = 37\ \text{J K}^{-1}\ \text{mol}^{-1}$ and $c_P(H_2O(g)) = 36\ \text{J K}^{-1}\ \text{mol}^{-1}$.
(c) When this reaction is performed in an open flame, almost all the heat produced in part (a) goes to increase the temperature of the products. Calculate the maxi-

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

mum flame temperature that is attainable in an open flame burning acetylene in oxygen. The actual flame temperature would be lower than this because heat is lost to the surroundings.

* 78. The enthalpy of reaction changes somewhat with temperature. Suppose we wish to calculate ΔH for a reaction at a temperature T that is different from 298 K. To do this, we can replace the direct reaction at T with a three-step process. In the first step, the temperature of the reactants is changed from T to 298 K. ΔH for this step can be calculated from the molar heat capacities of the reactants, which are assumed to be independent of temperature. In the second step, the reaction is conducted at 298 K with an enthalpy change $\Delta H°$. In the third step, the temperature of the products is changed from 298 K to T. The sum of these three enthalpy changes is ΔH for the reaction at temperature T.

An important process contributing to air pollution is the following chemical reaction

$$SO_2(g) + \tfrac{1}{2}\ O_2(g) \longrightarrow SO_3(g)$$

For $SO_2(g)$, the heat capacity c_P is 39.9, for $O_2(g)$ it is 29.4, and for $SO_3(g)$ it is 50.7 J K^{-1} mol^{-1}. Calculate ΔH for the preceding reaction at 500 K, using the enthalpies of formation at 298.15 K from Appendix D.

79. At the top of the compression stroke in one of the cylinders of an automobile engine (that is, at the minimum gas volume), the volume of the gas-air mixture is 150 mL, the temperature is 600 K, and the pressure is 12.0 atm. The ratio of the number of moles of octane vapor to the number of moles of air in the combustion mixture is 1.00:80.0. What is the maximum temperature attained in the gas if octane burns explosively before the power stroke of the piston (gas expansion) begins? The gases may be considered to be ideal, and their heat capacities at constant pressure (assumed to be temperature-independent) are

$$c_P(C_8H_{18}(g)) = 327\ \text{J K}^{-1}\ \text{mol}^{-1}$$

$$c_P(O_2(g)) = 35.2\ \text{J K}^{-1}\ \text{mol}^{-1}$$

$$c_P(N_2(g)) = 29.8\ \text{J K}^{-1}\ \text{mol}^{-1}$$

$$c_P(CO_2(g)) = 45.5\ \text{J K}^{-1}\ \text{mol}^{-1}$$

$$c_P(H_2O(g)) = 38.9\ \text{J K}^{-1}\ \text{mol}^{-1}$$

The enthalpy of formation of $C_8H_{18}(g)$ at 600 K is -57.4 kJ mol^{-1}.

80. Initially, 46.0 g oxygen is at a pressure of 1.00 atm and a temperature of 400 K. It expands adiabatically and reversibly until the pressure is reduced to 0.60 atm, and it is then compressed isothermally and reversibly until the volume returns to its original value. Calculate the final pressure and temperature of the oxygen, the work done and heat added to the oxygen in this process, and the energy change ΔU. Take $c_P(O_2) = 29.4$ J K^{-1} mol^{-1}.

81. A young chemist buys a "one-lung" motorcycle but, before learning how to drive it, wants to understand the processes that occur in its engine. The manual says the cylinder has a radius of 5.00 cm, a piston stroke of 12.00 cm, and a (volume) compression ratio of 8:1. If a mixture of gasoline vapor (taken to be C_8H_{18}) and air in mole ratio 1:62.5 is drawn into the cylinder at 80°C and 1.00 atm, calculate:

(a) The temperature of the compressed gases just before the spark plug ignites them. (Assume the gases are ideal, the compression is adiabatic, and the average heat capacity of the mixture of gasoline vapor and air is $c_P = 35$ J K^{-1} mol^{-1}.)

(b) The volume of the compressed gases just before ignition.

(c) The pressure of the compressed gases just before ignition.

(d) The maximum temperature of the combustion products, assuming combustion is completed before the piston begins its downstroke. Take $\Delta H_f^\circ(C_8H_{18}) = -57.4$ kJ mol^{-1}.

(e) The temperature of the exhaust gases, assuming the expansion stroke to be adiabatic.

82. Nitromethane, CH_3NO_2, is a good fuel. It is a liquid at ordinary temperatures. When the liquid is burned, the reaction involved is chiefly

$$2\ CH_3NO_2(\ell) + \tfrac{3}{2}\ O_2(g) \longrightarrow 2\ CO_2(g) + N_2(g) + 3\ H_2O(g)$$

The standard enthalpy of formation of liquid nitromethane at 25°C is -112 kJ mol^{-1}; other relevant values can be found in Appendix D.

(a) Calculate the enthalpy change in the burning of 1 mol liquid nitromethane to form gaseous products at 25°C. State explicitly whether the reaction is endothermic or exothermic.

(b) Would more or less heat be evolved if *gaseous* nitromethane were burned under the same conditions? Indicate what additional information (if any) you would need to calculate the exact amount of heat, and show just how you would use this information.

83. Dry air containing a small amount of CO was passed through a tube containing a catalyst for the oxidation of CO to CO_2. Because of the heat evolved in this oxidation, the temperature of the air increased by 3.2 K. Calculate the weight percentage of CO in the sample of air. Assume that the specific heat at constant pressure for air is 1.01 J K^{-1} g^{-1}.

84. When 1 mol isobutane, a gas with formula C_4H_8, is burned at 25°C and 1 atm to form CO_2 and gaseous water, the enthalpy change is -2528 kJ.

(a) Calculate, with the aid of any information needed from Table D-4 in Appendix D, the standard enthalpy of formation of isobutane.

(b) Suppose that 0.50 mol isobutane is burned adiabatically at constant pressure in the presence of an excess of oxygen, with 5.0 mol oxygen left at the end of the reaction. The heat capacity of the reaction vessel is 700 J K^{-1}, and pertinent molar heat capacities (in joules per kelvin per mole) are $CO_2(g)$, 37; $H_2O(g)$, 34; $O_2(g)$, 29. What is the approximate final temperature of this system (including the reaction vessel)?

85. Find the maximum possible temperature that may be reached when 0.050 mol $Ca(OH)_2(s)$ is allowed to react with 1.0 L of a 1.0-M HCl solution, both initially at 25°C. Assume that the final volume of the solution is 1.0 L, and that the specific heat at constant pressure of the solution is constant and equal to that of water, 4.18 J K^{-1} g^{-1}.

CUMULATIVE PROBLEMS

86. Suppose 32.1 g $ClF_3(g)$ and 17.3 g $Li(s)$ are mixed and allowed to react at atmospheric pressure and 25°C until one of the reactants is used up, producing $LiCl(s)$ and $LiF(s)$. Calculate the amount of heat evolved.

87. Calculate ΔH_f° and ΔU_f° for the formation of silane, $SiH_4(g)$, from its elements at 298 K, if 250 cm^3 of the gaseous compound at $T = 298$ K and $P = 0.658$ atm is burned in a constant-volume gas calorimeter in an excess of oxygen and causes the evolution of 9.757 kJ of heat. The combustion reaction is

$$SiH_4(g) + 2\ O_2(g) \longrightarrow SiO_2(s, \text{quartz}) + 2\ H_2O(\ell)$$

and the formation of silane from its elements is

$$Si(s) + 2\ H_2(g) \longrightarrow SiH_4(g)$$

88. (a) Draw Lewis diagrams for O_2, CO_2, H_2O, CH_4, C_8H_{18}, and C_2H_5OH. In C_8H_{18}, the eight carbon atoms form a chain with single bonds; in C_2H_5OH, the two carbon atoms are bonded to one another. Using average bond enthalpies from Table 12.5, compute the enthalpy change in each of the following reactions, if 1 mol of each carbon compound is burned, and all reactants and products are in the gas phase.
    (b) $CH_4 + 2\ O_2 \longrightarrow CO_2 + 2\ H_2O$ (burning methane, or natural gas)
    (c) $C_8H_{18} + \frac{25}{2}\ O_2 \longrightarrow 8\ CO_2 + 9\ H_2O$ (burning octane, in gasoline)
    (d) $C_2H_5OH + 3\ O_2 \longrightarrow 2\ CO_2 + 3\ H_2O$ (burning ethanol, in gasohol)

89. By considering the nature of the intermolecular forces in each case, rank the following substances from smallest to largest enthalpy of vaporization: KBr, Ar, NH_3, and He. Explain your reasoning.

90. A supersonic nozzle is a cone-shaped object with a small hole in the end through which a gas is forced. As it moves through the nozzle opening, the gas expands in a manner that can be approximated as reversible and adiabatic. Such nozzles are used in molecular beams (see Section 18.5) and in supersonic aircraft engines to provide thrust, because as the gas cools, its random thermal energy is converted into directed motion of the molecules with average velocity v. Little thermodynamic work is done because the external pressure is low; thus, the net effect is to convert thermal energy to net translational motion of the gas molecules. Suppose the gas in the nozzle is helium; its pressure is 50 atm and its temperature is 400 K before it begins its expansion.
    (a) What are the average speed and the average velocity of the molecules *before* the expansion?
    (b) What will be the temperature of the gas after its pressure has decreased to 1.0 atm in the expansion?
    (c) What is the average velocity of the molecules at this point in the expansion?

91. (a) Draw a Lewis diagram for carbonic acid, H_2CO_3, with a central carbon atom bonded to the three oxygen atoms.
    (b) Carbonic acid is unstable in aqueous solution and converts to dissolved carbon dioxide. Use bond enthalpies to estimate the enthalpy change for the following reaction:

$$H_2CO_3 \longrightarrow H_2O + CO_2$$

The reaction between solid sodium and gaseous chlorine proceeds imperceptibly, if at all, until the addition of a drop of water sets it off.

In both fundamental research and practical applications of chemistry, chemical reactions are carried out by mixing the reactants and regulating external conditions such as temperature and pressure. Two questions arise immediately:

1. Is it possible for the reaction to occur at the selected conditions?
2. If the reaction is possible, what determines the ratio of products and reactants at equilibrium?

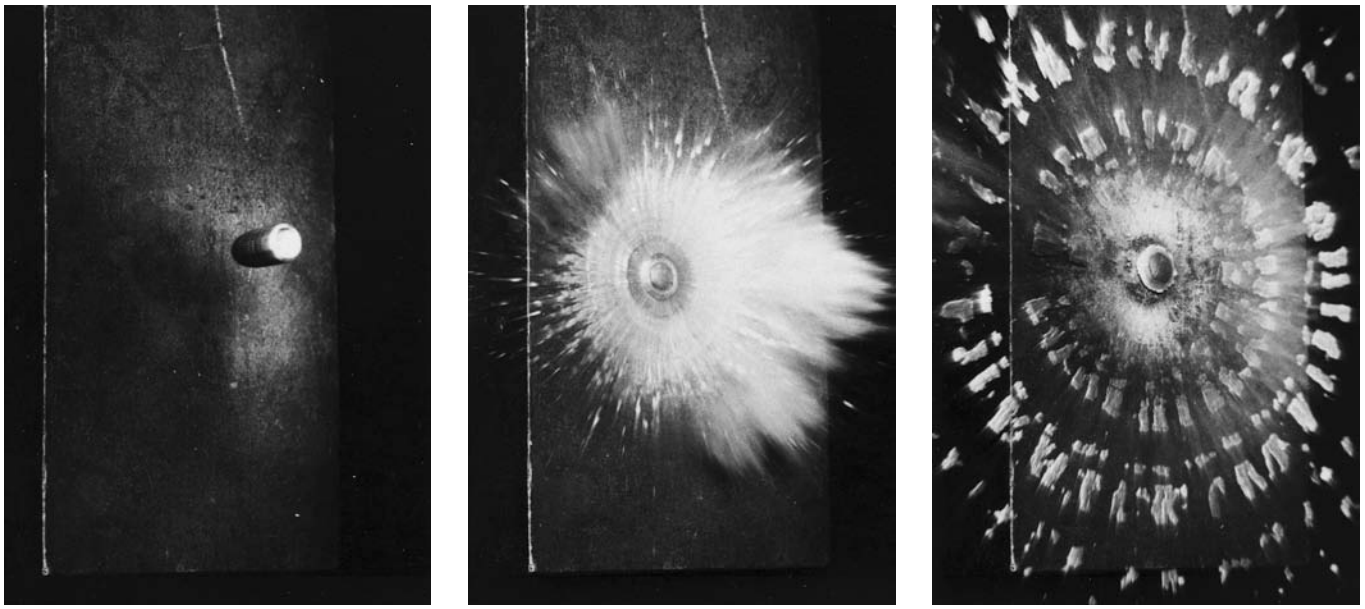
Predicting the equilibrium composition for a chemical reaction is the central goal of Unit 4, and in this chapter, we develop the conceptual basis for answering these two key questions.

Thermodynamics can tell us whether a proposed reaction is possible under particular conditions even before we attempt the reaction. We can find out whether a proposed reaction is possible by determining whether it is a spontaneous thermodynamic process. In this context, "spontaneous" has a precise technical meaning (see later for definition) that should not be confused with its conversational meaning, such as describing the spontaneous behavior of people in social situations. If the reaction is spontaneous, thermodynamics can also predict the ratio of concentrations of products and reactants at equilibrium. This chapter develops the thermodynamic methods for predicting whether a reaction is spontaneous, and Chapter 14 uses these results to determine the equilibrium ratio of products and reactants.

But, we cannot use thermodynamics to predict the rate of a spontaneous reaction or how long it will take to reach equilibrium. These questions are the subject of chemical kinetics. To obtain a large amount of product from a spontaneous reaction in a short time, we need a reaction that is spontaneous and fast. Chapter 18 discusses the rates of chemical reactions. Manipulating conditions to optimize the yield of chemical reactions in practical applications requires the concepts from thermodynamics and kinetics from all three chapters.

The criteria for predicting spontaneity of physical and chemical processes are provided by the second law of thermodynamics, which is a brilliant abstraction and generalization from the observed facts of directionality in processes involving heat transfer. This is accomplished by introducing a new state function called *entropy,* which is denoted by *S*. We define the entropy function in such a way that the total entropy change of a thermodynamic universe (system and surroundings) is positive in the direction of spontaneous processes: $\Delta S_{tot} > 0$. Sections 13.1 through 13.5 develop the second law and demonstrate methods for calculating ΔS_{univ} and predicting spontaneity.

When processes are conducted at constant *T* and *P,* the criteria for spontaneity and for equilibrium are stated more conveniently in terms of another state function called the *Gibbs free energy* (denoted by *G*), which is derived from *S*. Because chemical reactions are usually conducted at constant *T* and constant *P,* their thermodynamic description is based on ΔG rather than ΔS. This chapter concludes by restating the criteria for spontaneity of chemical reactions in terms of ΔG. Chapter 14 shows how to identify the equilibrium state of a reaction, and calculate the equilibrium constant from ΔG.



For all these reasons, ΔG is the most important thermodynamic concept in the entire field of chemical equilibrium. Your goals in this chapter should be to understand the meaning of the state function *G,* to become skilled in calculating its changes, ΔG, and to interpret both the magnitude and the sign of these changes.

13.1 THE NATURE OF SPONTANEOUS PROCESSES

In preparation for setting up the second law of thermodynamics, and stating precisely the criteria for spontaneity, we examine several familiar examples of spontaneous processes and describe their features in general terms. A spontaneous change is one that *will* occur by itself without outside intervention, once conditions have been established for its initiation. The change may be fast or slow, and we may have to wait a significant period to determine whether it *does* occur.

One of the most striking features of spontaneous change is that it follows a specific direction when starting from a particular initial condition. A quite dramatic example is shown in the series of photographs in Figure 13.1, which

FIGURE 13.1 A bullet hitting a steel plate at a speed of 1600 ft/sec melts as its kinetic energy is converted to heat, and metal droplets spray in all directions. These three photographs make sense only in the order shown; the reverse process is exceedingly unlikely.

show a speeding bullet that is fragmented on impact with a steel plate. We never observe a pile of metal fragments spontaneously assemble themselves into a speeding bullet. One of the goals of thermodynamics is to account for this *directionality* of spontaneous change. The first law of thermodynamics provides no guidance in predicting or explaining directionality. Energy is conserved both in a forward process and in its reverse; nothing in the first law indicates a preference for one direction of change over the other.

Spontaneous processes familiar in chemical laboratories also follow specific directions:

1. We measure *heat transfer* from a hot body to a cold one when they are brought into thermal contact, but we never detect heat flowing spontaneously in the opposite direction.
2. We observe a gas *expanding* into a region of lower pressure, but we never see the reverse process, a gas compressing itself spontaneously into a small part of its container.
3. We place a drop of red ink into a beaker of water and watch the color spread by *diffusion* of the ink particles until the water is uniformly pink, but we never see the ink spontaneously reorganize as a small red drop in a volume of otherwise colorless water.
4. We place 10 g sucrose (ordinary table sugar) in a beaker and add 100 mL water at 80°C. The sucrose *dissolves* to form a uniform solution. We never observe the spontaneous reappearance of a mound of sucrose at the bottom of a beaker of water.
5. We open a container of acetone on the laboratory bench. We detect the aroma of acetone because some of the molecules have *evaporated* from the liquid and then diffused through the atmosphere to our position. We never observe the molecules to retreat spontaneously into the container.

All the previous examples are physical processes that are both spontaneous and rapid. We initiate the process and see the result quickly thereafter, with no further intervention.

Like the simple physical processes described earlier, spontaneous chemical reactions are inherently directional. Ordinary experience shows that a mixture of hydrogen and oxygen gases exists indefinitely at room temperature. Yet, if the mixture is exposed to a small amount of powdered platinum metal, or an electric spark, the gases react explosively to produce water. The reverse reaction is not spontaneous; we never observe the spontaneous decomposition of water into gaseous hydrogen and oxygen. Figure 1.2 shows decomposition of water into hydrogen and oxygen gases by electrolysis in an electrochemical cell, where electrical energy is continually provided by the external circuit to drive this nonspontaneous reaction. Another example is shown in the photograph at the beginning of this chapter, where the reaction between sodium metal and chlorine gas occurs explosively after a drop of water is added. We never observe the spontaneous decomposition of sodium chloride into sodium metal and gaseous chlorine. A third example, less dramatic than the previous two, is the spontaneous reaction of copper metal with oxygen at room temperature. This is seen in many older municipal buildings, especially in Europe, where copper metal was used as roofing material. With time, these roofs develop the blue–green patina of copper oxides. We never observe the spontaneous reappearance of shiny metallic copper on these old roofs.

These three examples illustrate that the actual outcome of a spontaneous chemical reaction depends on the reaction rate. The possibility of reaction between hydrogen and oxygen was there all along, but the rate was too slow to be observed until the powdered metal or the electrical spark accelerated the reaction. The possibility of reaction between metallic copper and oxygen was there all along, and the rate was large enough to be observed, if not dramatically fast. Thermodynamics determines whether a reaction is possible, whereas chemical kinetics determines whether it is practical. At the end of this chapter, you will be able to predict whether a chemical reaction is spontaneous, and by the end of the next chapter, you will be able to predict its equilibrium state. But, you must wait until Chapter 18 to see whether a spontaneous reaction can be carried out at a useful rate.

The direction of each of these spontaneous processes is readily apparent by observing the initial and final states, regardless of their paths. This suggests the existence of a new *state function* that indicates the directionality of spontaneous processes. That state function will turn out to be **entropy,** and it will be defined so that the sign of its change indicates the direction in which a proposed process will be spontaneous. Entropy has the interesting property that we cannot predict spontaneity by considering the system alone; we must also consider the entropy changes in the surroundings during the process.

To develop the entropy function, we must first describe spontaneous processes in the language of thermodynamics summarized in Section 12.1. You should revisit each of the examples just discussed to see how it specifically fits this language. Initially, two objects in different thermodynamic states are brought into contact; one will be called "system" and the other "surroundings." Barriers (constraints) in place between them prevent their interaction. When the constraints are removed, a spontaneous process may occur in which the system and surroundings exchange energy and matter and in which the volume of both system and surroundings may change. Because the two together constitute a *thermodynamic universe,* the total amount of energy, volume, and matter shared between them is fixed. During the process, these quantities are redistributed between the system and surroundings.

EXAMPLE 13.1

In the following two spontaneous processes, identify the system, the surroundings, and the constraint(s) removed to enable the processes to occur: (a) a piece of hot metal is cooled by immersion into a barrel of cold water; (b) a teaspoon of table sugar is dissolved in a cup of hot tea.

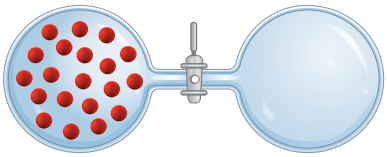
Solution

(a) The hot metal is the system, and the barrel of water is the surroundings. Initially we suppose they are brought into contact with an adiabatic wall between them to prevent thermal energy flow. We initiate the cooling process by removing the adiabatic wall, whereupon thermal energy flows from the metal to the water. The thermal energy initially contained just in the system is now dispersed throughout the combined system and surroundings. Together the system and the surroundings are enclosed within adiabatic walls, so there is no interaction with the rest of the physical universe. The spontaneous process involves only energy transfer between system and surroundings.

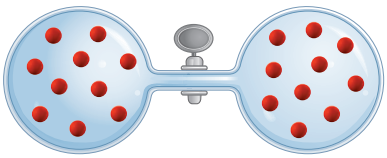
(b) The sugar is the system, and the hot tea is the surroundings. Initially we imagine that the spoonful of sugar is placed in contact with the hot tea, and is surrounded by an adiabatic wall that prevents thermal energy flow, a rigid wall that defines the volume of the sugar, and an impermeable wall that keeps the sugar separated from the tea. We initiate the dissolution process by removing the adiabatic wall, the rigid wall, and the impermeable wall. After this process the sugar molecules and the thermal energy are dispersed throughout the volume of the combined sytstem and surroundings. The system and surroundings together are enclosed within adiabatic, rigid, and impermeable walls so there is no interaction with the rest of the physical universe. The spontaneous process involves transfer of energy, sugar molecules, and volume between the system and the surroundings.

Related Problems: 1, 2



Spontaneous processes are particular examples of irreversible processes defined in Section 12.1. In stark contrast with reversible processes, they do not proceed through a sequence of equilibrium states, and their direction cannot be reversed by an infinitesimal change in the direction of some externally applied force. Spontaneous processes cannot be represented as paths on the equation-of-state surface in Figure 12.1, but their initial and final equilibrium states can be represented as points on that surface.

What determines whether a process under consideration will be spontaneous? Where does a spontaneous process end? How are energy, volume, and matter partitioned between the system and surroundings at equilibrium? What is the nature of the final equilibrium state? These questions cannot be answered by the first law. Their answers require the second law and properties of the entropy, and a few developments are necessary before we can address these questions. We define entropy in terms of molecular motions in Section 13.2 and in terms of macroscopic process variables in Section 13.3. Finally, we present the methods for calculating entropy changes and for predicting spontaneity in Sections 13.4 and 13.5.



13.2 ENTROPY AND SPONTANEITY: A MOLECULAR STATISTICAL INTERPRETATION

What is entropy and why should it be related to the spontaneity of processes in nature? These are deep questions that we can only begin to answer here. To do so, we step outside the confines of classical thermodynamics, which is concerned only with macroscopic properties, and examine the microscopic molecular basis for the second law. Such an approach, called **statistical thermodynamics,** shows that spontaneous change in nature can be understood by using probability theory to predict and explain the behavior of the many atoms and molecules that comprise a macroscopic sample of matter. Statistical thermodynamics also provides theoretical procedures for calculating the entropy of a system from molecular properties.

(a)

(b)

FIGURE 13.2 The free expansion of a gas into a vacuum. (a) The gas is initially confined to the bulb on the left, with the stopcock (the constraint) closed. (b) Half of the gas is found in each bulb, at equilibrium, after the stopcock is opened.

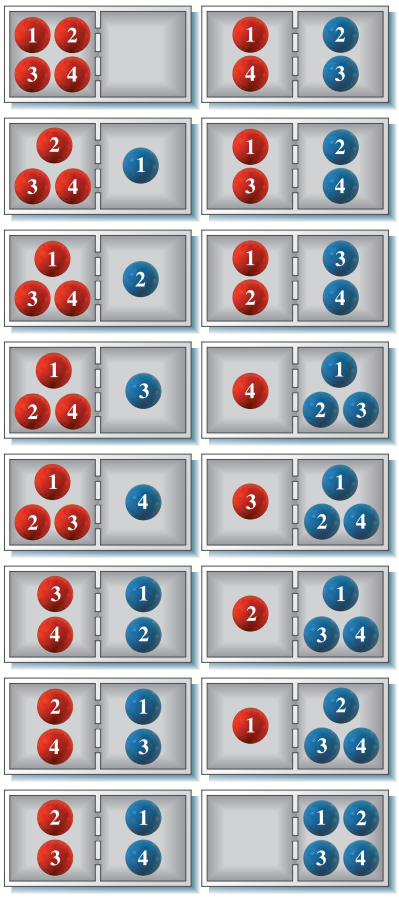

FIGURE 13.3 The 16 possible microstates of a system of 4 molecules that may occupy either side of a container. In only one of these are all four molecules on the left side.

Spontaneity and Molecular Motions

Consider a particularly simple spontaneous process: the free *adiabatic* expansion of 1 mol of an ideal gas into a vacuum (Fig. 13.2). The gas is initially held in the left bulb in volume $V/2$, whereas the right bulb is evacuated. Before it is opened, the stopcock is a constraint that holds all the molecules in the left bulb. After the stopcock is opened, the gas expands to fill the entire volume, V.

Now examine the same free expansion from a microscopic point of view. Imagine that the path of one particular tagged molecule can be followed during the expansion and for some period of time after final equilibrium has been established, perhaps through a series of time-lapse snapshots showing the locations of all molecules in the gas. From its starting position on the left side at the beginning of the experiment, the tagged molecule will cross to the right, then back to the left, and so forth. If enough time elapses, the molecule will eventually spend equal amounts of time on the two sides, because there is no physical reason for it to prefer one side to the other. Recall from Section 9.5 that the molecules in an ideal gas do not collide with each other, and their kinetic energy does not change in collisions with the walls. The energy of the molecules remains the same at all locations, and the two sides of the container are identical. No experimental way exists to track the progress of one specific molecule in the gas; therefore, the best we can ask for is the *probability* that the molecule is on the left side at any given instant. (See Appendix C.6 for a review of probability concepts and methods.) The physical reasoning just summarized justifies that the probability that the molecule is on the left side will be $\frac{1}{2}$, the same as the probability that it is on the right side. Probability provides the key to understanding the direction of spontaneous change because it enables us to compare the likelihood of finding all the molecules on the left side—after the constraint has been removed—with the likelihood of finding the molecules uniformly distributed over the combined volume of both sides.

Just how unlikely is a spontaneous compression of 1 mol gas from the combined volume back to the left side? The probability that one particular molecule is on the left side at a given time is $\frac{1}{2}$. A second specific molecule may be on either the left or the right, so the probability that both are on the left is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. As shown in Figure 13.3, in a gas containing a total of four molecules, all four molecules will be on the left only $\frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} = \frac{1}{16}$ of the time. Continuing this argument for all $N_A = 6.0 \times 10^{23}$ molecules leads to the probability that all N_A molecules are on the left:

$$\frac{1}{2} \times \frac{1}{2} \times \cdots \times \frac{1}{2} = \left(\frac{1}{2}\right)^{6.0\times10^{23}}$$

To evaluate this number, it is helpful to rewrite it in scientific notation as 1 divided by 10 raised to the power a (or, equivalently, as 10^{-a}):

$$\frac{1}{10^a} = \left(\frac{1}{2}\right)^{6.0\times10^{23}} = \frac{1}{2^{6.0\times10^{23}}}$$

A calculator can handle numbers this large (or this small) only if logarithms are used. Taking the base-10 logarithms of both denominators gives

$$\begin{aligned} a &= \log 2^{(6.0\times10^{23})} = 6.0 \times 10^{23} \log 2 \\ &= (6.0 \times 10^{23})(0.30) \\ &= 1.8 \times 10^{23} \end{aligned}$$

The probability that all the molecules will be on the left is 1 in $10^{1.8\times10^{23}}$.

This is a vanishingly small probability, because $10^{1.8\times10^{23}}$ is an unimaginably large number. It is vastly larger than the number 1.8×10^{23} (which is a large number already). To realize this, consider how such numbers would be written. The number 1.8×10^{23} is fairly straightforward to write out. It contains 22 zeros:

$$180{,}000{,}000{,}000{,}000{,}000{,}000{,}000$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The number $10^{1.8\times10^{23}}$ is 1 followed by 1.8×10^{23} zeros. Written out, such a number would more than fill all the books in the world. Put in other terms, 1.8×10^{23} corresponds to the number of molecules in about 5 cm^3 water, but $10^{1.8\times10^{23}}$ is far larger than the number of molecules in the entire universe!

The statistical molecular picture explains that the gas expands to fill the whole available volume when the constraint is removed because this more uniform configuration of the molecules is overwhelmingly more probable than the initial configuration with all the molecules on the left side. The same explanation shows that the gas is never observed to compress spontaneously into a smaller volume because this nonuniform configuration of the molecules is overwhelmingly improbable in the absence of the constraint. Nothing in the laws of mechanics prevents a gas from compressing spontaneously. But this event is never seen because it is so improbable.

Thus, spontaneity in nature results from the random, statistical behavior of large numbers of molecules. *The directionality of spontaneous change is a consequence of the large numbers of molecules in the macroscopic systems treated by thermodynamics.* In systems containing fewer molecules, the situation can be quite different because the uniform configuration of molecules, although still the most probable, is no longer so overwhelmingly the most probable configuration. For example, if there were only 6 molecules, instead of 6×10^{23}, it would not be surprising to find them all on the left side at a given time. In fact, the probability that 6 molecules are on the left side is $\left(\frac{1}{2}\right)^6 = \frac{1}{64}$, so there is 1 chance in 64 that this will occur. Such small systems exhibit *statistical fluctuations* of the molecular configuration. Some of the fluctuations correspond to the initial nonuniform configuration maintained by the constraint, despite the absence of the constraint.

EXAMPLE 13.2

Calculate the probability of a spontaneous compression of 1.00 mol gas by 0.01%—that is, the probability that all the molecules will be found in a volume $V' = 0.9999V$ at a certain time.

Solution

In this case, the probability that a given molecule is in V' is not $\frac{1}{2}$ but 0.9999 (the probability that it is in the remainder of V is 0.0001). The probability that all N_A molecules are in V' is

$$(0.9999)^{N_A} = 1/10^a$$

$$a = -N_A \log(0.9999) = (6.0 \times 10^{23})(4.3 \times 10^{-5})$$

$$= 2.6 \times 10^{19}$$

The chance of such a compression occurring spontaneously is 1 in $10^{2.6\times10^{19}}$, which is still vanishingly small. Thus, a spontaneous compression of even a fraction of a percent will not be seen.

Related Problems: 7, 8

Entropy and Molecular Motions

We want to define a new function called entropy that will increase when the system undergoes a spontaneous process. How can we relate entropy to the properties of the system and formulate a definition to achieve this goal? Spontaneous processes occur when constraints are removed from a system; the molecules respond by moving to explore the suddenly increased range of motions now available to them. In the free expansion of a gas, the molecules are initially confined

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

in one part of the container. After the constraint is removed (the stopcock is opened), they are free to stay where they were, but they also are free to move throughout the larger combined volume of the two regions. Qualitatively, the numerical value of the entropy of a macroscopic system held in a particular thermodynamic state should depend on the *range of possible motions* (that is, the range of possible positions and momenta) available to the molecules while the system is held in that particular thermodynamic state. Any change in the macroscopic properties that enables the molecules to move out into larger regions of space or that increases the range of molecular speeds should increase the entropy of the system.

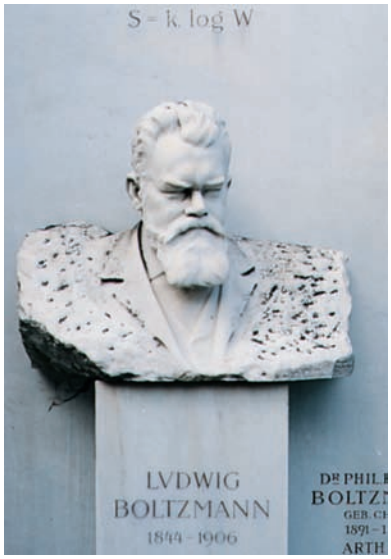
In preparation for defining entropy, we need a precise way to describe the "range of possible motions" of the molecules. This is accomplished by counting the number of microscopic, mechanical states, or **microstates,** available to molecules of the system. This number, denoted by Ω, counts all the possible combinations of positions and momenta available to the N molecules in the system when the system has internal energy U and volume V. For the simple model in Figure 13.3, $\Omega = 16$. In general, Ω is a function of U, V, and N, denoted as $\Omega(U, V, N)$. If the system is a monatomic ideal gas, the atoms do not interact. The position of each atom ranges freely throughout the entire volume, V. The internal energy consists of the total kinetic energy of the atoms, given as

$$U = \sum_{i=1}^{N} \varepsilon_i = \sum_{i=1}^{N} \frac{[p_{xi}^2 + p_{yi}^2 + p_{zi}^2]}{2m}$$

thus, the momenta of the atoms range through all values that satisfy the condition

$$2mU = \sum_{i=1}^{N} [p_{xi}^2 + p_{yi}^2 + p_{zi}^2]$$

Although we do not provide the details of the calculation, the value of Ω for a monatomic ideal gas is given by



$$\Omega(U, V, N) = g\, V^N U^{(3N/2)}$$

where g is a collection of constants. Now imagine the walls defining the system are manipulated to change the values of U and V. The range of positions and momenta available to the molecules will increase or decrease accordingly. Because N is a very large number—of order 10^{23}—the value of Ω will increase or decrease dramatically when the volume of the system is increased or decreased in an expansion or compression, respectively. It will increase or decrease dramatically when the internal energy of the system is increased or decreased by heating or cooling, respectively.

The equation connecting entropy S and the number of available microstates Ω is

$$S = k_B \ln \Omega \qquad [13.1]$$

which was originally discovered by the Austrian physicist Ludwig Boltzmann in the late 19th century (Fig. 13.4). **Boltzmann's constant** k_B (see Equation 9.14) is identified as R/N_A, the ratio of the universal gas constant R to Avogadro's number N_A. Thus, entropy has the physical dimensions J K^{-1}. It is impossible to overstate the importance of Boltzmann's relation, because it provides the link between the microscopic world of atoms and molecules and the macroscopic world of bulk matter and thermodynamics. Although this equation holds quite generally, it is difficult to apply because calculating Ω is a daunting theoretical task except for the simplest ideal systems. Other equations are used for practical applications in statistical thermodynamics. For our purposes here, the equation provides qualitative insight into the physical meaning of entropy and qualitative interpretation of the magnitude and sign of entropy changes caused by specific thermodynamic processes. The following example illustrates these insights in a simple case in which only the volume of the system changes in the process.

David Oxtoby

FIGURE 13.4 The fundamental relation between entropy (S) and the number of microstates (W) was derived by Ludwig Boltzmann in 1868. On his tombstone in Vienna is carved the equation he obtained, $S = k \log W$. We would write "ln" instead of "log" for the natural logarithm and Ω instead of "W" for the number of microstates.

EXAMPLE 13.3

Consider the free expansion of 1 mol gas from $V/2$ to V (see Fig. 13.2). Use Boltzmann's relation to estimate the change in entropy for this process.

Solution

Consider the entire apparatus consisting of the filled and the evacuated bulbs to be a thermodynamic universe, so any exchange of thermal energy occurs solely between them; the pair of bulbs is taken to be thermally insulated from their surroundings. Then examine the effects of doubling V on Ω. If the volume is doubled, the number of positions available to a given molecule is doubled also. Therefore, the number of states available to the molecule should be proportional to the volume, V:

$$\text{number of states available per molecule} = cV$$

where c is a proportionality constant. The state of a *two*-molecule system is given jointly by the states of the molecules in it, so the number of microscopic states available is just the product of the number of states for each molecule, $(cV) \times (cV) = (cV)^2$. For an N-molecule system,

$$\text{microscopic states available} = \Omega = (cV)^N$$

Inserting this expression into Boltzmann's relation gives the entropy change for the free expansion of 1 mol (N_A atoms) gas from a volume $V/2$ to V:

$$\begin{aligned}\Delta S(\text{microscopic}) &= N_A k_B \ln(cV) - N_A k_B \ln(cV/2) \\ &= N_A k_B \ln\left(\frac{cV}{cV/2}\right) = N_A k_B \ln 2\end{aligned}$$

Note that the constant c has dropped out. The calculated change in entropy on expansion of the gas is clearly positive, which is consistent with the increase in the number of available microstates on expansion.

In the next section, the entropy change for this process from the macroscopic view will be calculated to be

$$\Delta S \text{ (thermodynamic)} = R \ln 2$$

illustrating explicitly that Boltzmann's microscopic description accurately explains the measured macroscopic results.

Related Problems: 3, 4, 5, 6, 7, 8, 9, 10

This example illustrates why Boltzmann's relation must involve the logarithmic function. Because entropy is an extensive variable, its value is proportional to N. But Ω depends on N through the *power* to which cV is raised. Therefore, doubling N doubles S but leads to Ω being squared. The only mathematical function that can connect two such quantities is the logarithm.

Examples of other processes in which the entropy of the system increases include phase transitions such as the melting of a solid. In a solid, cohesive forces hold the atoms or molecules near their equilibrium positions in the crystal lattice, whereas in the liquid they can move far away from these fixed positions. More microstates are available to the molecules in the liquid, corresponding to a larger value of entropy; for melting of a solid, ΔS_{sys} is positive. In the same way, the entropy increases for evaporation of a liquid because the number of microstates available to the molecules increases enormously. Whereas the molecules in a liquid remain at the bottom of their container, those in a gas move throughout the container, so the number of microstates increases upon vaporization. In some solid-solid phase transformations it is difficult to predict qualitatively which phase has higher entropy. Nonetheless, calculating the relative number of microstates available correctly predicts the sign of the entropy change in a transformation from one such phase to the other.

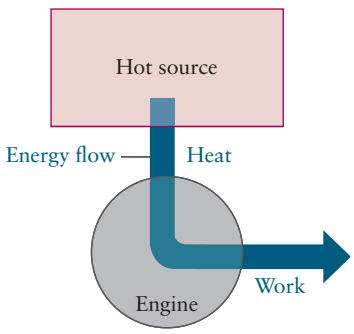
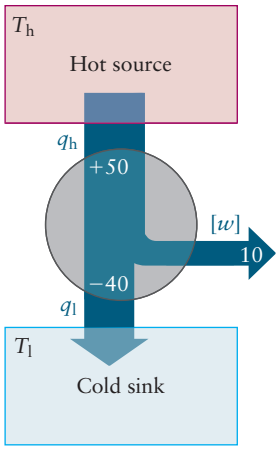
So far, we have considered microstates that involve only the positions of the molecules in a system. The distribution of energies can also contribute to the number of microstates. For example, a gas in which all the molecules have the same speed has fewer microstates available to it than does a gas with a distribution of molecular speeds; a spontaneous process is observed experimentally in which a system initially constrained to a single molecular speed moves toward the Maxwell–Boltzmann speed distribution, because this distribution maximizes the number of microstates available for a given total energy. This textbook gives only qualitative microscopic interpretations of these more complex examples. In later courses you will see more thorough interpretations based on the more advanced equations that replace Equation 13.1.



13.3 ENTROPY AND HEAT: MACROSCOPIC BASIS OF THE SECOND LAW OF THERMODYNAMICS

The second law of thermodynamics, which is stated as an abstract generalization of engineering observations on the efficiency of heat engines, has two important consequences for chemistry. It defines the entropy function in terms of measurable macroscopic quantities, providing a means to calculate the changes in entropy caused by specific processes. And, it defines the criterion for predicting whether a particular process will be spontaneous. It is thus useful to re-state the second law in a form directly applicable to chemistry: Part One defines the entropy function, and Part Two shows how to predict spontaneity. We start the discussion with a nonmathematical, qualitative summary of the arguments on efficiency, from which we state the second law in engineering terms and then define the entropy function (Part One of the second law). Section 13.4 applies the definition to calculate entropy changes for a wide variety of processes. Section 13.5 uses these calculations to predict spontaneity of processes (Part Two of the second law).

Section 13.8 presents a mathematical route to the same results developed qualitatively here. Either Section 13.3 or Section 13.8 provides adequate background for the calculations in Sections 13.4 and 13.5, which are essential for chemistry.



Background of the Second Law of Thermodynamics

The second law of thermodynamics originated in practical concerns over the efficiency of steam engines at the dawn of the Industrial Age, late in the 18th century, and required about a century for its complete development as an engineering tool. The central issues in that development are summarized as follows. In each stroke of a steam engine, a quantity of hot steam at high pressure is injected into a piston-cylinder assembly, where it immediately expands and pushes the piston outward against an external load, doing useful work by moving the load. The external mechanical structure to which the piston is attached includes a reciprocating mechanism that returns the piston to its original position at the end of the stroke so that a new quantity of steam can be injected to start the next stroke. The engine operates as a cyclic process, returning to the same state at the beginning of each stroke. In each stroke, the expansion process is highly irreversible because the steam is cooled and exhausted from the cylinder at the end of the stroke. In essence, the engine extracts thermal energy from a hot reservoir, uses some of this energy to accomplish useful work, then discards the remainder into a cooler reservoir (the environment). The energy lost to the envi-

Schematic representation of a heat engine.

Operation of a heat engine. In this example the engine withdraws 50 kJ of thermal energy from the hot reservoir, performs 10 kJ or work on its surroundings, and discharges 40 kJ of thermal energy to the lower temperature reservoir.

ronment cannot be recovered by the engine. The internal combustion engine operates in a similar manner, with injection of hot steam replaced by *in situ* ignition of combustible fuel that burns in highly exothermic reactions. Its expansion process is similarly irreversible, and some of the energy expended by the hot gases is unrecoverable.

In both engines the efficiency (that is, the ratio of work accomplished *by* the engine in a cycle to the heat invested to drive that cycle) can be improved by reducing the unrecoverable losses to the environment in each cycle. Seeking to maximize efficiency, Sadi Carnot, an officer in Napoleon's French Army Corps of Engineers, modeled operation of the engine with an idealized cyclic process now known as the *Carnot cycle*. He concluded that unrecoverable losses of energy to the environment cannot be completely eliminated, no matter how carefully the engine is designed. Even if the engine is operated as a reversible process (in which case, displacement of the external load is too slow to be of practical interest), its efficiency cannot exceed a fundamental limit known as the *thermodynamic efficiency*. Thus, an engine with 100% efficiency cannot be constructed.

Carnot's conclusion has been restated in more general terms by the English physicist Lord Kelvin in the following form:

> *There is no device that can transform heat withdrawn from a reservoir completely into work with no other effect.*

and by the German physicist Rudolf Clausius in the following form:

> *There is no device that can transfer heat from a colder to a warmer reservoir without net expenditure of work.*

These statements are consistent with ordinary experience that (1) heat always flows spontaneously from a hotter body to a colder body, and that (2) work is always required to refrigerate a body. With confidence based on experience, Clausius, Kelvin, and later scientists and engineers have assumed these statements to be valid for *all* heat transfer processes and labeled them as equivalent formulations of the second law of thermodynamics.

Definition of Entropy

How do we apply these general statements to chemical processes such as the examples described in Section 13.1, which at first glance bear no resemblance to heat engines? Highlights of the argument are summarized here, and a more detailed development is presented in Section 13.8.

Carnot's analysis of efficiency for a heat engine operating *reversibly* showed that in each cycle q/T at the high temperature reservoir and q/T at the low temperature environment summed to zero:

$$\frac{q_h}{T_h} + \frac{q_l}{T_l} = 0$$

This result suggests that q/T is a state function in a reversible process because the sum of its changes in a cyclic process is zero. Clausius extended this result to show that the quantity $\int(1/T)\, dq_{rev}$ is independent of path in *any* reversible process and is, therefore, a state function. Clausius then *defined* the entropy change $\Delta S = S_f - S_i$ of a system in a process starting in state i and ending in state f by the equation

$$\Delta S = S_f - S_i = \int_i^f \frac{dq_{rev}}{T} \qquad [13.2]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The definition in Equation 13.2 constitutes Part One of the second law in the form directly related to chemistry. Entropy is therefore a state function and has physical dimensions J K^{-1}. We calculate $\Delta S = S_f - S_i$ for a specific process by (1) identifying its initial and final equilibrium states i and f as points on the equation-of-state surface in Figure 12.1, (2) selecting *any convenient reversible path* between them along which dq_{rev} and T are known, and (3) evaluating this integral along the selected path. It does not matter that the actual process of interest may be irreversible. Because entropy is a state function, its change depends only on the initial and final states, and not at all on the path. *Therefore, we are free to choose any reversible path that connects the initial and final states, purely on grounds of convenience, for calculating ΔS.*

This is a beautiful consequence of the fact that S is a state function. Section 13.4 provides detailed procedures for calculating ΔS for numerous types of systems and processes. The calculated values of ΔS are then used in Section 13.5 in Part Two of the second law to predict whether a particular contemplated process will be spontaneous.

The preceding discussion emphasizes that the second law, like all other laws of science, is a bold extrapolation of the results of a great deal of direct experimental observation under controlled conditions. Based on his understanding of the Carnot cycle, Clausius assumed, or postulated, that Equation 13.2 is valid for all thermodynamic systems and all processes that begin and end in equilibrium states. For every system there exists a state function called entropy whose changes during a process depend only on the initial and final states, and the magnitude of the changes can be calculated along any convenient reversible path connecting these particular states. In Section 13.5 we see how these calculated entropy changes predict whether a process is spontaneous or not. The second law is not proved to be true by a single definitive experiment, it is not derived as a consequence of some more general theory, and it is not handed down by some higher authority. Rather, it is invoked as one of the "starting points" of thermodynamics, and conclusions drawn from its application to a great variety of processes (not necessarily involving heat engines) are compared with the results obtained in experimental studies. To date, no disagreements have been found between predictions properly made from the second law and the results of properly designed experiments.

13.4 ENTROPY CHANGES IN REVERSIBLE PROCESSES

This section outlines procedures for calculating entropy changes that occur in the system and in the surroundings during several types of processes.

ΔS_{sys} for Isothermal Processes

If the reversible process selected as the pathway connecting the initial and final states is isothermal, the calculation simplifies immediately. Because T is constant, it comes outside the integral:

$$\Delta S = \int_i^f \frac{dq_{rev}}{T} = \frac{1}{T}\int_i^f dq_{rev} = \frac{q_{rev}}{T} \qquad [13.3]$$

Here, q_{rev} is the *finite* amount of heat absorbed by the system during the entire reversible isothermal process.

Compression/Expansion of an Ideal Gas

Consider an ideal gas enclosed in a piston-cylinder arrangement that is maintained at constant temperature in a heat bath. The gas can be compressed (or expanded) reversibly by changing the position of the piston to accomplish a specified change in volume. In Section 12.7, the heat transferred between system and bath when the gas is expanded (or compressed) isothermally and reversibly from volume V_1 to V_2 is shown to be

$$q_{\text{rev}} = nRT \ln\left(\frac{V_2}{V_1}\right)$$

The resulting change in entropy, therefore, is

$$\Delta S = nR \ln\left(\frac{V_2}{V_1}\right) \quad \text{(constant } T\text{)} \qquad [13.4]$$

From Equation 13.4 we see that the entropy of a gas increases during an isothermal expansion ($V_2 > V_1$) and decreases during a compression ($V_2 < V_1$). Boltzmann's relation (see Eq. 13.1) provides the molecular interpretation of these results. The number of microstates available to the system, Ω, increases as the volume of the system increases and decreases as volume decreases, and the entropy of the system increases or decreases accordingly.

Phase Transitions

Another type of constant-temperature process is a phase transition such as the melting of a solid at constant pressure. This occurs reversibly at the fusion temperature, T_f, because an infinitesimal change in external conditions, such as reducing the temperature, can reverse the melting process. The reversible heat absorbed by the system when 1 mol of substance melts is $q_{\text{rev}} = \Delta H_{\text{fus}}$, so

$$\Delta S_{\text{fus}} = \frac{q_{\text{rev}}}{T_f} = \frac{\Delta H_{\text{fus}}}{T_f} \qquad [13.5]$$

The entropy increases when a solid melts or a liquid vaporizes, and it decreases when the phase transition occurs in the opposite direction. Again, Boltzmann's relation provides the molecular interpretation. When a solid melts or a liquid vaporizes, the number of accessible microstates Ω increases, and thus the entropy increases.

EXAMPLE 13.4

Calculate the entropy change when 3.00 mol benzene vaporizes reversibly at its normal boiling point of 80.1°C. The molar enthalpy of vaporization of benzene at this temperature is 30.8 kJ mol^{-1}.

Solution

The entropy change when 1 mol benzene is vaporized at 80.1°C (=353.25 K) is

$$\Delta S_{\text{vap}} = \frac{\Delta H_{\text{vap}}}{T_b} = \frac{30,800 \text{ J mol}^{-1}}{353.25 \text{ K}} = +87.2 \text{ J K}^{-1}$$

When 3.00 mol is vaporized, the entropy change is three times as great:

$$\Delta S = (3.00 \text{ mol})(+87.2 \text{ J K}^{-1} \text{ mol}^{-1}) = +262 \text{ J K}^{-1}$$

Related Problems: 11, 12

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Remarkably, most liquids have similar values for the molar entropy of vaporization. **Trouton's rule** summarizes this observation:

$$\Delta S_{vap} = 88 \pm 5 \text{ J K}^{-1} \text{ mol}^{-1} \quad [13.6]$$

Note that the ΔS_{vap} of benzene, calculated in Example 13.4, is within this range. The constancy of ΔS_{vap} means that ΔH_{vap} and T_b, which vary widely from substance to substance, must do so in the same proportion. Trouton's rule allows enthalpies of vaporization to be estimated from boiling temperatures. However, exceptions exist; the molar entropy of vaporization for water is 109 J K^{-1} mol^{-1}. The value for water is unusually high because hydrogen bonding in liquid water means there are many fewer allowed configurations (lower entropy) than in other liquids; thus, water shows a much greater increase in the number of microstates on vaporization.

ΔS_{sys} for Processes with Changing Temperature

Now consider a reversible process in which the temperature changes. In this case, Equation 13.2 must be used:

$$\Delta S = \int_i^f \frac{1}{T} dq_{rev}$$

In the integral, i and f represent, respectively, the initial and final equilibrium states for the process. The calculation must be conducted along a reversible path connecting i and f. For a reversible *adiabatic* process, $q = 0$ and, therefore, $\Delta S = 0$. Such a process is also called **isentropic** (that is, the entropy is constant).

In a reversible *isochoric* process, the volume is held constant and the system is heated or cooled by contact with a reservoir whose temperature differs from that of the system by an infinitesimal amount, dT. The heat transferred in this case is

$$dq_{rev} = nc_V \, dT$$

and the entropy change of the system as it is heated from T_1 to T_2 is

$$\Delta S = \int_{T_1}^{T_2} \frac{1}{T} \, dq_{rev} = \int_{T_1}^{T_2} \frac{nc_V}{T} dT$$

If c_V is independent of T over the temperature range of interest, it can be removed from the integral, giving the result

$$\Delta S = nc_V \int_{T_1}^{T_2} \frac{1}{T} dT = nc_V \ln\left(\frac{T_2}{T_1}\right) \quad \text{(constant } V\text{)} \quad [13.7]$$

The analogous result for the entropy change of the system in a reversible *isobaric* process (constant *pressure*) is

$$\Delta S = \int_{T_1}^{T_2} \frac{nc_P}{T} dT = nc_P \ln\left(\frac{T_2}{T_1}\right) \quad \text{(constant } P\text{)} \quad [13.8]$$

Entropy always increases with increasing temperature. From the kinetic theory of ideal gases in Chapter 9, it is clear that increasing the temperature of the gas increases the magnitude of the average kinetic energy per molecule and, therefore, the range of momenta available to molecules. This, in turn, increases Ω for the gas and, by Boltzmann's relation, the entropy of the gas.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Now consider an experiment in which identical samples of a gas are taken through identical temperature increases, one sample at constant V and the other at constant P. Let's compare the entropy changes in the two processes. From the previous discussion it follows that $\Delta S_P > \Delta S_V$ because $c_P > c_V$. The molecular interpretation is based on the discussion of c_P and c_V in Section 12.3. The gas heated at constant P increases in volume, as well as in temperature; its molecules therefore gain access to a greater range of positions, as well as a greater range of momenta. Consequently, the gas heated at constant P experiences a *greater* increase in Ω than does the gas heated at constant V and, therefore, a greater increase in S.

The following example illustrates that the entropy is a state function, for which changes are independent of the path followed.

EXAMPLE 13.5

(**a**) Calculate the entropy change for the process described in Example 12.10: 5.00 mol argon expands reversibly at a constant temperature of 298 K from a pressure of 10.0 to 1.00 atm.

(**b**) Calculate the entropy change for the same initial and final states as in part (**a**) but along a different path. First, the 5.00 mol argon expands reversibly and *adiabatically* between the same two pressures. This is the path followed in Example 12.11; it causes the temperature to decrease to 118.6 K. Then the gas is heated at constant pressure back to 298 K.

Solution

(**a**) At constant temperature, the entropy change is

$$\Delta S = nR \ln\left(\frac{V_2}{V_1}\right) = nR \ln\left(\frac{P_1}{P_2}\right)$$
$$= (5.00 \text{ mol})(8.315 \text{ J K}^{-1} \text{ mol}^{-1}) \ln 10.0$$
$$= +95.7 \text{ J K}^{-1}$$

(**b**) For the adiabatic part of this path, the entropy change is zero. When the gas is then heated reversibly at constant pressure from 118.6 to 298 K, the entropy change is

$$\Delta S = nc_P \ln\left(\frac{T_2}{T_1}\right)$$
$$= (5.00 \text{ mol})\left(\frac{5}{2} \times 8.315 \text{ J K}^{-1} \text{ mol}^{-1}\right) \ln \frac{298 \text{ K}}{118.6 \text{ K}}$$
$$= +95.7 \text{ J K}^{-1}$$

This is the same as the result from part (**a**), an illustration of the fact that the entropy is a state function. By contrast, the amounts of heat for the two paths are different: 28.5 and 18.6 kJ.

Related Problems: 15, 16

ΔS for Surroundings

Usually, the surroundings can be treated as a large *heat bath* that transfers heat to or from the system at the fixed temperature of the bath. In such cases, the heat capacity of the surroundings (heat bath) must be so large that the heat transferred during the process does not change the temperature of the bath. The heat gained by the surroundings during a process is the heat lost from the system. If the process occurs at constant P, then

$$q_{surr} = -\Delta H_{sys}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and the entropy change of the surroundings is

$$\Delta S_{surr} = \frac{-\Delta H_{sys}}{T_{surr}} \qquad [13.9]$$

If the process occurring in the system is exothermic, the surroundings gain heat and the entropy change of the surroundings is positive. Similarly, an endothermic process in the system is accompanied by a negative entropy change in the surroundings, because the surroundings give up heat during the process to keep the system at the temperature of the heat bath.

If the surroundings lack sufficient heat capacity to maintain constant temperature during the process, then entropy changes for the surroundings must be calculated by the methods demonstrated above for the system, taking explicit account of the temperature change and heat capacity of the surroundings. Examples of both cases are included in the problems at the end of this chapter.

13.5 ENTROPY CHANGES AND SPONTANEITY

Part Two of the second law states that a process can occur spontaneously if the total entropy change for the thermodynamic universe of the process is positive:

$$\Delta S_{tot} = \Delta S_{sys} + \Delta S_{surr} > 0$$

We illustrate the calculation first for spontaneous cooling of a hot body and then for irreversible expansion of an ideal gas. Finally we discuss the so-called inequality of Clausius, which provides the basis for Part Two of the second law.

Spontaneous Cooling of a Hot Body

Consider a spontaneous process in which a sample of hot metal is cooled by sudden immersion in a cold bath. Heat flows from the metal into the bath until they arrive at the same temperature. This spontaneous process is accompanied by an increase in the total entropy for the thermodynamic universe of the process, as illustrated by the following example.

EXAMPLE 13.6

A well-insulated ice-water bath at 0.0°C contains 20 g ice. Throughout this experiment, the bath is maintained at the constant pressure of 1 atm. When a piece of nickel at 100°C is dropped into the bath, 10.0 g of the ice melts. Calculate the total entropy change for the thermodynamic universe of this process. (Specific heats at constant *P:* nickel, 0.46 J K^{-1} g^{-1}; water, 4.18 J K^{-1} g^{-1}; ice, 2.09 J K^{-1} g^{-1}. Enthalpy of fusion of ice, 334 J K^{-1} g^{-1}.)

Solution

Consider the nickel to be the *system* and the ice-water bath to be the *surroundings* in this experiment. Heat flows from the nickel into the bath and melts some of the ice. Consequently, the entropy of the nickel decreases and the entropy of the bath increases. The final equilibrium temperature of both system and bath is 0.0°C, as indicated by the presence of some ice in the bath at equilibrium.

Before calculating ΔS_{Ni} it is necessary to calculate the mass of the nickel from the calorimetry equation as follows:

$$\text{heat lost by Ni} = \text{heat gained by ice bath} = \text{heat used in melting ice}$$

$$-M\,(0.46\ \text{J K}^{-1}\ \text{g}^{-1})(273.15\ \text{K} - 373.15\ \text{K}) = (10.0\ \text{g})(334\ \text{J g}^{-1})$$

$$M = 73\ \text{g}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Because the nickel is cooled at constant P, the entropy change for the nickel is calculated as

$$\Delta S_{\text{Ni}} = (73\text{ g})(0.46\text{ J g}^{-1}\text{ K}^{-1})\ln(0.73) = -10\text{ J K}^{-1}$$

Because the ice bath has remained at constant T throughout the experiment, it can be treated as a "large heat bath," and its entropy change is calculated as

$$\Delta S_{\text{bath}} = \frac{-\Delta H_{\text{sys}}}{T_{\text{bath}}} = \frac{-(-334\text{ J g}^{-1})(10.0\text{ g})}{273.15\text{ K}} = 12\text{ J K}^{-1}$$

Now,

$$\Delta S_{\text{tot}} = \Delta S_{\text{Ni}} + \Delta S_{\text{bath}} = -10 + 12 = +2\text{ J K}^{-1}$$

Thus, the process is spontaneous, driven by the fact that the entropy gain of the melting ice exceeds the entropy loss of the cooling metal.

Related Problems: 17, 18, 19, 20

Irreversible Expansion of an Ideal Gas

Consider a gas confined within a piston-cylinder arrangement and held at constant temperature in a heat bath. Suppose the external pressure is abruptly reduced and held constant at the new lower value. The gas immediately expands against the piston until its internal pressure declines to match the new external pressure. The total entropy of system plus surroundings will increase during this expansion. In preparation for a quantitative example, a general comparison of irreversible and reversible processes connecting the same initial and final states provides insight into why the total entropy increases in a spontaneous process.

The work performed *by* a system ($-w$) as it undergoes an irreversible isothermal expansion is always less than when the expansion is conducted reversibly. To see this, return to the definition of work done *on* a system:

$$w = -\int P_{\text{ext}}\,dV$$

During an expansion, P_{ext} must be less than P, the pressure of the gas. For a reversible expansion, P_{ext} is only infinitesimally smaller (so the system is always close to equilibrium); but for an irreversible expansion, P_{ext} is measurably smaller. Therefore, the area under a graph of P_{ext} plotted against V is less than that of a graph of P against V (Fig. 13.5), so

$$-w_{\text{irrev}} = \int P_{\text{ext}}\,dV < \int P\,dV = -w_{\text{rev}}$$

and the work performed by the system, $-w_{\text{irrev}}$, is less than $-w_{\text{rev}}$. If the system is viewed as an "engine" for performing useful work on the surroundings, a reversible process is always more efficient than an irreversible one.

If the reversible and irreversible processes have the same initial and final states, then ΔU is the same for both.

$$\Delta U = w_{\text{irrev}} + q_{\text{irrev}} = w_{\text{rev}} + q_{\text{rev}}$$

But because

$$-w_{\text{irrev}} < -w_{\text{rev}}$$

we must have

$$w_{\text{irrev}} > w_{\text{rev}}$$

and

$$q_{\text{irrev}} < q_{\text{rev}}$$

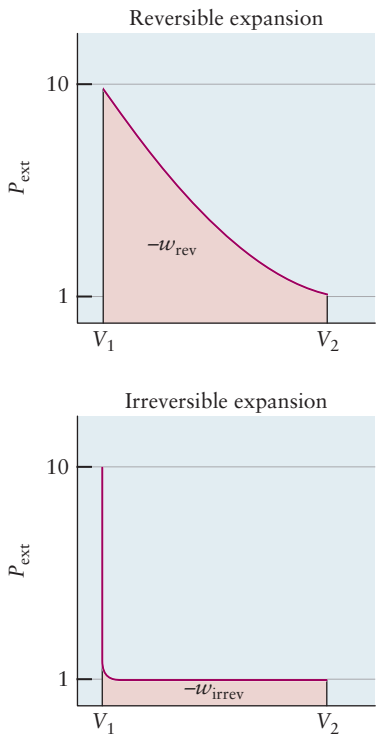

FIGURE 13.5 Work done by a system in reversible and irreversible expansions between the same initial and final states. The work performed is greater for the reversible process.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The heat absorbed is a *maximum* when the process is conducted reversibly.

The following example illustrates these inequalities.

EXAMPLE 13.7

Calculate the heat absorbed and the work done on a system of 5.00 mol of an ideal gas as it expands irreversibly at constant temperature $T = 298$ K from a pressure of 10.0 to 1.00 atm. The external pressure is held constant at 1.00 atm.

Solution

The initial volume V_1 is

$$V_1 = \frac{nRT}{P_1} = \frac{(5.00 \text{ mol})(0.08206 \text{ L atm K}^{-1} \text{ mol}^{-1})(298 \text{ K})}{10.0 \text{ atm}} = 12.2 \text{ L}$$

The final volume is 10 times this, or

$$V_2 = 122 \text{ L}$$

For a constant external pressure,

$$w_{\text{irrev}} = -P_{\text{ext}}\Delta V = -(1.00 \text{ atm})(122 \text{ L} - 12.2 \text{ L}) = -110 \text{ L atm}$$

$$= -11.1 \text{ kJ}$$

At constant T, $\Delta U = 0$, however, so

$$q_{\text{irrev}} = -w_{\text{irrev}} = 11.1 \text{ kJ}$$

In Example 12.10, a reversible expansion between the same two states was carried out, with the result that

$$w_{\text{rev}} = -28.5 \text{ kJ}$$

This demonstrates that

$$-w_{\text{irrev}} < -w_{\text{rev}}$$

and

$$q_{\text{irrev}} < q_{\text{rev}}$$

For reversible and irreversible processes connecting the same pair of initial and final states, it is always true that

$$q_{\text{rev}} > q_{\text{irrev}}$$

Dividing this expression by T, the temperature at which the heat is transferred, gives

$$\frac{q_{\text{rev}}}{T} > \frac{q_{\text{irrev}}}{T}$$

The left side is the entropy change ΔS_{sys},

$$\Delta S_{\text{sys}} = \frac{q_{\text{rev}}}{T}$$

so

$$\Delta S_{\text{sys}} > \frac{q_{\text{irrev}}}{T}$$

The last two equations can be combined as

$$\Delta S_{\text{sys}} \geq \frac{q}{T}$$

where the equality applies only to a reversible process. This expression, called the **inequality of Clausius,** states that in any spontaneous process the heat absorbed by the system from surroundings at the same temperature is always less than $T\Delta S_{sys}$. In a reversible process, the heat absorbed is equal to $T\Delta S_{sys}$.

Now let's apply Clausius's inequality to processes occurring within an *isolated* system. In this case, there is no transfer of heat into or out of the system, and $q = 0$. Therefore, for spontaneous processes within an isolated system, $\Delta S > 0$.

The thermodynamic universe of a process (that is, a system plus its surroundings) is clearly an isolated system to which Clausius's inequality can be applied. It follows that

1. *In a* reversible *process the total entropy of a system plus its surroundings is unchanged.*
2. *In an* irreversible *process the total entropy of a system plus its surroundings must increase.*
3. *A process for which* $\Delta S_{univ} < 0$ *is not spontaneous.*

These statements constitute the heart of the second law, because they justify its predictive power, which we stated as a postulate at the beginning of Section 13.5.

EXAMPLE 13.8

Calculate $\Delta S_{tot} = \Delta S_{sys} + \Delta S_{surr}$ for the reversible and irreversible isothermal expansions of Examples 12.10 and 13.7.

Solution

For the reversible expansion,

$$q_{rev} = 28.5 \text{ kJ}$$

$$\Delta S_{sys} = \frac{q_{rev}}{T} = \frac{28{,}500 \text{ J}}{298 \text{ K}} = +95.7 \text{ J K}^{-1}$$

The surroundings give up the same amount of heat at the same temperature. Hence,

$$\Delta S_{surr} = \frac{-28{,}500 \text{ J}}{298 \text{ K}} = -95.7 \text{ J K}^{-1}$$

or $\Delta S_{tot} = 95.7 - 95.7 = 0$ for the reversible process. For the irreversible expansion, it is still true that

$$\Delta S_{sys} = +95.7 \text{ J K}^{-1}$$

because S is a function of state, and the initial and final states are the same as for the reversible expansion. From Example 13.7, only 11.1 kJ of heat is given up by the surroundings in this case.[1] Hence,

$$\Delta S_{surr} = \frac{-11{,}100 \text{ J}}{298 \text{ K}} = -37.2 \text{ J K}^{-1}$$

and $\Delta S_{tot} = 95.7 - 37.2 = 58.5 \text{ J K}^{-1} > 0$ for the irreversible process.

[1]How can the heat from Example 13.7, which is irreversible from the perspective of the system, be reversible from the perspective of the surroundings? This can be accomplished by enclosing the gas in a material (such as a metal) that can efficiently transfer heat to and from the surroundings, and thus remain close to equilibrium, at the same time that the gas itself is far from equilibrium due to the gas currents that occur during the irreversible expansion.

13.6 THE THIRD LAW OF THERMODYNAMICS

In thermodynamic processes, only *changes* in entropy, ΔS, are measured, just as only changes in internal energy, ΔU, or enthalpy, ΔH, are measured. It is nevertheless useful to define absolute values of entropy relative to some reference state. An important experimental observation that simplifies the choice of reference state is:

> *In any thermodynamic process involving only pure phases in their equilibrium states, the entropy change* ΔS *approaches zero as* T *approaches* 0 K.

This observation is the **Nernst heat theorem,** named after its discoverer, the German physicist Walther Nernst. It immediately suggests a choice of reference state: The entropy of any pure element in its equilibrium state is defined to approach zero as T approaches 0 K. From the Nernst theorem, the entropy change for any chemical reaction, including one in which elements react to give a pure compound, approaches zero at 0 K. The most general form of this statement is the **third law of thermodynamics:**

> *The entropy of any pure substance (element or compound) in its equilibrium state approaches zero at the absolute zero of temperature.*

Absolute zero can never actually be reached; therefore, a small extrapolation is needed to make use of this result.

The third law, like the two laws that precede it, is a macroscopic law based on experimental measurements. It is consistent with the microscopic interpretation of the entropy presented in Section 13.2. From quantum mechanics and statistical thermodynamics, we know that the number of microstates available to a substance at equilibrium falls rapidly toward one as the temperature approaches absolute zero. Therefore, the absolute entropy defined as $k_B \ln \Omega$ should approach zero. The third law states that the entropy of a substance in its equilibrium state approaches zero at 0 K. In practice, equilibrium may be difficult to achieve at low temperatures, because particle motion becomes very slow. In solid CO, molecules remain randomly oriented (CO or OC) as the crystal is cooled, even though in the equilibrium state at low temperatures, each molecule would have a definite orientation. Because a molecule reorients slowly at low temperatures, such a crystal may not reach its equilibrium state in a measurable period. A nonzero entropy measured at low temperatures indicates that the system is not in equilibrium.

Standard-State Entropies

Because the entropy of any substance in its equilibrium state is zero at absolute zero, its entropy at any other temperature T is given by the entropy increase as it is heated from 0 K to T. If heat is added at constant pressure,

$$\Delta S = n\int_{T_1}^{T_2} \frac{c_P}{T}\, dT$$

Thus, S_T, the absolute entropy of 1 mol of substance at temperature T, is given by

$$S_T = \int_0^T \frac{c_P}{T}\, dT$$

It is necessary merely to measure c_P as a function of temperature and determine the area under a plot of c_P/T versus T from 0 K to any desired temperature. If a substance melts, boils, or undergoes some other phase change before reaching the temperature T, the entropy change for that process must be added to $\int (c_P/T)\, dT$.

To calculate entropy changes for chemical reactions, we find it convenient to use the same standard state already selected for enthalpy calculations in Sec-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

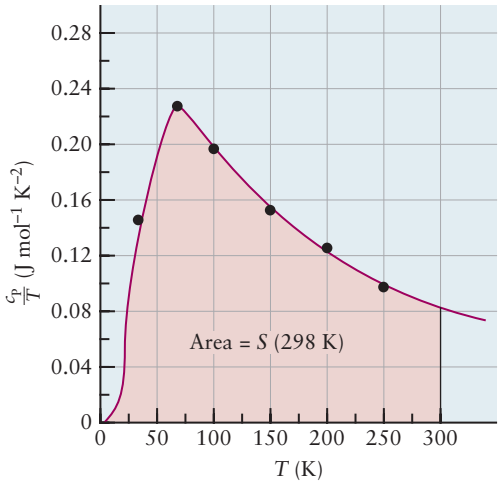

FIGURE 13.6 A graph of c_P/T versus T for platinum. The black dots represent experimental measurements. The area up to any temperature (here, 298 K) is the molar entropy at that temperature.

tion 12.3. For this purpose, we define the **standard molar entropy** to be the absolute molar entropy $S°$ at 298.15 K and 1 atm pressure (Fig. 13.6):

$$S° = \int_0^{298.15} \frac{c_P}{T} dT + \Delta S \text{ (phase changes between 0 and 298.15 K)} \qquad [13.10]$$

Standard molar entropies $S°$ are tabulated for a number of elements and compounds in Appendix D. If c_P is measured in J K^{-1} mol^{-1}, then the entropy $S°$ will have the same units. For dissolved ions, the arbitrary convention $S°\ (H^+(aq)) = 0$ is applied (just as for the standard enthalpy of formation of H^+ discussed in Section 12.3). For this reason, some $S°$ values are negative for aqueous ions—an impossibility for substances.

Tabulated standard molar entropies are used to calculate entropy changes in chemical reactions at 25°C and 1 atm, just as standard enthalpies of formation are combined to obtain enthalpies of reaction according to Hess's law (see Section 12.5).

EXAMPLE 13.9

Using the table of standard molar entropies in Appendix D, calculate $\Delta S°$ for the chemical reaction

$$N_2(g) + 2\ O_2(g) \longrightarrow 2\ NO_2(g)$$

with reactants and products at a temperature of 25°C and a pressure of 1 atm.

Solution

From the table,

$$S°(N_2(g)) = 191.50 \text{ J K}^{-1} \text{ mol}^{-1}$$
$$S°(O_2(g)) = 205.03 \text{ J K}^{-1} \text{ mol}^{-1}$$
$$S°(NO_2(g)) = 239.95 \text{ J K}^{-1} \text{ mol}^{-1}$$

The entropy change for the reaction is the sum of the entropies of the products, minus the sum of entropies of the reactants, each multiplied by its coefficient in the balanced chemical equation:

$$\begin{aligned}\Delta S° &= 2S°(NO_2(g)) - S°(N_2(g)) - 2S°(O_2(g)) \\ &= (2 \text{ mol})(239.95 \text{ J K}^{-1} \text{ mol}^{-1}) - (1 \text{ mol})(191.50 \text{ J K}^{-1} \text{ mol}^{-1}) - \\ &\quad (2 \text{ mol})(205.03 \text{ J K}^{-1} \text{ mol}^{-1}) \\ &= -121.66 \text{ J K}^{-1}\end{aligned}$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The factors of 2 multiply $S°$ for NO_2 and O_2 because 2 mol of each appears in the chemical equation. Note that standard molar entropies, unlike standard molar enthalpies of formation ΔH_f°, are not zero for elements at 25°C. The negative $\Delta S°$ results because this is the entropy change of the system only. The surroundings must undergo a positive entropy change in such a way that $\Delta S_{tot} \geq 0$.

Related Problems: 21, 22, 23, 24, 25, 26, 27, 28

13.7 THE GIBBS FREE ENERGY

In Section 13.5, we showed that the change in entropy of a system plus its surroundings (that is, the total change of entropy, ΔS_{tot}) provides a criterion for deciding whether a process is spontaneous, reversible, or non-spontaneous:

$$\Delta S_{tot} > 0 \quad \text{spontaneous} \qquad [13.11a]$$

$$\Delta S_{tot} = 0 \quad \text{reversible} \qquad [13.11b]$$

$$\Delta S_{tot} < 0 \quad \text{nonspontaneous} \qquad [13.11c]$$

Although the algebraic sign of ΔS_{tot} is a completely general criterion for determining the spontaneity of a process, it requires calculating the entropy change for the surroundings, as well as for the system. It would be much more convenient to have a state function that predicts the feasibility of a process in the system without explicit calculations for the surroundings.

For processes that occur at constant temperature and pressure, which is the most important set of conditions for chemical applications, such a state function exists. It is called the *Gibbs free energy* and is denoted by G. After a qualitative discussion of spontaneous laboratory processes at fixed T and P, we define G and develop its properties. Finally, we apply ΔG to identify conditions for spontaneity in phase transitions and chemical reactions.

The Nature of Spontaneous Processes at Fixed *T* and *P*

Consider a system enclosed in a piston-cylinder assembly, which maintains pressure at the value P. The assembly is immersed in a heat bath, which maintains temperature at the value T. Experience shows that spontaneous processes under these conditions consist of spontaneous flow of molecules across a boundary completely internal to the system, separating different regions (called *phases*) of the system (Fig. 13.7).

Under these conditions, we visualize starting a spontaneous process by bringing phases A and B in Figure 13.7 into contact—both already prepared at T and P—but separated by an impermeable membrane (a constraint) that prevents exchange of matter between the phases. Removing the constraint allows spontaneous flow of molecules across the interface between phases. The system does not exchange matter with the surroundings, and the distribution of energy and volume between system and surroundings is not described explicitly. The only function of the surroundings is to maintain T and P constant throughout the experiment. Consequently, as we show in the next subsection, spontaneity of the process is determined by the change in Gibbs free energy of the *system only* while T and P remain constant.

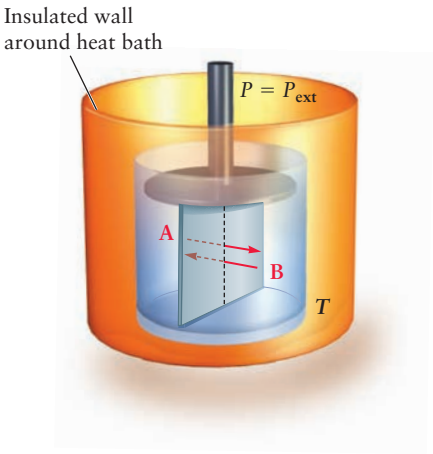

FIGURE 13.7 After the constraint between phases A and B is removed, matter can flow spontaneously between phases inside a system held at constant *T* (temperature) and *P* (pressure) by its surroundings.

These processes lead to changes in the structure or composition of the phases. Solutes are redistributed between immiscible solvents. Phase transitions occur between the solid, liquid, and gaseous states. Reactants become products. The system may gain or lose heat from the large heat reservoir while these rearrangements occur in its phases, but T remains constant. For example, the latent heat of fusion released during freezing of a liquid in the system is absorbed by the bath. Endothermic processes in the system will absorb heat from the bath, and exothermic processes will give heat to the bath. P–V work may be done on or by the system at constant P, depending on whether its density increases or decreases through the rearrangements of its phases.

Whether molecules flow spontaneously from phase A to B, or vice versa, is determined by the associated change in Gibbs free energy, as we show in the following subsection.

Gibbs Free Energy and Its Properties

During any process conducted at constant T and P as described earlier, the heat gained by the system is $\Delta H_{sys} = q_P$ and the heat transferred to the surroundings is $-q_P = -\Delta H_{sys}$. Because the surroundings remain at constant temperature during the process, the transfer of process heat must have the same effect on them as would a reversible transfer of the same amount of heat. Their entropy change is then

$$\Delta S_{surr} = \frac{-\Delta H_{sys}}{T_{surr}}$$

The total entropy change is

$$\Delta S_{tot} = \Delta S_{sys} + \Delta S_{surr} = \Delta S_{sys} - \frac{\Delta H_{sys}}{T_{surr}}$$

$$= \frac{-(\Delta H_{sys} - T_{surr}\ \Delta S_{sys})}{T_{surr}}$$

Because the temperature, T, is the same for both the system and the surroundings, we can rewrite this as

$$\Delta S_{tot} = \frac{-\Delta(H_{sys} - TS_{sys})}{T} \qquad [13.12]$$

We define the **Gibbs free energy** G as

$$G = H - TS \qquad [13.13]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

therefore, Equation 13.12 becomes

$$\Delta S_{tot} = \frac{-\Delta G_{sys}}{T} \qquad [13.14]$$

Because the absolute temperature T is always positive, ΔS_{tot} and ΔG_{sys} must have the opposite sign for processes occurring at constant T and P. It follows that

$$\Delta G_{sys} < 0 \quad \text{spontaneous processes} \qquad [13.15a]$$

$$\Delta G_{sys} = 0 \quad \text{reversible processes} \qquad [13.15b]$$

$$\Delta G_{sys} > 0 \quad \text{nonspontaneous processes} \qquad [13.15c]$$

for processes conducted at constant temperature and pressure. If $\Delta G_{sys} > 0$ for a proposed process, then $\Delta G_{sys} < 0$ for the *reverse* of the proposed process, and that reverse process can occur spontaneously. The connection of these relations to experiment is shown in Figure 13.7. Initially we prepare the system at chosen values of T and P, then release the appropriate constraint to allow the process to occur. The resulting "flow" of matter between phases A and B goes in the direction that reduces the value of G for the system, so that $\Delta G < 0$ at the selected values of T and P.

Gibbs Free Energy and Phase Transitions

As a simple application of the Gibbs free energy, consider the freezing of 1 mol liquid water to form ice:

$$H_2O(\ell) \longrightarrow H_2O(s)$$

First, let's examine what thermodynamics predicts when this process occurs at the ordinary freezing point of water under atmospheric pressure, 273.15 K. The measured enthalpy change (the heat absorbed at constant pressure) is

$$\Delta H_{273} = q_P = -6007 \text{ J mol}^{-1}$$

At $T_f = 273.15$ K, water freezes reversibly—the system remains close to equilibrium as it freezes. Therefore, the entropy change is

$$\Delta S_{273} = \frac{q_{rev}}{T_f} = \frac{-6007 \text{ J mol}^{-1}}{273.15 \text{ K}} = -21.99 \text{ J K}^{-1} \text{ mol}^{-1}$$

The Gibbs free energy change for freezing is $\Delta G_{freezing} = G_{ice} - G_{water}$ and its value at 273 K is

$$\Delta G_{273} = \Delta H_{273} - T\,\Delta S_{273} = -6007 \text{ J mol}^{-1} - (273.15 \text{ K})(-21.99 \text{ J K}^{-1} \text{ mol}^{-1}) = 0$$

At the normal freezing point, the Gibbs free energy change is zero because the freezing of water under these conditions is an equilibrium, reversible process.

Now, let's see what thermodynamics predicts as the water is cooled below 273.15 to 263.15 K (−10.00°C). Let's calculate the change in Gibbs free energy as water freezes at this lower temperature.

Assume that ΔH and ΔS for the freezing process do not depend on temperature. Then we can write

$$\Delta G_{263} = -6007 \text{ J mol}^{-1} - (263.15 \text{ K})(-21.99 \text{ J K}^{-1} \text{ mol}^{-1}) = -220 \text{ J mol}^{-1}$$

An exact calculation takes into account that ΔH and ΔS *do* depend slightly on temperature, and it leads to

$$\Delta G_{263} = -213 \text{ J mol}^{-1}$$

for the process. Because $\Delta G < 0$, thermodynamics predicts the undercooled water will freeze spontaneously at 263.15 K. At a temperature *higher* than T_f, ΔG is greater than

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. FIGURE 13.8 Plots of ΔH and $T\,\Delta S$ versus temperature for the freezing of water. At 273.15 K, the two curves cross, meaning that at this temperature, $\Delta G_{freezing} = 0$ and ice and water coexist. Below this temperature, $\Delta G_{freezing} < 0$ and the freezing of water to ice is spontaneous. Above this temperature $\Delta G_{freezing} > 0$ and the reverse process, the melting of ice to water, is spontaneous.

Cengage Learning/Leon Lewandowski

FIGURE 13.9 The dissolution of hydrogen chloride in water, HCl(*g*) → HCl(*aq*), is a spontaneous process, with $\Delta G° = -35.9$ kJ. In this demonstration, the upper flask is filled with gaseous hydrogen chloride, and a small amount of water is injected into it. As the hydrogen chloride dissolves spontaneously, its pressure declines. The resulting air pressure difference draws water up the tube from the lower flask, allowing more hydrogen chloride to dissolve. The change is so fast that a vigorous fountain of water sprays into the upper flask. The free energy change of the process appears as work, raising the water.

0, predicting that the liquid would not freeze. This agrees with our experience in nature. Water does not freeze at atmospheric pressure if the temperature is held greater than 273.15 K; instead, the reverse process occurs, and ice melts spontaneously.

Writing the Gibbs free energy change as $\Delta G = \Delta H - T\,\Delta S$ shows that a negative value of ΔG—and therefore a spontaneous process—is favored by a negative value of ΔH and a positive value of ΔS. For freezing a liquid, ΔH is negative, but ΔS for freezing is also negative. Whether a liquid freezes depends on the competition between two factors: an enthalpy change that favors freezing and an entropy change that disfavors freezing (Fig. 13.8). At temperatures less than T_f, the former dominates and the liquid freezes spontaneously, but at temperatures greater than T_f, the latter dominates and freezing does not occur. At T_f, the Gibbs free energies of the two phases are equal ($\Delta G = 0$), and the phases coexist at equilibrium. Similar types of analysis apply to other phase transitions, such as condensing a gas to a liquid.

Gibbs Free Energy and Chemical Reactions

The change in the Gibbs free energy provides a criterion for the spontaneity of any process occurring at constant temperature and pressure (Fig. 13.9). To predict whether a chemical reaction is spontaneous at given values of T and P, it is necessary to determine only the sign of ΔG for the reaction at these same conditions. From experience with other state functions, we would expect to calculate ΔG for reactions by consulting appropriate tabulations of free energy data. Because we cannot know the absolute value of the Gibbs free energy of a substance (just as we cannot know the absolute value of its internal energy U), it is convenient to define a **standard molar Gibbs free energy of formation,** ΔG_f°, analogous to the standard molar enthalpy of formation ΔH_f° introduced in Section 12.6. From tables of ΔG_f° we can calculate $\Delta G°$ for a wide range of chemical reactions, just as we used Hess's law to calculate $\Delta H°$ for a reaction from tables of ΔH_f° for products and reactants. The next few paragraphs show how tables of ΔG_f° are generated and how the data are used to determine spontaneity of reactions.

Standard-State Free Energies

The change in the Gibbs free energy for a chemical reaction performed at constant temperature is

$$\Delta G = \Delta H - T\,\Delta S \qquad [13.16]$$

where ΔH is the enthalpy change in the reaction (considered in Section 12.6) and ΔS is the entropy change in the reaction (see Section 13.4). The standard molar

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Gibbs free energy of formation ΔG_f° of a compound is the change in Gibbs free energy for the reaction in which 1 mol of the compound in its standard state is formed from its elements in their standard states. (You should review the definition of standard states in Section 12.6.) For example, ΔG_f° for $CO_2(g)$ is given by the Gibbs free energy change for the reaction

$$C(s) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta G_f^\circ = ?$$

The value of ΔG_f° can be constructed from Equation 13.16 by using ΔH_f° and $\Delta S°$ values for this reaction and setting T= 298.15 K. For this reaction, $\Delta H°$ is simply ΔH_f° for $CO_2(g)$, because graphite and oxygen are elements in their standard states,

$$\Delta H° = \Delta H_f^\circ(CO_2) = -393.51 \text{ kJ}$$

The value of $\Delta S°$ can be obtained from the absolute entropies of the substances involved at 25°C and 1 atm pressure (both elements and compounds, because the absolute entropy $S°$ of an element is not zero in its standard state).

$$\Delta S° = S°(CO_2) - S°(C) - S°(O_2) = 213.63 - 5.74 - 205.03 \text{ J K}^{-1}$$
$$= +2.86 \text{ J K}^{-1}$$

The ΔG_f° for CO_2 is then

$$\Delta G_f^\circ = \Delta H_f^\circ - T\,\Delta S° = -393.51 \text{ kJ} - (298.15 \text{ K})(2.86 \text{ J K}^{-1})(10^{-3} \text{ kJ J}^{-1})$$
$$= -394.36 \text{ kJ}$$

Appendix D includes a table of ΔG_f° values for numerous substances, all obtained by the method just illustrated. Note that our definition makes $\Delta G_f^\circ = 0$ for an *element* that is already in its standard state.

Because G is a state function, chemical equations can be added together—with their ΔG_f° values combined as in Hess's law for changes in enthalpy—to calculate Gibbs free energy changes for chemical reactions under standard-state conditions.

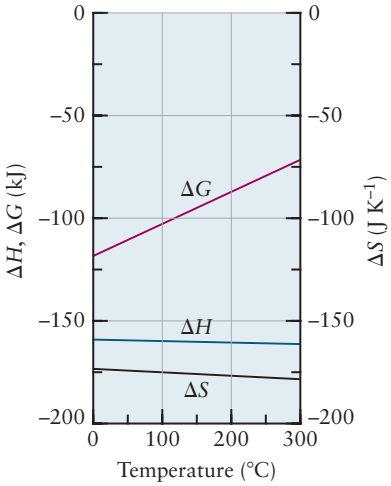

FIGURE 13.10 The entropy change of the reaction 3 NO(*g*) → $N_2O(g)$ + $NO_2(g)$ varies less than 5% between 0°C and 300°C; the enthalpy of reaction is even closer to constancy. The free energy change in the reaction shifts greatly over the temperature range, however, as the magnitude of $T\,\Delta S$ increases. Note that the units are very different on the left- (energy) and right-hand vertical axes (entropy).

EXAMPLE 13.10

Calculate $\Delta G°$ for the following reaction, using tabulated values for ΔG_f° from Appendix D.

$$3\,NO(g) \longrightarrow N_2O(g) + NO_2(g)$$

Solution

$$\Delta G° = \Delta G_f^\circ(N_2O) + \Delta G_f^\circ(NO_2) - 3\,\Delta G_f^\circ(NO)$$
$$= (1 \text{ mol})(104.18 \text{ kJ mol}^{-1}) + (1 \text{ mol})(51.29 \text{ kJ mol}^{-1}) - (3 \text{ mol})(86.55 \text{ kJ mol}^{-1})$$
$$= -104.18 \text{ kJ}$$

Effects of Temperature on ΔG

Values of $\Delta G°$ calculated from the data in Appendix D are accurate only at T = 298.15 K. Values of $\Delta G°$ can be estimated for reactions at other temperatures and at P = 1 atm using the equation

$$\Delta G° = \Delta H° - T\,\Delta S° \qquad [13.17]$$

and tables of standard entropies and standard enthalpies of formation. The estimates will be close to the true value if $\Delta H°$ and $\Delta S°$ are not strongly dependent on T, which is usually the case (Fig. 13.10).

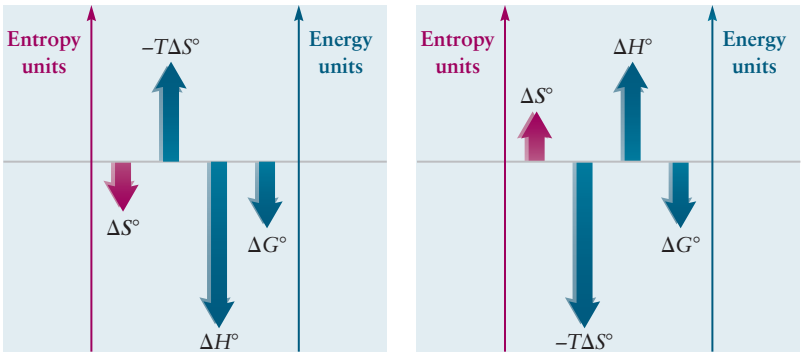

FIGURE 13.11 The competition between $\Delta H°$ and $\Delta S°$ determines the temperature range in which a reaction is spontaneous. (a) If both $\Delta H°$ and $\Delta S°$ are negative, the reaction is spontaneous at temperatures less than $T^* = \Delta H°/\Delta S°$. (b) If both $\Delta H°$ and $\Delta S°$ are positive, the reaction is spontaneous at temperatures greater than $T^* = \Delta H°/\Delta S°$.

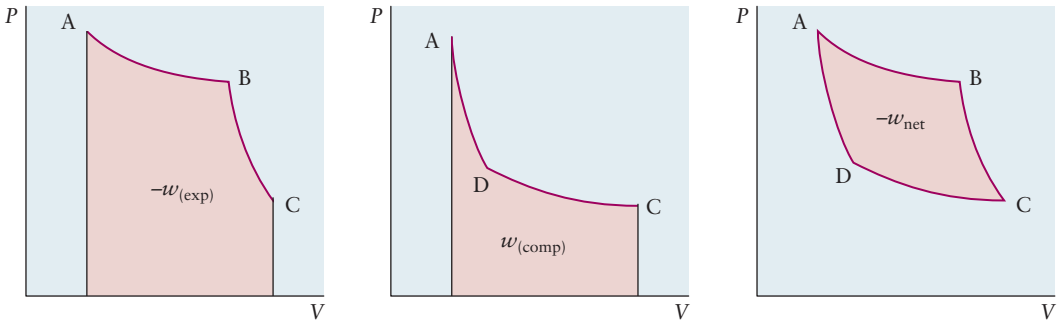
The value and the sign of $\Delta G°$ can depend strongly on T, even when the values of $\Delta H°$ and $\Delta S°$ do not, because of the competition between $\Delta H°$ and $T\,\Delta S°$ in Equation 13.17. If $\Delta H°$ is negative and $\Delta S°$ is positive, then the reaction is spontaneous at all temperatures when reactants and products are at atmospheric pressure. If $\Delta H°$ is positive and $\Delta S°$ is negative, the reaction is never spontaneous. For the other possible combinations, there exists a special temperature T^*, defined by

$$T^* = \frac{\Delta H°}{\Delta S°} \qquad [13.18]$$

at which $\Delta G°$ equals zero. If both $\Delta H°$ and $\Delta S°$ are positive, the reaction will be spontaneous at temperatures greater than T^*. If both are negative, the reaction will be spontaneous at temperatures less than T^* (Fig. 13.11). This discussion demonstrates an important result from chemical thermodynamics with enormous practical importance: With knowledge of $\Delta H°$ and $\Delta S°$, we can manipulate conditions to make a reaction spontaneous.

A DEEPER LOOK



13.8 CARNOT CYCLES, EFFICIENCY, AND ENTROPY

This section provides a mathematical development of the relation between entropy and heat already presented qualitatively in Section 13.3. No additional results are obtained, but considerably greater insight is provided.

The Carnot Cycle

A heat engine and its operation are shown schematically on page 581. The engine is a thermodynamic system which interacts with its surroundings in the course of a cyclic process. The engine withdraws (gains) energy in the form of heat from the high-temperature reservoir, and uses part of that energy to perform work on its surroundings. The remainder of the thermal energy is discharged (lost by the engine) to the lower temperature reservoir. In a Carnot cycle (Figure 13.12), the engine (system) traverses two isothermal and two adiabatic paths to return to its original state. Each path is carried out reversibly (that is, in thermal equilibrium, with internal and external forces nearly bal-

(a) Expansion (b) Compression (c) Complete cycle

FIGURE 13.12 Stages of the Carnot cycle. The work done by the system in expansion (a) and on the system by compression (b) is shown by the shaded areas. (c) The net work done per cycle is the area enclosed by the curve ABCDA.

anced at every step). As the system proceeds from state A to C through state B, the system performs work (Fig. 13.12a):

$$w_{ABC} = -\int_{V_A}^{V_C} P\,dV$$

(Path ABC)

and it is clearly negative for this (expansion) process. If the system then returns from state C to A through state D,

$$w_{CDA} = -\int_{V_C}^{V_A} P\,dV$$

(Path CDA)

which is now a positive quantity for this (compression) process; work is performed on the system (see Fig. 13.12b). In the course of the cycle, the work performed by the system is the area under curve ABC, whereas that performed on the system is the (smaller) area under curve ADC. The net result of the whole cycle is that work is performed by the system, and the amount of this work is the difference between the two areas, which is the area enclosed by the cycle (see Fig. 13.12c). As in any cyclic process, the overall energy change ΔU is zero, thus the net work equals the negative of the total heat added to the system.

We have not yet specified the material contained in the system. Assume initially that it is an ideal gas, for which the results from Section 12.7 apply directly, with T_h defined to be the higher temperature in the cycle and T_l the lower temperature.

Path AB: Isothermal Expansion (temperature T_h)

$$w_{AB} = -q_{AB} = -nRT_h \ln\left(\frac{V_B}{V_A}\right)$$

Path BC: Adiabatic Expansion

$$q_{BC} = 0$$

$$w_{BC} = nc_V(T_l - T_h) = -nc_V(T_h - T_l)$$

Path CD: Isothermal Compression (temperature T_l)

$$w_{CD} = -q_{CD} = -nRT_l \ln\left(\frac{V_D}{V_C}\right)$$

$$= nRT_l \ln\left(\frac{V_C}{V_D}\right)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Path DA: Adiabatic Compression

$$q_{DA} = 0$$
$$w_{DA} = nc_V(T_h - T_l)$$

The net work done on the system is

$$\begin{aligned} w_{net} &= w_{AB} + w_{BC} + w_{CD} + w_{DA} \\ &= -nRT_h \ln\left(\frac{V_B}{V_A}\right) - nc_V(T_h - T_l) \\ &\quad + nRT_l \ln\left(\frac{V_C}{V_D}\right) + nc_V(T_h - T_l) \\ &= -nRT_h \ln\left(\frac{V_B}{V_A}\right) + nRT_l \ln\left(\frac{V_C}{V_D}\right) \end{aligned}$$

This can be simplified by noting that V_B and V_C lie on one adiabatic path, and V_A and V_D lie on another. In Section 12.7, the relation for a reversible adiabatic process was found:

$$\frac{T_2}{T_1} = \left(\frac{V_1}{V_2}\right)^{\gamma-1}$$

Hence,

$$\frac{T_h}{T_l} = \left(\frac{V_C}{V_B}\right)^{\gamma-1} \text{ for path BC}$$

and

$$\frac{T_h}{T_l} = \left(\frac{V_D}{V_A}\right)^{\gamma-1} \text{ for path DA}$$

Equating these expressions gives

$$\left(\frac{V_C}{V_B}\right)^{\gamma-1} = \left(\frac{V_D}{V_A}\right)^{\gamma-1}$$

or

$$\frac{V_C}{V_B} = \frac{V_D}{V_A} \text{ and } \frac{V_B}{V_A} = \frac{V_C}{V_D}$$

Hence, the net work done in one passage around the Carnot cycle is

$$w_{net} = -nR(T_h - T_l)\ln\frac{V_B}{V_A} \qquad [13.19]$$

Heat Engines

The Carnot cycle is an idealized model for a heat engine. When a certain amount of heat, q_{AB}, is added to the system at the higher temperature, T_h, a net amount of work, $-w_{net}$, is obtained from the system. In addition, some heat q_{CD} is discharged at the lower temperature, but this energy is "degraded" and is no longer available for use in the engine. The **efficiency,** ϵ, of such an engine is the ratio of the negative of the net work done on the system, $-w_{net}$, to the heat added along the high-temperature isothermal path:

$$\epsilon = \frac{-w_{net}}{q_{AB}}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

It is the net work that is available for the performance of useful mechanical tasks such as turning electrical generators or dynamos, but it is the heat, q_{AB}, absorbed at the higher temperature, T_h, that must be "paid for" in terms of coal or oil consumed to supply it. The efficiency, ϵ, must be maximized to get out the most work possible for the lowest cost.

For the ideal gas Carnot cycle, the efficiency is easily calculated:

$$\epsilon = \frac{-w_{net}}{q_{AB}} = \frac{nR(T_h - T_l)\ln(V_B/V_A)}{nRT_h \ln(V_B/V_A)}$$

$$\epsilon = \frac{T_h - T_l}{T_h} = 1 - \frac{T_l}{T_h} \qquad [13.20]$$

This result, called the Carnot efficiency or the **thermodynamic efficiency,** places a fundamental limit on the efficiency with which heat can be converted to mechanical work. Only if the high temperature, T_h, were infinite or the low temperature, T_l, were zero would it be possible to have a heat engine operate with 100% efficiency. To maximize efficiency, the greatest possible temperature difference should be used. Although we derived this result specifically for the ideal gas, we will show later in this section that it applies to *any* reversible engine operating between two temperatures. For a *real* engine, which must operate irreversibly, the actual efficiency must be lower than the thermodynamic efficiency.

EXAMPLE 13.11

Suppose a heat engine absorbs 10.0 kJ of heat from a high-temperature source at T_h = 450 K and discards heat to a low-temperature reservoir at T_l = 350 K. Calculate the thermodynamic efficiency, ϵ, of conversion of heat to work; the amount of work performed, $-w_{net}$; and the amount of heat discharged at T_l, q_{CD}.

Solution

$$\epsilon = \frac{T_h - T_l}{T_h} = \frac{450\text{ K} - 350\text{ K}}{450\text{ K}} = 0.222$$

Therefore, the engine can be, at most, 22.2% efficient. Because $\epsilon = -w_{net}/q_{AB}$,

$$w_{net} = -\epsilon q_{AB} = -(0.222)(10.0\text{ kJ}) = -2.22\text{ kJ}$$

Because ΔU for the whole cycle is 0,

$$\Delta U = 0 = q_{AB} + q_{CD} + w_{net}$$

$$q_{CD} = -q_{AB} - w_{net} = -10.0 + 2.22 = -7.8\text{ kJ}$$

Therefore, 7.8 kJ is discharged at 350 K. This heat must be removed from the vicinity of the engine by a cooling system; otherwise, it will cause T_l to increase and reduce the efficiency of the engine.

Related Problems: 39, 40

Efficiency of General Carnot Engines

This subsection shows that all Carnot engines operating reversibly between two temperatures, T_h and T_l, have the same efficiency:

$$\epsilon = \frac{-w_{net}}{q_h} = \frac{T_h - T_l}{T_h} \qquad [13.21]$$

That is, the efficiency calculated for an ideal gas applies equally to any other working fluid. To demonstrate this, we assume the *contrary* true and show that assumption leads to a contradiction with experience. The assumption is, therefore, deemed false.

Assume that there *are* two reversible machines operating between the same two temperatures, T_h and T_l, one of which has an efficiency, ϵ_1, that is greater than the efficiency, ϵ_2, of the other. The two machines are adjusted so that the total work output is the same for both. The more efficient machine is run as a heat engine so that it produces mechanical work $-w_1$. This work is used to operate the other machine in the opposite sense (as a heat pump) so that $w_2 = -w_1$. The net work input to the *combined* machines is then zero, because the work produced by the first machine is used to run the second.

Now, let's examine what happens to heat in this situation. Because engine 1 is more efficient than engine 2 and because the work is the same for both, engine 1 must withdraw less heat from the hot reservoir at T_h than is discharged into the same reservoir by engine 2; there is a net transfer of heat *into* the high-temperature reservoir. For the combined engines, $\Delta U_{tot} = w_{tot} = 0$; so q_{tot} must also be zero, and a net transfer of heat *out of* the low-temperature reservoir must therefore occur. By this reasoning we have devised an apparatus that can transfer heat from a low-temperature to a high-temperature reservoir with no net expenditure of work.

But that is impossible. All our experience shows we cannot make a device that transfers heat from a cold body to a hot body without doing work. In fact, exactly the opposite is seen: Heat flows spontaneously from hotter to colder bodies. Our experience is summarized and generalized in the following statement:

> *It is impossible to construct a device that will transfer heat from a cold reservoir to a hot reservoir in a continuous cycle with no net expenditure of work.*

This is one form of the second law of thermodynamics, as stated by Rudolf Clausius.

Further Discussion of Efficiency

Our assumption led to a conclusion that contradicts experience. Therefore, the original assumption must have been wrong, and there *cannot* be two reversible engines operating between the same two temperatures with different efficiencies. That is, all Carnot engines must have the same efficiency, which is

$$\epsilon = \frac{T_h - T_l}{T_h}$$

for the ideal gas. For any substance, ideal or not, undergoing a Carnot cycle,

$$\epsilon = \frac{-w_{net}}{q_h} = \frac{q_h + q_l}{q_h} = \frac{T_h - T_l}{T_h}$$

The Carnot cycle forms the basis for a *thermodynamic* scale of temperature. Because $\epsilon = 1 - (T_l/T_h)$, the Carnot efficiencies determine temperature ratios and thereby establish a temperature scale. The difficulty of operating real engines close to the reversible limit makes this definition of temperature scale impractical. Instead, real gases at low pressures are used to define and determine temperatures (see Section 9.2).

The last two terms of the preceding equation can be rewritten as

$$1 + \frac{q_l}{q_h} = 1 - \frac{T_l}{T_h}$$

and simplified to

$$\frac{q_h}{T_h} + \frac{q_l}{T_l} = 0 \qquad [13.22]$$

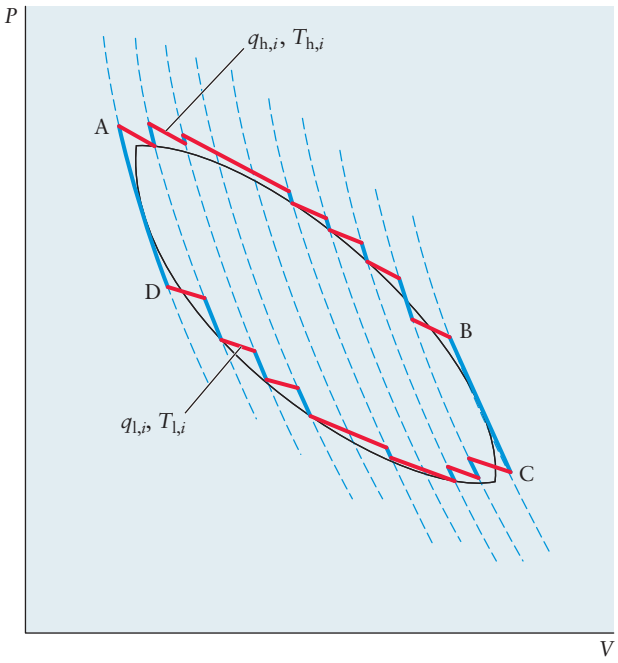

FIGURE 13.13 A general cyclic process (ABCDA) can be approximated to arbitrary accuracy by the sum of a series of Carnot cycles.

This simple equation has profound importance because it contains the essence of the second law of thermodynamics, namely, that q/T is a state function. To see this, consider a *general* reversible cyclic process and draw a series of closely spaced adiabats, as shown in Figure 13.13. (An adiabat is a curve on the PV diagram showing those thermodynamic states connected by a particular reversible adiabatic process.) Now replace each segment along the given cycle (ABCDA) with a series of alternating isothermal and adiabatic segments. Clearly, we can construct a path that is arbitrarily close to the desired curve by taking more and more closely spaced adiabats.

Now follow the evolution of $\Sigma_i(q_i/T_i)$ along this curve. The key observation is that the contributions q_i/T_i appear in pairs: For each $q_{h,i}/T_{h,i}$ from an isothermal segment along the ABC path, there is a $q_{l,i}/T_{l,i}$ along the CDA path. Any given pair forms two sides of a Carnot cycle, with the other two sides determined by adiabats; thus,

$$\frac{q_{h,i}}{T_{h,i}} + \frac{q_{l,i}}{T_{l,i}} = 0$$

Summing over i shows that

$$\sum_i \left(\frac{q_{h,i}}{T_{h,i}} + \frac{q_{l,i}}{T_{l,i}} \right) = 0$$

Because this summation follows the original reversible path to an arbitrary accuracy (if the lengths of the segments are made short enough), it follows that

$$\int \frac{1}{T} dq_{rev} = 0$$

for *any* closed, reversible path. Although q is not a state function, q_{rev}/T is a state function because, like energy and enthalpy, its total change is zero for any process that begins and ends in the same state. From this result, Clausius *defined* the entropy change $\Delta S = S_f - S_i$ of a system in a process starting in state i and ending in state f by the equation

$$\Delta S = \int_i^f \frac{dq_{rev}}{T} \qquad [13.23]$$

As we have stated, the principles of thermodynamics are based on observations of nature and are not subject to mathematical proof. We have accomplished something quite significant, however. From the assumption—based on physical observation—that heat cannot be transferred from a low-temperature to a high-temperature body without expenditure of work, we have derived the result that $\int(1/T)\, dq_{rev}$ is independent of path and, therefore, is a state function. This result has been subjected to rigorous testing, and no proper test has found it to be invalid. Therefore, we have great confidence in the generality of this result and are entirely comfortable in calling it a scientific law. Some critics might say, "If we have to make some assumption anyway, why don't we just assume that $\int(1/T)\, dq_{rev}$ is path independent to start with?" This is certainly possible and is practiced in many presentations of thermodynamics. Our approach is different; we prefer to base our assumptions directly on physical observation, not on abstract mathematical axioms.

CHAPTER SUMMARY

This chapter opened with the quest for methods of predicting whether a chemical reaction can occur spontaneously under a given set of conditions. The second law provides the answer: Any process is spontaneous under conditions where the total entropy of the *system and its surroundings* can increase during the process. For the particular case of constant temperature (T) and pressure (P)—the conditions most widely used for chemical reaction—the second law asserts that any process is spontaneous when the Gibbs free energy of the *system alone* can decrease during the process. The temperature dependence of the Gibbs free energy change shows that with knowledge of $\Delta H°$ and $\Delta S°$, we can identify the temperature range in which a given reaction is spontaneous. From the point of view of chemistry, predicting this temperature range is the most important result from the second law. All other material in this chapter can be viewed as preliminary background for arriving at this one crucial result.

The Gibbs free energy is the thermodynamic state function most naturally suited to describing the progress of chemical reactions at constant T and P. It provides the basis for predicting the equilibrium composition of the reaction mixture in Chapter 14.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 13.1 – The Nature of Spontaneous Processes

Identify the system and surroundings involved in a spontaneous process and identify the constraint that was removed to enable the process to occur (Problems 1–2).

- Initially the system is separated from the surroundings by special walls (constraints) that prevent interaction between them. Adiabatic walls prevent flow of thermal energy (heat), rigid walls keep their volumes fixed, and impermeable walls prevent flow of matter. Removing one or more of the constraints allows the system and surroundings to exchange energy, matter, volume, or some combination of these. Then, a spontaneous process can occur if that process would increase the total entropy of the combined system and surroundings. Whether a spontaneous process does occur perceptibly depends on its rate. Thermodynamics cannot describe or predict the rates of processes.

Section 13.2 – Entropy and Spontaneity: A Molecular Statistical Interpretation

Provide a statistical interpretation of the change in entropy that occurs when a gas undergoes a change in volume (Problems 3–10).

- Increasing the volume increases the range of possible positions available to the molecules, thereby increasing Ω, the number of microstates available to the system. The entropy will increase according to Boltzmann's equation $S = k_B \ln\Omega$. Doubling the volume will change the entropy by the amount $\Delta S = N_A k_B \ln 2$. Similarly, decreasing the volume will decrease the entropy. Reducing the volume by half will change the entropy by the amount $\Delta S = N_A k_B \ln(0.5)$.

Section 13.3 – Entropy and Heat: Macroscopic Basis of the Second Law of Thermodynamics

Summarize the justification that entropy is a state function.

- By analyzing the Carnot cycle description of macroscopic energy transfer processes, Clausius demonstrated that the quantity $\int(1/T)dq_{rev}$ is a state function, because its change in value for any reversible process is independent of the path. Based on this result, Clausius defined the procedure for calculating the entropy change $\Delta S = S_f - S_i$ for a system between any thermodynamic states i and f as $\Delta S = \int_i^f (1/T)\, dq_{rev}$. The integral can be evaluated along any reversible path between i and f so long as T and dq_{rev} are known along the path. Because S is a state function, this procedure is valid for any process—even an irreversible one—that connects states i and f.

Sections 13.4 and 13.5 – Entropy Changes in Reversible Processes and Entropy Changes and Spontaneity

Calculate the entropy change for the system and the surroundings for reversible and irreversible processes. (Problems 11–20).

- Because entropy is a state function, changes in entropy are always calculated along a reversible path connecting the specified initial and final states. The details of the calculation depend on the conditions of the reversible path selected (constant T, constant P, or constant V). Specific cases are summarized as follows and in the list of Key Equations.
  - It is easy to calculate entropy changes for isothermal processes, because T is constant and comes outside the integral to give $\Delta S = q_{rev}/T$. A specific example is the isothermal compression or expansion of an ideal gas, for which $\Delta S = nR \ln(V_f/V_i)$. A second example is any phase transition at constant pressure and temperature where the phases are in equilibrium; for this case $q_{rev} = \Delta H_{trans}$. The entropy change is then $\Delta S_{trans} = \Delta H_{trans}/T_{trans}$.
  - When the temperature changes during a process that does not include a phase transition, we account for the variation of T along the process path by writing $dq_{rev} = nc_X dT$, where X represents V or P for a constant volume or a constant pressure process, respectively. When c_X is constant, the integral gives $\Delta S = nc_X \ln(T_f/T_i)$.
  - Usually the surroundings are sufficiently large that they can be considered a constant temperature and constant pressure heat bath during the process. The heat lost by the system during the process is gained by the surroundings, so the entropy change for the surroundings is $\Delta S_{surr} = -\Delta H_{sys}/T_{surr}$. If the surroundings are not large enough to be treated in this way, ΔS_{surr} is calculated by the same procedures as ΔS_{sys}.
  - To determine whether a process is spontaneous, we must calculate the total entropy change, $\Delta S_{tot} = \Delta S_{sys} + \Delta S_{surr}$. If $\Delta S_{tot} > 0$, the process is spontaneous. If $\Delta S_{tot} < 0$, the process cannot occur spontaneously. If $\Delta S_{tot} = 0$, the system is at equilibrium, and no process will occur.

Section 13.6 – The Third Law of Thermodynamics

Describe the measurements of absolute entropy, and calculate standard-state entropy changes for chemical reactions (Problems 21–28).

- The third law of thermodynamics states that the entropy of any pure substance in equilibrium approaches 0 as the temperature approaches absolute zero. Therefore the absolute entropy at any value of T can be obtained by measuring c_P and integrating the ratio c_P/T over this temperature range. The entropy changes for any phase transitions that occur in the temperature range must be included. Standard state values at $T = 298.15$ K are tabulated from results based on the equation

$$S^\circ = \int_0^{298.15} (c_P/T)\,dT + \Delta S \text{ (for all phase changes between 0 and 298.15 K)}$$

- The standard state entropy change for a chemical reaction is calculated by summing the standard state entropy values for the products (multiplied by stoichiometric coefficients from the balanced equation for the reaction) and subtracting the standard state entropy values for the reactants (multiplied by stoichiometric coefficients).

Section 13.7 – The Gibbs Free Energy

Define the Gibbs free energy function and state the criterion it provides for the spontaneity of a process.

- When processes are conducted at fixed temperature and pressure, spontaneity is determined by changes in the Gibbs free energy, $G = H - TS$, for the system with no consideration of changes in the surroundings. If $\Delta G < 0$, the process is spontaneous. If $\Delta G > 0$, the process cannot occur spontaneously. If $\Delta G = 0$, the system is at equilibrium, and no process will occur.

Calculate the change in Gibbs free energy for reversible and spontaneous phase transition (Problems 29–32).

- This change is calculated using $\Delta G = \Delta H - T_{tr}\Delta S$ at the temperature T_{tr} of the transition. ΔH_{tr} is the measured enthalpy change of the transition occurring at constant pressure. The entropy change is calculated as $\Delta S_{tr} = \Delta H_{tr}/T_{tr}$. These terms are summed to obtain ΔG_{tr} for the transition.

Calculate the change in Gibbs free energy for chemical reactions and identify temperature ranges in which a particular reaction is spontaneous (Problems 33–38).

- Tabulations of the standard Gibbs free energy of formation for each substance in its standard state have been prepared by combining absolute entropy values with standard enthalpy of formation values. We can determine whether any chemical reaction is spontaneous by calculating its value of ΔG from the tabulated standard Gibbs free energy for its reactants and products. The algebraic sign of ΔG tells us whether the reaction is spontaneous. When the reactants and products are in their standard state partial pressures or concentrations, whether a reaction is spontaneous depends on the relation between ΔH° and ΔS° at the temperature of the reaction. If $\Delta H^\circ < 0$ and $\Delta S^\circ > 0$, the reaction is spontaneous at all temperatures. If $\Delta H^\circ > 0$ and $\Delta S^\circ < 0$, the reaction is never spontaneous. For other combinations, there is a special temperature $T^* = \Delta H^\circ/\Delta S^\circ$ at which $\Delta G^\circ = 0$. If both ΔH° and ΔS° are positive, the reaction is spontaneous for temperatures greater than T^*. If both ΔH° and ΔS° are negative, the reaction is spontaneous for temperatures less than T^*.

KEY EQUATIONS

Sections 13.4 and 13.5—Entropy Changes in Reversible Processes. Entropy Changes and Spontaneity.

$$\Delta S = \int_i^f \frac{dq_{rev}}{T}$$ (for all processes)

$$\Delta S = \int_i^f \frac{dq_{rev}}{T} = \frac{1}{T}\int_i^f dq_{rev} = \frac{q_{rev}}{T}$$ (constant T)

$$\Delta S_{trans} = \frac{q_{rev}}{T_{trans}} = \frac{\Delta H_{trans}}{T_{trans}}$$ (reversible phase transitions at constant T and P)

$$\Delta S = nR \ln\left(\frac{V_2}{V_1}\right)$$ (ideal gas, change of V at constant T)

$$\Delta S = \int_{T_1}^{T_2} \frac{nc_V}{T}\,dT = nc_V \ln\left(\frac{T_2}{T_1}\right)$$ (constant V and constant c_V)

$$\Delta S = \int_{T_1}^{T_2} \frac{nc_P}{T}\,dT = nc_P \ln\left(\frac{T_2}{T_1}\right)$$ (constant P and constant c_P)

$$\Delta S_{surr} = \frac{-\Delta H_{sys}}{T_{surr}}$$ (surroundings are a large "heat bath" and pressure of the system is constant)

$$\Delta S_{tot} = \Delta S_{sys} + \Delta S_{surr} > 0$$ (spontaneous process)

CUMULATIVE EXERCISE

Purifying Nickel from Its Ores

Impure nickel, obtained from the smelting of its sulfide ores in a blast furnace, can be converted to metal of 99.90% to 99.99% purity by the Mond process, which relies on the equilibrium

$$Ni(s) + 4\ CO(g) \rightleftharpoons Ni(CO)_4(g)$$

The standard enthalpy of formation of nickel tetracarbonyl, $Ni(CO)_4(g)$, is -602.9 kJ mol^{-1}, and its absolute entropy $S°$ is 410.6 J K^{-1} mol^{-1}.

(a) Predict (without referring to a table) whether the entropy change of the system (the reacting atoms and molecules) is positive or negative in this process.

(b) At a temperature where this reaction is spontaneous, predict whether the entropy change of the surroundings is positive or negative.

(c) Use the data in Appendix D to calculate $\Delta H°$ and $\Delta S°$ for this reaction.

(d) At what temperature is $\Delta G° = 0$ for this reaction?

(e) The first step in the Mond process is the equilibration of impure nickel with CO and $Ni(CO)_4$ at about 50°C. In this step, the goal is to draw as much nickel as possible into the vapor-phase complex. Calculate $\Delta G°$ for the preceding reaction at 50°C.

(f) In the second step of the Mond process, the gases are removed from the reaction chamber and heated to about 230°C. At high enough temperatures, the sign of $\Delta G°$ is reversed and the reaction occurs in the opposite direction, depositing pure nickel. In this step, the goal is to deposit as much nickel as possible from the vapor-phase complex. Calculate $\Delta G°$ for the preceding reaction at 230°C.

(g) The Mond process relies on the volatility of $Ni(CO)_4$ for its success. Under room conditions, this compound is a liquid, but it boils at 42.2°C with an

enthalpy of vaporization of 29.0 kJ mol^{-1}. Calculate the entropy of vaporization of $Ni(CO)_4$, and compare it with that predicted by Trouton's rule.

(h) A recently developed variation of the Mond process carries out the first step at higher pressures and at a temperature of 150°C. Estimate the maximum pressure of $Ni(CO)_4(g)$ that can be attained before the gas will liquefy at this temperature (that is, calculate the vapor pressure of $Ni(CO)_4(\ell)$ at 150°C).

Answers

(a) Negative

(b) Positive

(c) $\Delta H° = -160.8$ kJ; $\Delta S° = -409.5$ J K^{-1}

(d) 392.7 K = 119.5°C

(e) $\Delta G° = -28.4$ kJ

(f) $\Delta G° = +46.0$ kJ

(g) 92.0 J K^{-1} mol^{-1}, close to the Trouton's rule value of 88 J K^{-1} mol^{-1}

(h) 16.7 atm

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

The Nature of Spontaneous Processes

1. For each of the following processes, identify the system and the surroundings. Identify those processes that are spontaneous. For each spontaneous process, identify the constraint that has been removed to enable the process to occur:
(a) Ammonium nitrate dissolves in water.
(b) Hydrogen and oxygen explode in a closed bomb.
(c) A rubber band is rapidly extended by a hanging weight.
(d) The gas in a chamber is slowly compressed by a weighted piston.
(e) A glass shatters on the floor.

2. For each of the following processes, identify the system and the surroundings. Identify those processes that are spontaneous. For each spontaneous process, identify the constraint that has been removed to enable the process to occur:
(a) A solution of hydrochloric acid is titrated with a solution of sodium hydroxide.
(b) Zinc pellets dissolve in aqueous hydrochloric acid.
(c) A rubber band is slowly extended by a hanging weight.
(d) The gas in a chamber is rapidly compressed by a weighted piston.
(e) A tray of water freezes in the freezing compartment of an electric refrigerator.

Entropy and Spontaneity: A Molecular Statistical Interpretation

3. (a) How many "microstates" are there for the numbers that come up on a pair of dice?
(b) What is the probability that a roll of a pair of dice will show two sixes?

4. (a) Suppose a volume is divided into three equal parts. How many microstates can be written for all possible ways of distributing four molecules among the three parts?
(b) What is the probability that all four molecules are in the leftmost third of the volume at the same time?

5. When $H_2O(\ell)$ and $D_2O(\ell)$ are mixed, the following reaction occurs spontaneously:

$$H_2O(\ell) + D_2O(\ell) \longrightarrow 2\ HOD(\ell)$$

There is little difference between the enthalpy of an O—H bond and that of an O—D bond. What is the main driving force for this reaction?

6. The two gases $BF_3(g)$ and $BCl_3(g)$ are mixed in equal molar amounts. All B—F bonds have about the same bond enthalpy, as do all B—Cl bonds. Explain why the mixture tends to react to form $BF_2Cl(g)$ and $BCl_2F(g)$.

7. Two large glass bulbs of identical volume are connected by means of a stopcock. One bulb initially contains 1.00 mol H_2; the other contains 1.00 mol helium (He). The stopcock is opened and the gases are allowed to mix and reach equilibrium. What is the probability that all the H_2 in the first bulb will diffuse into the second bulb and all the He gas in the second bulb will diffuse into the first bulb?

8. A mixture of 2.00 mol nitrogen and 1.00 mol oxygen is in thermal equilibrium in a 100-L container at 25°C. Calculate the probability that at a given time all the nitrogen will be found in the left half of the container and all the oxygen in the right half.

9. Predict the sign of the system's entropy change in each of the following processes.
(a) Sodium chloride melts.
(b) A building is demolished.
(c) A volume of air is divided into three separate volumes of nitrogen, oxygen, and argon, each at the same pressure and temperature as the original air.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

10. Predict the sign of the system's entropy change in each of the following processes.
    (a) A computer is constructed from iron, copper, carbon, silicon, gallium, and arsenic.
    (b) A container holding a compressed gas develops a leak and the gas enters the atmosphere.
    (c) Solid carbon dioxide (dry ice) sublimes to gaseous carbon dioxide.

Entropy Changes in Reversible Processes

11. Tungsten melts at 3410°C and has an enthalpy change of fusion of 35.4 kJ mol^{-1}. Calculate the entropy of fusion of tungsten.

12. Tetraphenylgermane, $(C_6H_5)_4Ge$, has a melting point of 232.5°C, and its enthalpy increases by 106.7 J g^{-1} during fusion. Calculate the molar enthalpy of fusion and molar entropy of fusion of tetraphenylgermane.

13. The normal boiling point of acetone is 56.2°C. Use Trouton's rule to estimate its molar enthalpy of vaporization.

14. The molar enthalpy of vaporization of liquid hydrogen chloride is 16.15 kJ mol^{-1}. Use Trouton's rule to estimate its normal boiling point.

15. If 4.00 mol hydrogen (c_P = 28.8 J K^{-1} mol^{-1}) is expanded reversibly and isothermally at 400 K from an initial volume of 12.0 L to a final volume of 30.0 L, calculate ΔU, q, w, ΔH, and ΔS for the gas.

16. Suppose 60.0 g hydrogen bromide, HBr(g), is heated reversibly from 300 to 500 K at a constant volume of 50.0 L, and then allowed to expand isothermally and reversibly until the original pressure is reached. Using $c_P(HBr(g))$ = 29.1 J K^{-1} mol^{-1}, calculate ΔU, q, w, ΔH, and ΔS for this process. Assume that HBr is an ideal gas under these conditions.

Entropy Changes and Spontaneity

17. Exactly 1 mol ice is heated reversibly at atmospheric pressure from −20°C to 0°C, melted reversibly at 0°C, and then heated reversibly at atmospheric pressure to 20°C. ΔH_{fus} = 6007 J mol^{-1}; c_P(ice) = 38 J K^{-1} mol^{-1}; and c_P(water) = 75 J K^{-1} mol^{-1}. Calculate ΔS for the system, the surroundings, and the thermodynamic universe for this process.

18. Suppose 1.00 mol water at 25°C is flash-evaporated by allowing it to fall into an iron crucible maintained at 150°C. Calculate ΔS for the water, ΔS for the iron crucible, and ΔS_{tot}, if $c_P(H_2O(\ell))$ = 75.4 J K^{-1} mol^{-1} and $c_P(H_2O(g))$ = 36.0 J K^{-1} mol^{-1}. Take ΔH_{vap} = 40.68 kJ mol^{-1} for water at its boiling point of 100°C.

19. In Example 12.3, a process was considered in which 72.4 g iron initially at 100.0°C was added to 100.0 g water initially at 10.0°C, and an equilibrium temperature of 16.5°C was reached. Take c_P(Fe) to be 25.1 J K^{-1} mol^{-1} and $c_P(H_2O)$ to be 75.3 J K^{-1} mol^{-1}, independent of temperature. Calculate ΔS for the iron, ΔS for the water, and ΔS_{tot} in this process.

20. Iron has a heat capacity of 25.1 J K^{-1} mol^{-1}, approximately independent of temperature between 0°C and 100°C.
    (a) Calculate the enthalpy and entropy change of 1.00 mol iron as it is cooled at atmospheric pressure from 100°C to 0°C.
    (b) A piece of iron weighing 55.85 g and at 100°C is placed in a large reservoir of water held at 0°C. It cools irreversibly until its temperature equals that of the water. Assuming the water reservoir is large enough that its temperature remains close to 0°C, calculate the entropy changes for the iron and the water and the total entropy change in this process.

The Third Law of Thermodynamics

21. (a) Use data from Appendix D to calculate the standard entropy change at 25°C for the reaction

$$N_2H_4(\ell) + 3\ O_2(g) \longrightarrow 2\ NO_2(g) + 2\ H_2O(\ell)$$

    (b) Suppose the hydrazine (N_2H_4) is in the gaseous, rather than liquid, state. Will the entropy change for its reaction with oxygen be higher or lower than that calculated in part (a)? (*Hint:* Entropies of reaction can be added when chemical equations are added, in the same way that Hess's law allows enthalpies to be added.)

22. (a) Use data from Appendix D to calculate the standard entropy change at 25°C for the reaction

$$CH_3COOH(g) + NH_3(g) \longrightarrow CH_3NH_2(g) + CO_2(g) + H_2(g)$$

    (b) Suppose that 1.00 mol each of solid acetamide, $CH_3CONH_2(s)$, and water, $H_2O(\ell)$, react to give the same products. Will the standard entropy change be larger or smaller than that calculated for the reaction in part (a)?

23. The alkali metals react with chlorine to give salts:

$$2\ Li(s) + Cl_2(g) \longrightarrow 2\ LiCl(s)$$
$$2\ Na(s) + Cl_2(g) \longrightarrow 2\ NaCl(s)$$
$$2\ K(s) + Cl_2(g) \longrightarrow 2\ KCl(s)$$
$$2\ Rb(s) + Cl_2(g) \longrightarrow 2\ RbCl(s)$$
$$2\ Cs(s) + Cl_2(g) \longrightarrow 2\ CsCl(s)$$

    Using the data in Appendix D, compute $\Delta S°$ of each reaction and identify a periodic trend, if any.

24. All of the halogens react directly with $H_2(g)$ to give binary compounds. The reactions are

$$F_2(g) + H_2(g) \longrightarrow 2\ HF(g)$$
$$Cl_2(g) + H_2(g) \longrightarrow 2\ HCl(g)$$
$$Br_2(g) + H_2(g) \longrightarrow 2\ HBr(g)$$
$$I_2(g) + H_2(g) \longrightarrow 2\ HI(g)$$

    Using the data in Appendix D, compute $\Delta S°$ of each reaction and identify a periodic trend, if any.

25. The dissolution of calcium chloride in water

$$CaCl_2(s) \longrightarrow Ca^{2+}(aq) + 2\ Cl^-(aq)$$

    is a spontaneous process at 25°C, even though the standard entropy change of the preceding reaction is negative ($\Delta S°$ = −44.7 J K^{-1}). What conclusion can you draw about the change in entropy of the surroundings in this process?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

26. Quartz, $SiO_2(s)$, does not spontaneously decompose to silicon and oxygen at 25°C in the reaction

$$SiO_2(s) \longrightarrow Si(s) + O_2(g)$$

even though the standard entropy change of the reaction is large and positive ($\Delta S° = +182.02\ J\ K^{-1}$). Explain.

27. Use the microscopic interpretation of entropy from Section 13.2 to explain why the entropy change of the system in Problem 26 is positive.

28. (a) Why is the entropy change of the system negative for the reaction in Problem 25, when the ions become dispersed through a large volume of solution? (*Hint:* Think about the role of the solvent, water.)
(b) Use Appendix D to calculate $\Delta S°$ for the corresponding dissolution of $CaF_2(s)$. Explain why this value is even more negative than that given in Problem 25.

The Gibbs Free Energy

29. The molar enthalpy of fusion of solid ammonia is 5.65 kJ mol^{-1}, and the molar entropy of fusion is 28.9 J K^{-1} mol^{-1}.
(a) Calculate the Gibbs free energy change for the melting of 1.00 mol ammonia at 170 K.
(b) Calculate the Gibbs free energy change for the conversion of 3.60 mol solid ammonia to liquid ammonia at 170 K.
(c) Will ammonia melt spontaneously at 170 K?
(d) At what temperature are solid and liquid ammonia in equilibrium at a pressure of 1 atm?

30. Solid tin exists in two forms: white and gray. For the transformation

$$Sn(s,\ \text{white}) \longrightarrow Sn(s,\ \text{gray})$$

the enthalpy change is −2.1 kJ and the entropy change is $-7.4\ J\ K^{-1}$.
(a) Calculate the Gibbs free energy change for the conversion of 1.00 mol white tin to gray tin at −30°C.
(b) Calculate the Gibbs free energy change for the conversion of 2.50 mol white tin to gray tin at −30°C.
(c) Will white tin convert spontaneously to gray tin at −30°C?
(d) At what temperature are white and gray tin in equilibrium at a pressure of 1 atm?

31. Ethanol's enthalpy of vaporization is 38.7 kJ mol^{-1} at its normal boiling point, 78°C. Calculate q, w, ΔU, ΔS_{sys}, and ΔG when 1.00 mol ethanol is vaporized reversibly at 78°C and 1 atm. Assume that the vapor is an ideal gas and neglect the volume of liquid ethanol relative to that of its vapor.

32. Suppose 1.00 mol superheated ice melts to liquid water at 25°C. Assume the specific heats of ice and liquid water have the same value and are independent of temperature. The enthalpy change for the melting of ice at 0°C is 6007 J mol^{-1}. Calculate ΔH, ΔS_{sys}, and ΔG for this process.

33. At 1200°C, the reduction of iron oxide to elemental iron and oxygen is not spontaneous:

$$2\ Fe_2O_3(s) \longrightarrow 4\ Fe(s) + 3\ O_2(g) \qquad \Delta G = +840\ kJ$$

Show how this process can be made to proceed if all the oxygen generated reacts with carbon:

$$C(s) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta G = -400\ kJ$$

This observation is the basis for the smelting of iron ore with coke to extract metallic iron.

34. The primary medium for free energy storage in living cells is adenosine triphosphate (ATP). Its formation from adenosine diphosphate (ADP) is not spontaneous:

$$ADP^{3-}(aq) + HPO_4^{2-}(aq) + H^+(aq) \longrightarrow ATP^{4-}(aq) + H_2O(\ell) \qquad \Delta G = +34.5\ kJ$$

Cells couple ATP production with the metabolism of glucose (a sugar):

$$C_6H_{12}O_6(aq) + 6\ O_2(g) \longrightarrow 6\ CO_2(g) + 6\ H_2O(\ell) \qquad \Delta G = -2872\ kJ$$

The reaction of 1 molecule of glucose leads to the formation of 38 molecules of ATP from ADP. Show how the coupling makes this reaction spontaneous. What fraction of the free energy released in the oxidation of glucose is stored in the ATP?

35. A process at constant T and P can be described as spontaneous if $\Delta G < 0$ and nonspontaneous if $\Delta G > 0$. Over what range of temperatures is each of the following processes spontaneous? Assume that all gases are at a pressure of 1 atm. (*Hint:* Use Appendix D to calculate ΔH and ΔS [assumed independent of temperature and equal to $\Delta H°$ and $\Delta S°$, respectively], and then use the definition of ΔG.)
(a) The rusting of iron, a complex reaction that can be approximated as

$$4\ Fe(s) + 3\ O_2(g) \longrightarrow 2\ Fe_2O_3(s)$$

(b) The preparation of $SO_3(g)$ from $SO_2(g)$, a step in the manufacture of sulfuric acid:

$$SO_2(g) + \tfrac{1}{2}\ O_2(g) \longrightarrow SO_3(g)$$

(c) The production of the anesthetic dinitrogen oxide through the decomposition of ammonium nitrate:

$$NH_4NO_3(s) \longrightarrow N_2O(g) + 2\ H_2O(g)$$

36. Follow the same procedure used in Problem 35 to determine the range of temperatures over which each of the following processes is spontaneous.
(a) The preparation of the poisonous gas phosgene:

$$CO(g) + Cl_2(g) \longrightarrow COCl_2(g)$$

(b) The laboratory-scale production of oxygen from the decomposition of potassium chlorate:

$$2\ KClO_3(s) \longrightarrow 2\ KCl(s) + 3\ O_2(g)$$

(c) The reduction of iron(II) oxide (wüstite) by coke (carbon), a step in the production of iron in a blast furnace:

$$FeO(s) + C(s,\ \text{gr}) \longrightarrow Fe(s) + CO(g)$$

37. Explain how it is possible to reduce tungsten(VI) oxide (WO_3) to metal with hydrogen at an elevated temperature. Over what temperature range is this reaction spontaneous? Use the data of Appendix D.

38. Tungsten(VI) oxide can also be reduced to tungsten by heating it with carbon in an electric furnace:

$$2\ WO_3(s) + 3\ C(s) \longrightarrow 2\ W(s) + 3\ CO_2(g)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) Calculate the standard free energy change ($\Delta G°$) for this reaction, and comment on the feasibility of the process at room conditions.
(b) What must be done to make the process thermodynamically feasible, assuming ΔH and ΔS are nearly independent of temperature?

A Deeper Look . . . Carnot Cycles, Efficiency, and Entropy

39. A thermodynamic engine operates cyclically and reversibly between two temperature reservoirs, absorbing heat from the high-temperature bath at 450 K and discharging heat to the low-temperature bath at 300 K.
(a) What is the thermodynamic efficiency of the engine?
(b) How much heat is discarded to the low-temperature bath if 1500 J of heat is absorbed from the high-temperature bath during each cycle?
(c) How much work does the engine perform in one cycle of operation?

40. In each cycle of its operation, a thermal engine absorbs 1000 J of heat from a large heat reservoir at 400 K and discharges heat to another large heat sink at 300 K. Calculate:
(a) The thermodynamic efficiency of the heat engine, operated reversibly
(b) The quantity of heat discharged to the low-temperature sink each cycle
(c) The maximum amount of work the engine can perform each cycle

ADDITIONAL PROBLEMS

41. Ethanol (CH_3CH_2OH) has a normal boiling point of 78.4°C and a molar enthalpy of vaporization of 38.74 kJ mol^{-1}. Calculate the molar entropy of vaporization of ethanol and compare it with the prediction of Trouton's rule.

42. A quantity of ice is mixed with a quantity of hot water in a sealed, rigid, insulated container. The insulation prevents heat exchange between the ice–water mixture and the surroundings. The contents of the container soon reach equilibrium. State whether the total *internal energy* of the contents decreases, remains the same, or increases in this process. Make a similar statement about the total *entropy* of the contents. Explain your answers.

43. (a) If 2.60 mol $O_2(g)$ (c_P = 29.4 J K^{-1} mol^{-1}) is compressed reversibly and adiabatically from an initial pressure of 1.00 atm and 300 K to a final pressure of 8.00 atm, calculate ΔS for the gas.
(b) Suppose a different path from that in part (a) is used. The gas is first heated at constant pressure to the same final temperature, and then compressed reversibly and isothermally to the same final pressure. Calculate ΔS for this path and show that it is equal to that found in part (a).

44. One mole of a monatomic ideal gas begins in a state with P = 1.00 atm and T = 300 K. It is expanded reversibly and adiabatically until the volume has doubled; then it is expanded irreversibly and isothermally into a vacuum until the volume has doubled again; and then it is heated reversibly at constant volume to 400 K. Finally, it is compressed reversibly and isothermally until a final state with P = 1.00 atm and T = 400 K is reached. Calculate ΔS_{sys} for this process. (*Hint:* There are two ways to solve this problem—an easy way and a hard way.)

* **45.** The motion of air masses through the atmosphere can be approximated as adiabatic (because air is a poor conductor of heat) and reversible (because pressure differences in the atmosphere are small). To a good approximation, air can be treated as an ideal gas with average molar mass 29 g mol^{-1} and average heat capacity 29 J K^{-1} mol^{-1}.
(a) Show that the displacement of the air masses occurs at constant entropy (ΔS = 0).
(b) Suppose the average atmospheric pressure near the earth's surface is P_0 and the temperature is T_0. The air is displaced upward until its temperature is T and its pressure is P. Determine the relation between P and T. (*Hint:* Consider the process as occurring in two steps: first a cooling from T_0 to T at constant pressure, and then an expansion from P_0 to P at constant temperature. Equate the sum of the two entropy changes to $\Delta S_{tot} = 0$.)
(c) In the lower atmosphere, the dependence of pressure on height, h, above the earth's surface can be approximated as

$$\ln (P/P_0) = -\mathcal{M}gh/RT$$

where $\mathcal{M}$ is the molar mass (kg mol^{-1}), g the acceleration due to gravity (9.8 m s^{-2}), and R the gas constant. If the air temperature at sea level near the equator is 38°C (~100°F), calculate the air temperature at the summit of Mount Kilimanjaro, 5.9 km above sea level. (For further discussion of this problem, see L. K. Nash, *J. Chem. Educ.* 61:23, 1984.)

46. Calculate the entropy change that results from mixing 54.0 g water at 273 K with 27.0 g water at 373 K in a vessel whose walls are perfectly insulated from the surroundings. Consider the specific heat of water to be constant over the temperature range from 273 to 373 K and to have the value 4.18 J K^{-1} g^{-1}.

47. Problem 20 asked for the entropy change when a piece of iron is cooled by immersion in a reservoir of water at 0°C.
(a) Repeat Problem 20(b), supposing that the iron is cooled to 50°C in a large water reservoir held at that temperature before being placed in the 0°C reservoir.
(b) Repeat the calculation supposing that four water reservoirs at 75°C, 50°C, 25°C, and 0°C are used.
(c) As more reservoirs are used, what happens to ΔS for the iron, for the water, and for the universe? How would you attempt to conduct a reversible cooling of the iron?

48. Problem 42 in Chapter 9 described an optical atomic trap. In one experiment, a gas of 500 sodium atoms is confined in a volume of 1000 μm^3. The temperature of the system is

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

0.00024 K. Compute the probability that, by chance, these 500 slowly moving sodium atoms will all congregate in the left half of the available volume. Express your answer in scientific notation.

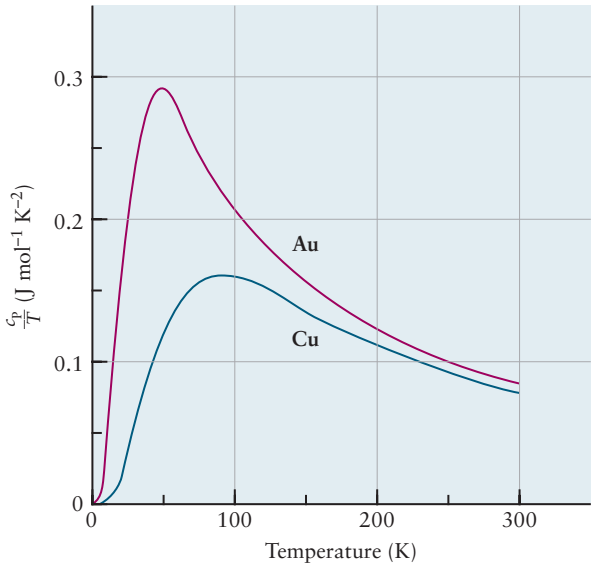
* 49. Suppose we have several different ideal gases, $i = 1, 2, 3, \ldots, N$, each occupying its own volume V_i, all at the same pressure and temperature. The boundaries between the volumes are removed so that the gases mix at constant temperature in the total volume $V = \Sigma_i V_i$.

(a) Using the microscopic interpretation of entropy, show that

$$\Delta S = -nR\sum\nolimits_i X_i \ln X_i$$

for this process, where n is the total number of moles of gas and X_i is the mole fraction of gas i.

(b) Calculate the entropy change when 50 g each of $O_2(g)$, $N_2(g)$, and $Ar(g)$ are mixed at 1 atm and 0°C.



(c) Using Table 9.1, calculate the entropy change when 100 L of air (assumed to be a mixture of ideal gases) at 1 atm and 25°C is separated into its component gases at the same pressure and temperature.

* 50. The N_2O molecule has the structure N—N—O. In an ordered crystal of N_2O, the molecules are lined up in a regular fashion, with the orientation of each determined by its position in the crystal. In a random crystal (formed on rapid freezing), each molecule has two equally likely orientations.

(a) Calculate the number of microstates available to a random crystal of N_A (Avogadro's number) of molecules.

(b) Calculate the entropy change when 1.00 mol of a random crystal is converted to an ordered crystal.

51. By examining the following graphs, predict which element—copper or gold—has the higher absolute entropy at a temperature of 200 K.

* 52. Consider the process described in Problem 19 in Chapter 12. Use the results from that problem to do the following.

(a) Calculate ΔS for the system, the surroundings, and the universe.

(b) If the absolute entropy per mole of the gas *before* the expansion is 158.2 J K^{-1} mol^{-1}, calculate ΔG_{sys} for the process.

53. Two different crystalline forms of sulfur are the rhombic form and the monoclinic form. At atmospheric pressure, rhombic sulfur undergoes a transition to monoclinic when it is heated above 368.5 K:

$$S(s,\ \text{rhombic}) \longrightarrow S(s,\ \text{monoclinic})$$

(a) What is the sign of the entropy change (ΔS) for this transition?

(b) $|\Delta H|$ for this transition is 400 J mol^{-1}. Calculate ΔS for the transition.

* 54. Use data from Appendix D to estimate the temperature at which $I_2(g)$ and $I_2(s)$ are in equilibrium at a pressure of 1 atm. Can this equilibrium actually be achieved? Refer to Appendix F for data on iodine.

55. The molar enthalpy of fusion of ice at 0°C is 6.02 kJ mol^{-1}; the molar heat capacity of undercooled water is 75.3 J mol^{-1} K^{-1}. (a) One mole of undercooled water at −10°C is induced to crystallize in a heat-insulated vessel. The result is a mixture of ice and water at 0°C. What fraction of this mixture is ice? (b) Calculate ΔS for the system.

56. A certain substance consists of two modifications A and B; $\Delta G°$ for the transition from A to B is positive. The two modifications produce the same vapor. Which has the higher vapor pressure? Which is the more soluble in a solvent common to both?

57. From the values in Appendix D, calculate the values of $\Delta G°$ and $\Delta H°$ for the reaction.

$$3\ Fe_2O_3(s) \longrightarrow 2\ Fe_3O_4(s) + \tfrac{1}{2}\ O_2(g)$$

at 25°C. Which of the two oxides is more stable at 25°C and $P_{O_2} = 1$ atm?

58. The strongest known chemical bond is that in carbon monoxide, CO, with bond enthalpy of 1.05×10^3 kJ mol^{-1}. Furthermore, the entropy increase in a gaseous dissociation of the kind AB $\rightleftarrows$ A + B is about 110 J mol^{-1} K^{-1}. These factors establish a temperature above which there is essentially no chemistry of molecules. Show why this is so, and find the temperature.

59. The ΔG_f° of $Si_3N_4(s)$ is −642.6 kJ mol^{-1}. Use this fact and the data in Appendix D to compute $\Delta G°$ of the reaction.

$$3\ CO_2(g) + Si_3N_4(s) \longrightarrow$$
$$3\ SiO_2(\text{quartz}) + 2\ N_2(g) + 3\ C(s,\ \text{gr})$$

60. The compound $Pt(NH_3)_2I_2$ comes in two forms, the cis and the trans, which differ in their molecular structure. The following data are available:

	ΔH_f° (kJ mol^{-1})	ΔG_f° (kJ mol^{-1})
cis	−286.56	−130.25
trans	−316.94	−161.50

Combine these data with data from Appendix D to compute the standard entropies ($S°$) of both of these compounds at 25°C.

61. (a) Use data from Appendix D to calculate $\Delta H°$ and $\Delta S°$ at 25°C for the reaction

$$2\ CuCl_2(s) \rightleftharpoons 2\ CuCl(s) + Cl_2(g)$$

(b) Calculate ΔG at 590 K, assuming $\Delta H°$ and $\Delta S°$ are independent of temperature.

(c) Careful high-temperature measurements show that when this reaction is performed at 590 K, ΔH_{590} is 158.36 kJ and ΔS_{590} is 177.74 J K^{-1}. Use these facts to compute an improved value of ΔG_{590} for this reaction. Determine the percentage error in ΔG_{590} that comes from using the 298-K values in place of 590-K values in this case.

62. (a) The normal boiling point of carbon tetrachloride (CCl_4) is 76.5°C. A student looks up the standard enthalpies of formation of $CCl_4(\ell)$ and of $CCl_4(g)$ in Appendix D. They are listed as −135.44 and −102.9 kJ mol^{-1}, respectively. By subtracting the first from the second, she computes $\Delta H°$ for the vaporization of CCl_4 to be 32.5 kJ mol^{-1}. But Table 12.2 states that the ΔH_{vap} of CCl_4 is 30.0 kJ mol^{-1}. Explain the discrepancy.

(b) Calculate the molar entropy change of vaporization (ΔS_{vap}) of CCl_4 at 76.5°C.

63. The typical potassium ion concentration in the fluid outside a cell is 0.0050 M, whereas that inside a muscle cell is 0.15 M.

(a) What is the spontaneous direction of motion of ions through the cell wall?

(b) In *active transport,* cells use free energy stored in ATP (see Problem 34) to move ions in the direction opposite their spontaneous direction of flow. Calculate the cost in free energy to move 1.00 mol K^+ through the cell wall by active transport. Assume no change in K^+ concentrations during this process.

CUMULATIVE PROBLEMS

64. When a gas undergoes a reversible adiabatic expansion, its entropy remains constant even though the volume increases. Explain how this can be consistent with the microscopic interpretation of entropy developed in Section 13.2. (*Hint:* Consider what happens to the distribution of velocities in the gas.)

65. The normal boiling point of liquid ammonia is 240 K; the enthalpy of vaporization at that temperature is 23.4 kJ mol^{-1}. The heat capacity of gaseous ammonia at constant pressure is 38 J mol^{-1} K^{-1}.

(a) Calculate q, w, ΔH, and ΔU for the following change in state:

$$2.00\ mol\ NH_3(\ell, 1\ atm, 240\ K) \longrightarrow 2.00\ mol\ NH_3(g, 1\ atm, 298\ K)$$

Assume that the gas behaves ideally and that the volume occupied by the liquid is negligible.

(b) Calculate the entropy of vaporization of NH_3 at 240 K.

Gaseous ammonia, NH_3, and gaseous hydrogen chloride, HCl, react to form solid NH_4Cl, the white "smoke." In the reverse reaction, solid NH_4Cl decomposes when heated to form gaseous NH_3 and HCl.

Every time we carry out a chemical reaction—from fundamental research studies to practical industrial applications—the *yield* of the reaction is extremely important. Did we obtain all the product we could expect? Chapter 2 shows how to calculate the amount of product expected when we start a reaction with particular amounts of the reactants. This calculation assumes that the reaction goes to completion—that is, all of the limiting reagent is consumed. The resulting number, called the theoretical yield, represents the maximum amount of product that could be obtained from that reaction.

In practice, many reactions do not go to completion but rather approach a state or position of **equilibrium.** This equilibrium position, at which the reaction apparently comes to an end, is a mixture of products and unconsumed reactants present in fixed relative amounts. Once equilibrium has been achieved, there is no further net conversion of reactants to products unless the experimental conditions of the reaction (temperature and pressure) are changed. The equilibrium state is characterized by the **equilibrium constant,** which has a unique value for each reaction. Knowing the equilibrium constant and the initial amounts of reactants and products, we can calculate the composition of the equilibrium reaction mixture. Knowing the equilibrium constant and its dependence on experimental conditions, we can manipulate conditions to maximize the practical yield of that reaction. Calculating the equilibrium composition for a particular reaction and its dependence on experimental conditions is therefore a practical skill of enormous importance in chemistry.

In this chapter we define the equilibrium constant, its dependence on conditions, and its role in manipulating the yield of reactions. We illustrate these general principles with applications to reactions in the gas phase and to heterogeneous reactions. Detailed applications to reactions in aqueous solutions and electrochemical reactions are presented in the three following chapters.

The fact that reactions go to the equilibrium position was discovered empirically, and the equilibrium constant was first defined empirically. All the aforementioned applications can be accomplished with empirically determined equilibrium constants. Nonetheless, the empirical approach leaves unanswered several important fundamental questions: Why should the equilibrium state exist? Why does the equilibrium constant take its particular mathematical form? These and related questions are answered by recognizing that the chemical equilibrium position is the *thermodynamic equilibrium state* of the reaction mixture. Once we have made that connection, thermodynamics explains the existence and the mathematical form of the equilibrium constant. Thermodynamics also gives procedures for calculating the value of the equilibrium constant from the thermochemical properties of the pure reactants and products, as well as procedures for predicting its dependence on experimental conditions.

Some instructors prefer to introduce equilibrium from the empirical viewpoint and later use thermodynamics to explain the empirical developments. Others prefer to develop the background of thermodynamics first and then apply it to chemical equilibrium. We have organized this chapter to allow either approach. After an introductory section on the general nature of chemical equilibrium, we define the equilibrium constant empirically in Section 14.2, and then give a thermodynamic description in Section 14.3. Similarly, we discuss the direction of change in chemical reactions empirically in Section 14.6 and give a thermodynamic treatment in Section 14.7. Readers who have studied thermodynamics before starting this chapter should read the sections in the order presented. Readers who have not yet studied thermodynamics should skip over Sections 14.3 and 14.7 and return to them after studying Chapters 12 and 13 on thermodynamics. We provide signposts for both sets of readers at the end of each section.

14.1 THE NATURE OF CHEMICAL EQUILIBRIUM

Approach to Equilibrium

Most chemical reactions are carried out by mixing the selected reactants in a vessel and adjusting T and P until the desired products appear. Once reaction conditions have been identified, the greatest concern is to maximize the yield of the reaction.

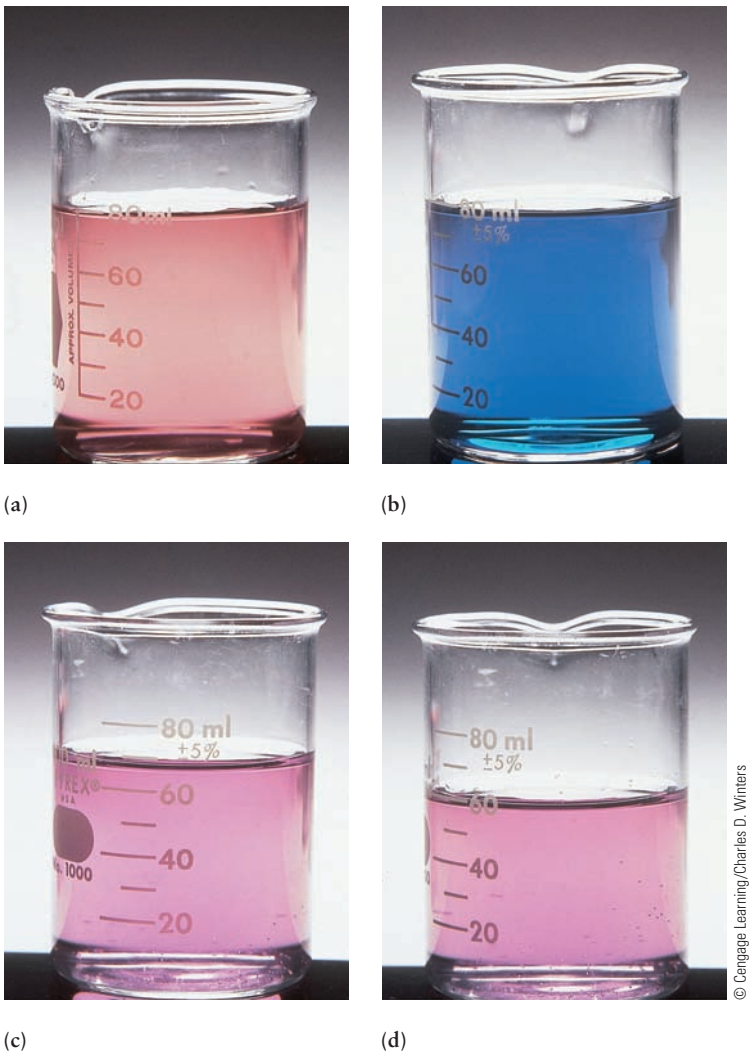

FIGURE 14.1 Chemical equilibrium in the cobalt chloride–HCl system. (a) The pink color is due to the hexaaqua complex ion $[Co(H_2O)_6]^{2+}$. (b) The blue color is due to the tetrachloro complex ion $[CoCl_4]^{2-}$. (c) Adding HCl to the pink solution in (a) converts some of the Co(II) to the tetrachloro complex. The lavender color is produced by the combination of pink hexaaqua species and blue tetrachloro species. (d) Adding water to the blue solution in (b) converts some of the Co(II) to the hexaaqua species. The combination of the two gives the lavender color. The same equilibrium state is reached by running the reaction from the left (c) and from the right (d).

© Cengage Learning/Charles D. Winters

Let's start by observing a particular reaction that illustrates all the aspects of equilibrium we need to understand. We have selected the reactions of cobalt(II) ions in aqueous solutions in which chloride ion is also present because the progress and outcome of the reactions are directly visible. The cobalt(II) ions can form various different complex ions, depending on the amount of chloride present. For example, if $CoCl_2 \cdot 6H_2O$ is dissolved in pure water to the concentration 0.08 M, the resulting solution is pale pink in color due to the hexaaquacobalt(II) complex ion $[Co(H_2O)_6]^{2+}$ (Fig. 14.1a). If $CoCl_2 \cdot 6H_2O$ is dissolved in 10 M HCl to the concentration 0.08 M, the solution is deep blue due to the tetrachlorocobalt(II) complex ion $[CoCl_4]^{2-}$ (see Fig. 14.1b). Solutions containing a mixture of both Co(II) species are lavender, as shown in Figure 14.1c, d.

The hexaaqua complex can be converted into the tetrachloro complex by reaction with chloride ion:

$$\underset{\text{A}}{[Co(H_2O)_6]^{2+}} + 4\ \underset{\text{B}}{Cl^-} \rightleftharpoons \underset{\text{C}}{[CoCl_4]^{2-}} + 6\ \underset{\text{D}}{H_2O}$$

If we add concentrated HCl (reactant B, on the left side of the equation) to the pink solution in Figure 14.1a until the Co(II) concentration is 0.044 M and the HCl concentration is 5.5 M, the result is a lavender-colored solution, *a sample of which* is shown in Figure 14.1c. Optical absorption spectroscopy measurements to be described in Chapter 20 confirm the presence of both Co(II) species in the solution in Figure 14.1c. Ninety-eight percent of the Co is found in the pink hexaaqua com-

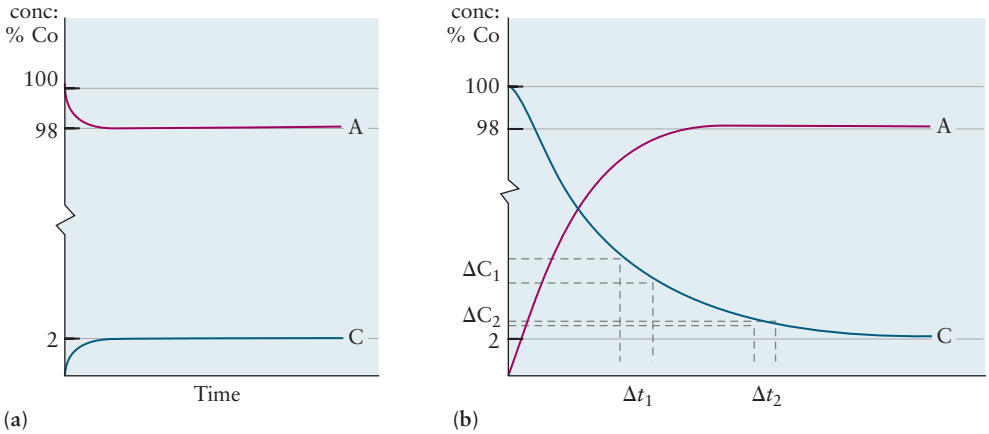

FIGURE 14.2 Sketch of the change with time of the concentrations of products and reactants in the spontaneous reactions illustrated in Figure 14.1. For ease of display, concentrations are expressed as percent of the total Co(II) present in each species. (a) Partial conversion of pink hexaaqua complex A into blue tetrachloro complex C. (b) Partial conversion of blue tetrachloro complex C into pink hexaaqua complex A. After changes in the slope of each species, concentrations become imperceptibly small, and we say the reaction has arrived at chemical equilibrium.

plex, and the remaining two percent is in the blue tetrachloro complex.[1] If the lavender solution is allowed to stand at constant temperature for several hours and the measurements repeated, the results are the same.

The reaction can also be carried out from "right to left" as written. If we add pure water (product D, on the right side of the equation) to the blue solution in Figure 14.1b until the cobalt concentration is 0.044 M and the HCl concentration is 5.5 M, the result is a lavender-colored solution, *a sample of which* is shown in Figure 14.1d. Just as we saw after running the reaction "left to right," optical absorption spectroscopy confirms that 98% of the Co(II) is present in the pink hexaaqua complex and 2% is present in the blue tetrachloro complex. Again, we find no further change in composition of the mixture, even after a long wait.

These data show that the reaction has not gone to completion but has apparently halted at an intermediate state containing products as well as unconsumed reactants. Moreover, the same final state can be achieved from either direction. This result is typical of most chemical reactions, even though it is not generally as visually apparent as here.

The questions raised in the first paragraph require quantitative investigations of the reaction mixture, which we carry out as follows. In the first experiment, we start the reaction by mixing initial concentrations of A and B, denoted as $[A]_0$ and $[B]_0$. As the reaction proceeds, we periodically sample the reaction mixture. For each sample, we measure the concentration of A, B, and C and plot concentration of each species versus time. The results of the first experiment are represented schematically in Figure 14.2a, which shows the consumption of A and the production of C. Similarly, we start the second experiment with the initial concentration $[C]_0$, and add water. The results are represented schematically in Figure 14.2b, which shows the consumption of C and the production of A.

As the reaction proceeds, we see that the concentration of each species changes progressively more slowly. This fact is indicated by the decreasing values of the slope [$m = \Delta(\text{conc.})/\Delta t$] sketched on the concentration curves during progressively later time intervals. Eventually, the slopes become close enough to zero to show that the concentration of each species has become constant in time. When this con-

[1]It may appear surprising to find such imbalance in the concentration of the Co(II) species when the color intensities of the pink and lavender solutions in Figure 14.1a and Figure 14.1c appear quite similar. This difference is explained by the fact that the blue tetrachloro complex absorbs light much more efficiently than the pink hexaaqua complex.

dition has been achieved, we say the reaction is at *chemical equilibrium*, and the reaction mixture is at the *equilibrium composition*.[2] At later times, there is no further change in composition of the reaction mixture; the concentration of each of the species X = A, B, C remains at its equilibrium value denoted by $[X]_{eq}$.

Characteristics of the Equilibrium State

We can gain insight into the equilibrium state by comparing chemical reactions to the familiar phase equilibrium between liquid water and water vapor (see Section 10.4 and Figure 10.16). Let's represent the transfer of water molecules in this phase equilibrium as a chemical equation:

$$H_2O(\ell) \rightleftharpoons H_2O(g)$$

The double arrows ($\rightleftharpoons$) emphasize the dynamic nature of phase equilibrium: Liquid water evaporates to form water vapor, and at the same time vapor condenses to give liquid. An analogous dynamic description applies to a chemical equilibrium, in which bonds are broken or formed as atoms move back and forth between reactant and product molecules. When the initial concentrations of the reactants are high, collisions between their molecules cause product molecules to form. Once the concentrations of the products have increased sufficiently, the reverse reaction (forming "reactants" from "products") begins to occur. As the equilibrium state is approached, the forward and backward rates of reaction become equal and there is no further net change in reactant or product concentrations. Just as the equilibrium between liquid water and water vapor is a dynamic process on the molecular scale, with evaporation and condensation taking place simultaneously, the chemical equilibrium between reactants and products also occurs through the continuous formation of molecules of product from reactant molecules and their reaction back into reactant molecules with equal rates. Chemical equilibrium is not a static condition, although macroscopic properties such as concentrations do stop changing when equilibrium is attained. *Chemical equilibrium is the consequence of a dynamic balance between forward and backward reactions.*

The experimental results shown in Figures 14.1 and 14.2 demonstrate that the same equilibrium state is reached whether one starts with the reactants or with the products. This fact can be used to test whether a system is truly in equilibrium or whether the reaction is just so slow that changes in concentration are unmeasurably small, even though the system is far from equilibrium. If the same state is reached starting from either reactants or products, that state is a true equilibrium state.

Equilibrium states have four fundamental characteristics:

1. They display no macroscopic evidence of change.
2. They are reached through spontaneous (in the sense of Chapter 13) processes.
3. They show a dynamic balance of forward and reverse processes.
4. They are the same regardless of direction of approach.

We frequently also encounter so-called *steady states* in which the macroscopic concentrations of species are not changing with time, even though the system is not at equilibrium. Steady states are maintained not by a dynamic balance between forward and reverse processes, but rather by the competition between a process that supplies the species to the system and a process that removes the species from the system. Many chemical reactions occur in living systems in steady states and do not represent an equilibrium between reactants and products. You must be certain that a reaction is at equilibrium and not in steady state before applying the methods of this chapter to explain the relative concentrations of reactants and products.

[2]You must exercise judgment in deciding when the slope is "sufficiently close to zero" and the concentrations are "effectively constant." There is no one instant at which equilibrium is achieved.

14.2 THE EMPIRICAL LAW OF MASS ACTION

Extensive studies of the type summarized in Figure 14.2 for broad classes of reactions represented generally as

$$aA + bB \rightleftharpoons cC + dD$$

have demonstrated a most remarkable result. No matter what initial concentrations of reactants are selected at the beginning of the experiment, the value of the ratio

$$\frac{[C]_{eq}^{c}[D]_{eq}^{d}}{[A]_{eq}^{a}[B]_{eq}^{b}}$$

measured *at equilibrium* is always the same. Even if the experiment is started with an arbitrary initial mixture of reactants and products, the reaction will consume some species and produce others until it achieves this same value of this ratio at equilibrium. This ratio is called the **empirical equilibrium constant** for the reaction and denoted as K_C. The results of these studies are summarized in the following equation called the **law of mass action,** first stated in approximate form in 1864 by two Norwegians, C. M. Guldberg (a mathematician) and his brother-in-law P. Waage (a chemist):

$$\frac{[C]_{eq}^{c}[D]_{eq}^{d}}{[A]_{eq}^{a}[B]_{eq}^{b}} = K_C \qquad \textbf{[14.1a]}$$

The subscript C denotes that the reaction is carried out in solution and that the empirical equilibrium constant K_C is evaluated by directly measuring the concentration of each species in the equilibrium state of the reaction. In general, K_C has dimensions $(\text{concentration})^{c+d-a-b}$; it will be dimensionless only for those reactions for which $a + b = c + d$.

Similar results have been obtained for reactions carried out in the gas phase, where the amount of each reactant and product in the reaction mixture is measured by its partial pressure P_X. For gas-phase reactions, the empirical law of mass action takes the form

$$\frac{(P_C)_{eq}^{c}(P_D)_{eq}^{d}}{(P_A)_{eq}^{a}(P_B)_{eq}^{b}} = K_P \qquad \textbf{[14.1b]}$$

In general, K_P has dimensions $(\text{pressure})^{c+d-a-b}$; it will be dimensionless only for those reactions for which $a + b = c + d$.

The significance of the empirical law of mass action is twofold. First, the numerical value of K_C or K_P is an inherent property of the chemical reaction itself and does not depend on the specific initial concentrations of reactants and products selected. Second, the magnitude of K_P or K_C gives direct information about the nature of the equilibrium state or position of the reaction. If the equilibrium constant is very large, then at equilibrium the concentration or partial pressures of products are large compared with those of the reactants. In this case, stoichiometry can be used to estimate the number of moles or the masses of product formed because the reaction is near completion. If the equilibrium constant is very small, the concentration or partial pressures of reactants are large compared with those for products, and the extent of reaction is very limited. If the equilibrium constant has a value close to 1, both reactants and products are present in significant proportions at equilibrium.

The law of mass action is the basis for equilibrium calculations, which pervade the science of chemistry. All follow the same general pattern: Suppose we know the numerical value of K_C or K_P for a reaction of interest, and suppose we run an experiment by mixing selected initial concentrations of reactants. We can then use Equation 14.1 to calculate the concentration of the products and reactants at equi-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

librium, without doing the laborious measurements described in Figure 14.2. In this and succeeding chapters in Unit 4, we demonstrate these calculations for reactions in the gas phase, for acid–base reactions involving ionic species in aqueous solutions, and for heterogeneous reactions occurring at the interface between different states of matter. In preparation for these calculations, we now show how to write the empirical law of mass action for these classes of reactions.

Law of Mass Action for Gas-Phase Reactions

Many reactions are conveniently carried out entirely in the gas phase. Molecules in the gas phase are highly mobile, and the collisions necessary for chemical reactions occur frequently. Two examples are the key steps in the production of hydrogen from the methane in natural gas. The first is the **reforming reaction:**

$$CH_4(g) + H_2O(g) \longrightarrow CO(g) + 3H_2(g)$$

The second step is called the **water gas shift reaction:**

$$CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$$

This process is currently the main industrial method for the preparation of hydrogen. Its success relies critically on application of the equilibrium principles developed in this chapter.

To write the mass action law, a first glance at Equation 14.1b suggests we need only examine the balanced equation for the reaction and insert the partial pressure of each reactant and product into Equation 14.1b and raise it to a power equivalent to its stoichiometric coefficient in the balanced equation. A deeper study of equilibrium shows that instead of inserting just the partial pressure for each reactant or product, we must insert the value of the partial pressure *relative to* a specified reference pressure P_{ref}. The result is the following expression, denoted by K with no subscript

$$\frac{(P_C/P_{ref})^c (P_D/P_{ref})^d}{(P_A/P_{ref})^a (P_B/P_{ref})^b} = K$$

Note that K is dimensionless. Collecting the terms involving P_{ref} on the right side of the equation gives

$$\frac{P_C^c P_D^d}{P_A^a P_B^b} = K(P_{ref})^{(c+d-a-b)}$$

which must be equal to K_P. It is customary to choose P_{ref} as atmospheric pressure, which can be expressed as $P_{ref} = 1$ atm, $P_{ref} = 760$ torr, or $P_{ref} = 101{,}325$ Pa. If all pressures are expressed in atmospheres, then $P_{ref} = 1$ atm, and the right side shows that K_P has the same *numerical value* as the dimensionless quantity K, with P_{ref} factors serving only to make the equation dimensionally correct. If some other unit is chosen for pressures, the P_{ref} factors no longer have a numerical value of unity and must be inserted explicitly into the equilibrium expression.

The dimensionless quantity K is the **thermodynamic equilibrium constant,** which can be calculated from tabulated data on the products and reactants, even if the empirical equilibrium constant defined in Equation 14.1b is not known (see Section 14.3). Therefore, K is the preferred tool for analyzing reaction equilibria in general. The informal procedure by which we replaced K_P with K is made rigorous by the thermodynamic treatment of equilibrium in Section 14.3. Meantime, we can freely use the result in advance of formal justification.

The convention we follow in this book is always to describe chemical equilibrium in terms of the thermodynamic equilibrium constant K, even when analyzing reactions empirically. We express all partial pressures in units of atmospheres, and choose $P_{ref} = 1$ atm for gas phase reactions. This choice allows us to use the dimensionless thermodynamic equilibrium constant because P_{ref} raised to any power

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

equals one. The P_{ref} factors will not be explicitly included because their value is unity with these choices of pressure unit and reference pressure. Thus, we write the mass action law for a general reaction involving ideal gases as

$$\frac{(P_C)^c(P_D)^d}{(P_A)^a(P_B)^b} = K \qquad [14.2a]$$

with K dimensionless. The following example illustrates these practices.

EXAMPLE 14.1

Write equilibrium expressions for the following gas-phase chemical equilibria.

(a) $2\ NOCl(g) \rightleftharpoons 2\ NO(g) + Cl_2(g)$

(b) $CO(g) + \frac{1}{2}O_2(g) \rightleftharpoons CO_2(g)$

Solution

(a)
$$\frac{(P_{NO})^2(P_{Cl_2})}{(P_{NOCl})^2} = K$$

The powers of 2 come from the factors of 2 in the balanced equation.

(b)
$$\frac{(P_{CO_2})}{(P_{CO})(P_{O_2})^{1/2}} = K$$

Fractional powers appear in the equilibrium expression whenever they are present in the balanced equation.

Related Problems: 1, 2, 3, 4

Law of Mass Action for Reactions in Solution

A great many reactions are carried out in a convenient solvent for reactants and products. Dissolved reactants can be rapidly mixed, and the reaction process is easily handled. Water is a specially favored solvent because its polar structure allows a broad range of polar and ionic species to be dissolved. Water itself is partially ionized in solution, liberating H^+ and OH^- ions that can participate in reactions with the dissolved species. This leads to the important subject of acid–base equilibria in aqueous solutions (see Chapter 15), which is based on the equilibrium principles developed in this chapter. We limit the discussion in this subsection to cases in which the solvent does not participate in the reaction.

The procedure for reactions in solution is the same as that for gas-phase reactions. A deeper study of equilibrium shows that we must insert the value of concentration *relative to* a specified reference concentration c_{ref} in Equation 14.1a. The result is the following expression, denoted by K with no subscript

$$\frac{([C]/c_{ref})^c([D]/c_{ref})^d}{([A]/c_{ref})^a([B]/c_{ref})^b} = K$$

The square bracket [X] represents the concentration of species X in units of mol L^{-1}. If all factors containing c_{ref} are collected on the right side and the reference state for each reactant and product is defined to be an ideal solution with a concentration c_{ref} = 1 M, the dimensionless thermodynamic equilibrium constant K is numerically equal to K_C.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Just as with gaseous reactions, the convention we follow in this book is to describe solution equilibria in terms of the thermodynamic equilibrium constant K. Thus, we express solution concentrations in units of mol L^{-1} with the reference state as $c_{ref} = 1$ M, and we state values of K without dimensions. Thus, the mass action law for solution reactions becomes

$$\frac{[C]^c[D]^d}{[A]^c[B]^b} = K \qquad [14.2b]$$

The following example illustrates these practices.

EXAMPLE 14.2

Household laundry bleach is a solution of sodium hypochlorite (NaOCl) prepared by adding gaseous Cl_2 to a solution of sodium hydroxide:

$$Cl_2(aq) + 2\ OH^-(aq) \rightleftharpoons ClO^-(aq) + Cl^-(aq) + H_2O(\ell)$$

The active bleaching agent is the hypochlorite ion, which can decompose to chloride and chlorate ions in a side reaction that competes with bleaching:

$$3\ ClO^-(aq) \rightleftharpoons 2\ Cl^-(aq) + ClO_3^-(aq)$$

Write the equilibrium expression for the decomposition reaction.

Solution

$$\frac{[Cl^-]^2[ClO_3^-]}{[ClO^-]^3} = K$$

The exponents come from the coefficients in the balanced chemical equation.

Related Problems: 7, 8

Law of Mass Action for Reactions Involving Pure Substances and Multiple Phases

A variety of equilibria occur in heterogeneous systems that involve pure solids and liquids as well as gases and dissolved species. Molecular species cross the interfaces between phases in order to participate in reactions. A whole class of examples (Chapter 16) is based on the dissolution of slightly soluble salts, where the dissolved ions are in equilibrium with the pure solid. Another class includes the reaction of pure metals with acids to produce hydrogen gas:

$$Zn(s) + 2\ H_3O^+(aq) \rightleftharpoons Zn^{2+}(aq) + H_2(g) + 2\ H_2O(\ell)$$

Yet another example shows how iron sulfide residues from mining operations introduce iron and sulfur as pollutants in water streams:

$$4\ FeS_2(s) + 15\ O_2(g) + 6\ H_2O(\ell) \rightleftharpoons 4\ Fe(OH)^{2+}(aq) + 8\ HSO_4^-(aq)$$

Reactions in aqueous solution sometimes involve water as a direct participant. In addition to familiar aqueous acid–base chemistry, many organic reactions fall into this class. One example is the hydrolysis of ethyl acetate to produce acetic acid and ethanol:

$$CH_3COOC_2H_5(aq) + H_2O(\ell) \rightleftharpoons CH_3COOH(aq) + C_2H_5OH(aq)$$

Several examples illustrate the procedures for writing the mass action law for heterogeneous reactions and for reactions involving pure solids or liquids.

1. Recall the phase equilibrium between liquid water and water vapor from Section 10.4:

$$H_2O(\ell) \rightleftharpoons H_2O(g) \qquad P_{H_2O} = K$$

Experiments show that as long as *some* liquid water is in the container, the pressure of water vapor at 25°C is 0.03126 atm. The position of this equilibrium is not affected by the amount of liquid water present, and therefore liquid water should not appear in the mass action law. Recall that for a gas or solute, a ratio of pressures or concentrations appears in the law of mass action. This ratio is equal to 1 when the gas or solute is in its reference state (1 atm or 1 M). For a pure liquid appearing in an equilibrium chemical equation, the convention is to take that pure liquid as the reference state, so the liquid water contributes only a factor of 1 to the equilibrium expression and can thus be omitted. We postpone justification of this rule to Section 14.3.

2. An analogous situation occurs in the equilibrium between solid iodine and iodine dissolved in aqueous solution:

$$I_2(s) \rightleftharpoons I_2(aq) \qquad [I_2] = K$$

Experiment shows that the position of the equilibrium (given by the concentration of I_2 dissolved at a given temperature) is independent of the amount of solid present, as long as there is some. The pure solid iodine does not appear in the mass action law.

3. Another example involves the decomposition of calcium carbonate:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g) \qquad P_{CO_2} = K$$

If calcium carbonate is heated, it decomposes into calcium oxide (lime) and carbon dioxide; the reverse reaction is favored at sufficiently high pressures of carbon dioxide. The equilibrium can be studied experimentally, and it is found that at any given temperature the pressure of $CO_2(g)$ is constant, independent of the amounts of $CaCO_3(s)$ and $CaO(s)$, as long as some of each is present (Fig. 14.3). The two pure solids do not appear in the mass action law, which reduces to the partial pressure of CO_2.

The general procedure for writing the mass action law for these more complex reactions is:

1. Gases enter the equilibrium expression as partial pressures, measured in atmospheres.
2. Dissolved species enter as concentrations, in moles per liter.
3. Pure solids and pure liquids do not appear in equilibrium expressions; neither does a solvent that participates in a chemical reaction, provided the solution is dilute.

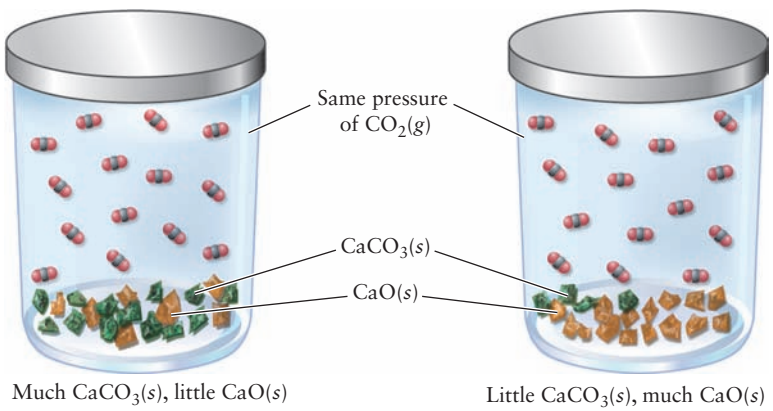

FIGURE 14.3 As long as both $CaO(s)$ and $CaCO_3(s)$ are present at equilibrium in a closed container, the partial pressure of $CO_2(g)$ at a fixed temperature does not depend on the amounts of the two solids present.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Partial pressures and concentrations of products appear in the numerator, and those of reactants in the denominator; each is raised to a power equal to its coefficient in the balanced chemical equation for the reaction.

This procedure gives the dimensionless thermodynamic equilibrium constant K and the resulting expressions will be justified by the thermodynamic treatment of equilibrium in Section 14.3.

The following example illustrates these practices.

EXAMPLE 14.3

Hypochlorous acid (HOCl) is produced by bubbling chlorine through an agitated suspension of mercury(II) oxide in water. The chemical equation for this process is

$$2\ Cl_2(g) + 2\ HgO(s) + H_2O(\ell) \rightleftharpoons HgO \cdot HgCl_2(s) + 2\ HOCl(aq)$$

Write the equilibrium expression for this reaction.

Solution

$$\frac{[HOCl]^2}{P_{Cl_2}^2} = K$$

The HgO and $HgO{\cdot}HgCl_2$ do not appear because they are solids, and water does not appear because it is a pure liquid. Chlorine, as a gas, enters as its partial pressure in atmospheres. The HOCl appears as its concentration, in moles per liter. Both the concentration of HOCl and the partial pressure of Cl_2 are raised to the second power because their coefficients in the balanced chemical equation are 2.

Related Problems: 9, 10, 11, 12

The preceding discussion has specified the procedures for setting up the mass action law for broad classes of chemical reactions and are ready to be used in equilibrium calculations.

The empirical procedures leave unanswered numerous fundamental questions about chemical equilibrium. Why should the law of mass action exist in the first place, and why should it take the particular mathematical form shown here? Why should the equilibrium constant take a unique value for each individual chemical reaction? What factors determine that value? Why does the value of the equilibrium constant change slightly when studied over broad ranges of concentration? Why should the equilibrium constant depend on temperature? Is there a quantitative explanation for the temperature dependence?

All these questions are answered by the thermodynamic description of the equilibrium constant, provided in the next section. Readers who have already studied thermodynamics should continue to Section 14.3.

Readers who have not yet studied thermodynamics should go to Sections 14.4 and 14.5, which give detailed applications of equilibrium calculations based on the mass action law procedures just described. Sections 14.4 and 14.5 do not require background in thermodynamics.

14.3 THERMODYNAMIC DESCRIPTION OF THE EQUILIBRIUM STATE

Thermodynamics views a chemical reaction as a process in which atoms "flow" from reactants to products. If the reaction is spontaneous and is carried out at constant T and P, thermodynamics requires that $\Delta G < 0$ for the process (see Sec-

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tion 13.7). Consequently, G always *decreases* during a spontaneous chemical reaction. When a chemical reaction has reached equilibrium, $\Delta G = 0$; that is, there is no further tendency for the reaction to occur in either the forward or the reverse direction. We will use the condition $\Delta G = 0$ in the following three subsections to develop the mass action law and the thermodynamic equilibrium constant for gaseous, solution, and heterogeneous reactions.

Reactions among Ideal Gases

As background, it is necessary to know how the Gibbs free energy changes with pressure at constant temperature, because in chemical equilibria, the partial pressures of gases can differ from 1 atm.

Dependence of Gibbs Free Energy of an Ideal Gas on Pressure

If the pressure of an ideal gas is changed from P_1 to P_2 with the temperature held constant, the free energy change is

$$\Delta G = \Delta(H - TS) = \Delta H - T\Delta S = -T\Delta S$$

The last equality is true because $\Delta H = 0$ when the pressure of an ideal gas is changed at constant temperature. The entropy change for an ideal gas in an isothermal process was calculated in Section 13.5:

$$\Delta S = nR \ln\left(\frac{V_2}{V_1}\right) = nR \ln\left(\frac{P_1}{P_2}\right) = -nR \ln\left(\frac{P_2}{P_1}\right)$$

so

$$\Delta G = nRT \ln\left(\frac{P_2}{P_1}\right) \qquad \textbf{[14.3a]}$$

Let us choose the value of P_1 to be 1 atm, which has already been defined as the standard state of gaseous substances for measurements both of enthalpy of formation (see Section 12.6) and Gibbs free energy of formation (see Section 13.7). Then, Equation 14.3a relates the Gibbs free energy of the gas at any pressure P_2 to its value at 1 atm. If we call 1 atm the *reference state* for the gas, then the change in Gibbs free energy in taking the gas from the reference state to any pressure P is given by

$$\Delta G = nRT \ln\left(\frac{P}{P_{\text{ref}}}\right) = nRT \ln P \qquad \textbf{[14.3b]}$$

Equation 14.3b is a shorthand version that can be used only when the pressure P is expressed in atm. The presence of P_{ref} in the denominator makes the argument of the natural logarithm function dimensionless. Choosing $P_{\text{ref}} = 1$ atm gives P_{ref} the numerical value 1, which for convenience we do not write explicitly. Nonetheless, you should always remember this (invisible) P_{ref} is required to make the equation dimensionally correct when the general pressure P in the equation is expressed in atm. If some unit of pressure other than atm is selected, P_{ref} no longer has value 1 and the P_{ref} selected must be carried explicitly in the equations.

The Equilibrium Expression for Reactions in the Gas Phase

Consider now a mixture of gases that react chemically, such as the NO, N_2O, and NO_2 given in Example 13.10:

$$3\ NO(g) \rightleftharpoons N_2O(g) + NO_2(g)$$

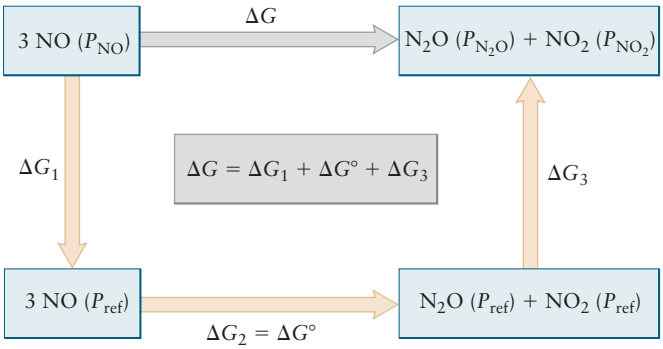

FIGURE 14.4 A three-step process (red arrows) to calculate ΔG of a reaction (blue arrow) for which reactants and products are not in their standard states of 1 atm. This figure suggests that the reaction is run at pressure higher than 1 atm, which is true for most industrial processes. But, the procedure is valid at any pressure.

If all of the partial pressures are 1 atm, then ΔG for this reaction is just ΔG° at 25°C. If the pressures differ from 1 atm, ΔG must be calculated from a three-step process (Fig. 14.4). In step 1 the partial pressure of the reactant (in this case, 3 mol of NO) is changed from its initial value, P_{NO}, to the reference pressure $P_{ref} = 1$ atm:

$$\Delta G_1 = 3RT \ln\left(\frac{P_{ref}}{P_{NO}}\right) = RT \ln\left(\frac{P_{ref}}{P_{NO}}\right)^3$$

In step 2 the reaction is carried out with all reactants and products at partial pressures of $P_{ref} = 1$ atm:

$$\Delta G_2 = \Delta G^\circ$$

In step 3 the partial pressures of the products (in this case, 1 mol of N_2O and 1 mol of NO_2) are changed from $P_{ref} = 1$ atm to P_{N_2O} and P_{NO_2}:

$$\Delta G_3 = RT \ln\left(\frac{P_{N_2O}}{P_{ref}}\right) + RT \ln\left(\frac{P_{NO_2}}{P_{ref}}\right) = RT \ln\left[\left(\frac{P_{N_2O}}{P_{ref}}\right)\left(\frac{P_{NO_2}}{P_{ref}}\right)\right]$$

The overall Gibbs free energy change ΔG for the reaction is the sum of the free energy changes for the three steps in the path:

$$\Delta G = \Delta G_1 + \Delta G_2 + \Delta G_3$$
$$= \Delta G^\circ + RT \ln\left[\frac{(P_{N_2O}/P_{ref})(P_{NO_2}/P_{ref})}{(P_{NO}/P_{ref})^3}\right]$$

When a chemical reaction has reached equilibrium, $\Delta G = 0$. Under these conditions the preceding equation becomes

$$-\Delta G^\circ = RT \ln\left[\frac{(P_{N_2O}/P_{ref})(P_{NO_2}/P_{ref})}{(P_{NO}/P_{ref})^3}\right]$$

Because ΔG° depends only on temperature, the quantity $\Delta G^\circ/RT$ must be a constant at each value of T. Therefore, in the last equation, the ratio of partial pressures inside the natural logarithm function must also be constant *at equilibrium* at each value of T. Consequently, this ratio of partial pressures is denoted by $K(T)$ and is called the *thermodynamic equilibrium constant* for the reaction. Finally, we have

$$-\Delta G^\circ = RT \ln K(T) \qquad [14.4]$$

For the general reaction

$$aA + bB \longrightarrow cC + dD$$

the result, obtained in the same way, is

$$-\Delta G^\circ = RT \ln\left[\frac{(P_C/P_{ref})^c (P_D/P_{ref})^d}{(P_A/P_{ref})^a (P_B/P_{ref})^b}\right] = RT \ln K(T) \qquad (\text{at equilibrium})$$

The thermodynamic equilibrium constant for reactions involving ideal gases,

$$\left[\frac{(P_C/P_{ref})^c(P_D/P_{ref})^d}{(P_A/P_{ref})^a(P_B/P_{ref})^b}\right] = K$$

has the same form as the empirical law of mass action with K_P for gaseous reactions introduced in Section 14.2. The thermodynamic expression provides deeper understanding of that empirical result in three important ways. First, the law of mass action is seen to be a consequence of the reaction system being in thermodynamic equilibrium. Second, the thermodynamic equilibrium constant can be calculated from $\Delta G°$ (that is, from $\Delta H°$ and $\Delta S°$), so the *extent* of any equilibrium chemical reaction can be deduced from calorimetric data alone. Third, unlike K_P, the thermodynamic equilibrium constant K is always a dimensionless quantity because the pressure of a reactant or product always appears as a ratio to the reference pressure P_{ref}. The algebraic rearrangements leading to Equation 14.2a have already shown that K is numerically equal to K_P if we express all partial pressures in units of atm and select the reference state to be $P_{ref} = 1$ atm. Other choices of pressure units or reference states require the P_{ref} factors to be carried explicitly.

The convention we follow in this book, already stated in Section 14.2, is to describe chemical equilibrium in terms of the thermodynamic equilibrium constant K. The mass action law for a general reaction involving ideal gases is written as

$$\frac{(P_C)^c(P_D)^d}{(P_A)^a(P_B)^b} = K$$

with K dimensionless. The value of K can be calculated from Equation 14.4 using tables of data in Appendix D. The following example illustrates these practices.

EXAMPLE 14.4

The $\Delta G°$ of the chemical reaction

$$3\ NO(g) \longrightarrow N_2O(g) + NO_2(g)$$

was calculated in Example 13.10. Now calculate the equilibrium constant of this reaction at 25°C.

Solution

The standard free energy change for the conversion of 3 mol of NO to 1 mol of N_2O and 1 mol of NO_2 was found to be −104.18 kJ. To keep the units of the calculation correct, the $\Delta G°$ is rewritten as $-104.18\ kJ\ mol^{-1}$, where "per mole" signifies "per mole of the reaction as it is written," that is, per 3 mol of NO, 1 mol of N_2O, and 1 mol of NO_2, the number of moles in the balanced equation. Substitution gives

$$\ln K = \frac{-\Delta G°}{RT} = \frac{-(-104{,}180\ J\ mol^{-1})}{(8.315\ J\ K^{-1}mol^{-1})(298.15\ K)} = 42.03$$

$$K = e^{42.03} = 1.8 \times 10^{18}$$

Related Problems: 13, 14

The conversion of $NO(g)$ to $N_2O(g)$ plus $NO_2(g)$ is spontaneous under standard conditions. The forward reaction under these conditions is scarcely observed because its rate is so slow. Nonetheless, its equilibrium constant can be calculated! Such calculations often have enormous impact in evaluating proposed solutions to practical problems. For example, the calculation shows that this reaction could be used to reduce the amount of NO in cooled exhaust gases from

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

automobiles. The fundamental reaction tendency is there, but successful application requires finding a route to increasing the reaction rate at standard conditions. Had the equilibrium constant calculated from thermodynamics been small, this proposed application would be doomed at the outset and investment in it would not be justified.

Reactions in Ideal Solutions

The thermodynamic description of reactions in solution parallels that for ideal gas reactions. Although the result is not derived here, the Gibbs free energy change for n mol of a solute, as an ideal (dilute) solution changes in concentration from c_1 to c_2 mol L^{-1}, is

$$\Delta G = nRT \ln\left(\frac{c_2}{c_1}\right) \qquad [14.5a]$$

If the reference state for the solute is defined to be an ideal solution with a concentration $c_{ref} = 1$ M, the change in Gibbs free energy for taking the solution from the reference state to the concentration c is given by

$$\Delta G = nRT \ln\left(\frac{c}{c_{ref}}\right) = nRT \ln c \qquad [14.5b]$$

The overall change in Gibbs free energy for a reaction in solution is

$$\Delta G = \Delta G^\circ + RT \ln\left[\frac{([C]/c_{ref})^c([D]/c_{ref})^d}{([A]/c_{ref})^a([B]/c_{ref})^b}\right]$$

where the square bracket [X] represents the concentration of species X in units of mol L^{-1}. When the reaction arrives at equilibrium, $\Delta G = 0$, and the equilibrium constant is given by

$$-\Delta G^\circ = RT \ln K \qquad [14.6]$$

for reactions involving dissolved species.

In this book we describe solution equilibria in terms of the thermodynamic equilibrium constant K rather than the empirical K_C introduced in Section 14.2. Thus, we give solution concentrations in units of mol L^{-1} with the reference state as $c_{ref} = 1$ M, and state values of K as dimensionless quantities. The mass action law for solution reactions becomes

$$\frac{[C]^c[D]^d}{[A]^a[B]^b} = K$$

and is numerically equivalent to K_C. When working with this expression, you must keep in mind the role of the (invisible) c_{ref} factors in making the equation dimensionally correct. This expression is the foundation for the discussions of acid–base equilibria in aqueous solutions in the next chapter.

Solution-phase equilibrium constants can be calculated from tables of standard free energies for solutes in aqueous solution at 25°C (see Appendix D). The procedure is demonstrated by the following example.

EXAMPLE 14.5

Calculate ΔG° and the equilibrium constant at 25°C for the chemical reaction

$$3\ ClO^-(aq) \rightleftharpoons 2\ Cl^-(aq) + ClO_3^-(aq)$$

whose equilibrium expression we developed in Example 14.2.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

We calculate the change in standard Gibbs free energy using the ΔG_f° values for these aqueous ions in their standard states tabulated in Appendix D:

$$\begin{aligned}\Delta G^\circ &= 2\,\Delta G_f^\circ(Cl^-(aq)) + \Delta G_f^\circ(ClO_3^-(aq)) - 3\,\Delta G_f^\circ(ClO^-(aq))\\ &= (2\text{ mol})(-131.23\text{ kJ mol}^{-1}) + (1\text{ mol})(-7.95\text{ kJ mol}^{-1}) -\\ &\quad (3\text{ mol})(-36.8\text{ kJ mol}^{-1})\\ &= -160.01\text{ kJ}\end{aligned}$$

As in Example 14.4, we calculate K by inserting the value for ΔG° into the equation

$$\ln K = \frac{-\Delta G^\circ}{RT} = \frac{-(-160,010\text{ J mol}^{-1})}{(8.315\text{ J K}^{-1}\text{mol}^{-1})(298.15\text{ K})} = 64.54$$

$$K = e^{64.54} = 1.1\times 10^{28}$$

The decomposition of hypochlorite ion in bleach is thus a spontaneous process, with a very large equilibrium constant at 25°C. But, this reaction is very slow at room temperature, so the laundry bleach solution remains stable. If the temperature is raised to about 75°C, the reaction occurs rapidly and the bleach solution decomposes.

Reactions Involving Pure Solids and Liquids and Multiple Phases: The Concept of Activity

The mass action law for homogeneous reactions in ideal gases and ideal solutions is written in Section 14.2 by straightforward inspection of the balanced equation for the reaction under study. If one or more of the reactants or products is a solid or liquid in its pure state, the procedure is less obvious, because "concentration" has no meaning for a pure species. This apparent difficulty is resolved by the concept of **activity,** which is a convenient means for comparing the properties of a substance in a general thermodynamic state with its properties in a specially selected reference state. A full treatment of equilibrium in terms of activity requires thermodynamic results beyond the scope of this book. Here we sketch the essential ideas leading to the more general form of the mass action law and merely state the range of validity of the idealized expressions presented.

The activity concept arises from the dependence of the Gibbs free energy on the pressure of a pure substance or on the composition of a solution, regardless of the phase of the system. The discussion just before Equation 14.3 shows that the change in Gibbs free energy when a gas is taken from a reference state P_{ref} to any pressure P is given by

$$\Delta G = nRT\ln\left(\frac{P}{P_{ref}}\right) = nRT\ln P$$

The last form is used only when pressure P is expressed in atmospheres and P_{ref} = 1 atm. A similar equation can be developed for more complex systems—and keep the same simple mathematical form—if we *define* the activity a by the equation

$$\Delta G = nRT\ln a \qquad [14.7]$$

Of course if a system is already in its reference state, then $\Delta G = 0$ and the activity in this state is 1. The change in Gibbs free energy in taking a system from the reference state to any general thermodynamic state determines the activity a in the general state.

The activity is connected to pressure or to concentration by the **activity coefficient.** The *activity coefficient* γ_i of a nonideal gaseous species at pressure P_i is defined by the equation

$$a_i = \frac{\gamma_i P_i}{P_{ref}} \qquad [14.8a]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The reference state is chosen to be an ideal gas at one atmosphere. Comparing Equations 14.7 and 14.8a with Equation 14.3 shows that γ_i takes the value 1 for ideal gases. The activity of an ideal gas is the ratio of its pressure to the selected reference pressure. If pressures are given in units of atmospheres, then the activity of an ideal gas is numerically equal to its pressure. Similarly, the activity coefficient γ_i for solute i in a solution at concentration c_i is defined by the equation

$$a_i = \frac{\gamma_i c_i}{c_{ref}} \qquad [14.8b]$$

The activity coefficient γ_i equals 1 in the reference state, selected as an ideal solution with convenient concentration. For solute species in the dilute solutions considered in this book, concentration is most conveniently expressed in molarity, and the reference state is selected to be an ideal solution at concentration $c_{ref} = 1$ M.

The reference states for pure solids and liquids are chosen to be those forms stable at 1 atm, just as in the definition of standard states for enthalpy of formation (see Chapter 12) and Gibbs free energy of formation (see Chapter 13). Pure substances in their reference states are assigned activity of value 1.

Once reference states have been defined, the activity coefficients γ_i can be determined from experimental *P-V-T* and calorimetric data by procedures that are not described in this book. Then, Equation 14.7 can be written explicitly in terms of pressure, temperature, and concentrations when needed for specific calculations. In its present version, Equation 14.7 is especially well suited for general discussions, because it summarizes much complicated information about nonideal systems in a simple and compact form.

Starting from Equation 14.7, arguments similar to those preceding Equation 14.4 lead to the thermodynamic equilibrium constant K regardless of the phase of each product or reactant:

$$\frac{a_C^c \cdot a_D^d}{a_A^a \cdot a_B^b} = K \qquad [14.9]$$

Substituting the appropriate ideal expression for the activity of gaseous or dissolved species from Equation 14.8a or 14.8b leads to the forms of the mass action law and the equilibrium constant K already derived earlier in Section 14.3 for reactions in ideal gases or in ideal solutions. We write the mass action law for reactions involving pure solids and liquids and multiple phases by substituting unity for the activity of pure liquids or solids and the appropriate ideal expression for the activity of each gaseous or dissolved species into Equation 14.9. Once a proper reference state and concentration units have been identified for *each* reactant and product, we use tabulated free energies based on these reference states to calculate the equilibrium constant.

The following example illustrates the method.

EXAMPLE 14.6

The compound urea, important in biochemistry, can be prepared in aqueous solution by the following reaction:

$$CO_2(g) + 2\ NH_3(g) \rightleftharpoons CO(NH_2)_2(aq) + H_2O(\ell)$$

(**a**) Write the mass action law for this reaction. (**b**) Calculate $\Delta G°$ for this reaction at 25°C. (**c**) Calculate K for this reaction at 25°C.

Solution

(**a**) In terms of activities for each species, the equilibrium expression is

$$\frac{a_{urea} \cdot a_{H_2O}}{a_{CO_2} \cdot a_{NH_3}^2} = K$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Choose the reference state for the gases to be $P_{ref} = 1$ atm, for the urea to be $c_{ref} = 1$ M, and for water to be the pure liquid with unit activity. Then at low pressures and concentrations, the limiting idealized mass action law is

$$\frac{[\text{urea}]}{P_{CO_2} \cdot P_{NH_3}^2} = K$$

with [urea] in units of mol L^{-1} and the partial pressures in atm. The (invisible) P_{ref} and c_{ref} factors must always be kept in mind, because they make K dimensionless in this expression. This expression can be extended to higher pressures and concentrations, where nonideality becomes important, by inserting the appropriate activity coefficients.

(**b**) The procedure is the same as in Examples 14.4 and 14.5. The ΔG_f° values for gaseous CO_2 and NH_3 and liquid H_2O with the reference states just specified are obtained directly from Appendix D. Because the data for urea in Appendix D are based on a *solid* reference state, we consult an alternate source[3] to obtain $\Delta G_f^\circ(\text{urea}(aq)) = -203.84$ kJ mol^{-1} with the reference state an ideal solution with $c = 1$ M. From these data we obtain

$$\Delta G^\circ = -203.84 - 237.18 + 394.36 + 2(16.48) = -13.70 \text{ kJ mol}^{-1}$$

(**c**) Following the procedure in Example 14.5 we find $K = 251.1$.
This example illustrates a very important point: Before using ΔG_f° values to estimate equilibrium constants, *be certain* you know the reference state for the tabulated values.

Related Problems: 15, 16

Equilibrium expressions written in this way are accurate to about 5% when the pressures of gases do not exceed several atmospheres and the concentrations of solutes do not exceed 0.1 M. These cases cover all the applications discussed in this book, so we do not need correction factors. For concentrated ionic solutions, the corrections can become very large. In accurate studies of solution equilibria, especially in biochemical applications, activities must be used in place of partial pressures or concentrations. You should consult more advanced books when you need these techniques.

14.4 THE LAW OF MASS ACTION FOR RELATED AND SIMULTANEOUS EQUILIBRIA

Each time we write the mass action law, it is based on a specific balanced chemical equation in which the reaction is carried out as written "left to right." Chemical reactions can be carried out in various alternative ways, including "in reverse" and in concert with other reactions. These variations lead to relationships among equilibrium expressions, which are best illustrated in a series of examples.

Relationships among Equilibrium Expressions

(**1**) Suppose a reaction is written in two opposing directions:

$$2\ H_2(g) + O_2(g) \rightleftharpoons 2\ H_2O(g) \qquad \frac{P_{H_2O}^2}{P_{H_2}^2 P_{O_2}} = K_1$$

$$2\ H_2O(g) \rightleftharpoons 2\ H_2(g) + O_2(g) \qquad \frac{P_{H_2}^2 P_{O_2}}{P_{H_2O}^2} = K_2$$

[3]Thermodynamic data for many biological molecules in solution are given in F. H. Carpenter, *J. Am. Chem. Soc.*, *82*, 1120 (1960).

In the first reaction, hydrogen and oxygen combine to form water vapor, whereas in the second, water vapor dissociates into hydrogen and oxygen. The equilibrium constants K_1 and K_2 are clearly the inverse of each other, so their product $K_1K_2 = 1$. This is true quite generally: The equilibrium constant for a reverse reaction is the reciprocal of the equilibrium constant for the corresponding forward reaction.

(2) What happens if a balanced chemical equation is multiplied by a constant? In the preceding example, multiplying the first equation by $\frac{1}{2}$ gives

$$H_2(g) + \tfrac{1}{2}\ O_2(g) \rightleftharpoons H_2O(g)$$

This is a perfectly satisfactory way to write the equation for the chemical reaction; it says that 1 mol of hydrogen reacts with $\frac{1}{2}$ mol of oxygen to yield 1 mol of water vapor. The corresponding equilibrium expression is

$$\frac{P_{H_2O}}{P_{H_2}P_{O_2}^{1/2}} = K_3$$

Comparison with the expression for K_1 shows that

$$K_3 = K_1^{1/2}$$

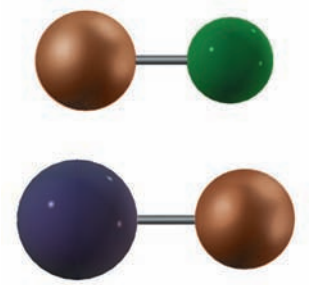
When a balanced chemical equation is multiplied by a constant factor, the corresponding equilibrium constant is raised to a power equal to that factor.

(3) A further variation is to add two equations to give a third. In this case the equilibrium constant for the third equation is the product of the equilibrium constants for the first two. For example, at 25°C,

$$2\ BrCl(g) \rightleftharpoons Cl_2(g) + Br_2(g) \qquad \frac{P_{Cl_2}P_{Br_2}}{P_{BrCl}^2} = K_1 = 0.45$$

$$Br_2(g) + I_2(g) \rightleftharpoons 2\ IBr(g) \qquad \frac{P_{IBr}^2}{P_{Br_2}P_{I_2}} = K_2 = 0.051$$

Adding the two chemical equations gives



$$2\ BrCl(g) + Br_2(g) + I_2(g) \rightleftharpoons 2\ IBr(g) + Cl_2(g) + Br_2(g)$$

Removing $Br_2(g)$ from both sides leaves

$$2\ BrCl(g) + I_2(g) \rightleftharpoons 2\ IBr(g) + Cl_2(g) \qquad \frac{P_{IBr}^2P_{Cl_2}}{P_{BrCl}^2P_{I_2}} = K_3$$

and, by inspection, $K_3 = K_1K_2 = (0.45)(0.051) = 0.023$.

(4) If a second equation is *subtracted* from the first, the resulting equilibrium constant is that of the first *divided* by that of the second (subtracting a reaction is the same as adding the reverse reaction). The operations of addition and subtraction applied to chemical equations transform into multiplication and division of the equilibrium expressions and equilibrium constants.

Bromine chloride, BrCl (top), and iodine bromide, IBr (bottom), are two examples of *interhalogens,* combinations of two or more halogen elements.

EXAMPLE 14.7

The concentrations of the oxides of nitrogen are monitored in air-pollution reports. At 25°C, the equilibrium constant for the reaction

$$NO(g) + \tfrac{1}{2}\,O_2(g) \rightleftharpoons NO_2(g)$$

is

$$\frac{P_{NO_2}}{P_{NO}P_{O_2}^{1/2}} = K_1 = 1.3 \times 10^6$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

and that for

$$\tfrac{1}{2}\,N_2(g) + \tfrac{1}{2}\,O_2(g) \longrightarrow NO(g)$$

is

$$\frac{P_{NO}}{P_{N_2}^{1/2} P_{O_2}^{1/2}} = K_2 = 6.5 \times 10^{-16}$$

Find the equilibrium constant K_3 for the reaction

$$N_2(g) + 2\ O_2(g) \rightleftharpoons 2\ NO_2(g)$$

Solution

Adding the chemical equations for the first two reactions gives

$$\tfrac{1}{2}\,N_2(g) + O_2(g) \rightleftharpoons NO_2(g)$$

The equilibrium constant for this reaction, K_3', is just the product of K_1 and K_2, or K_1K_2. The constant sought, K_3, is defined by a chemical equation that is twice this, so K_3' must be raised to the power 2 (that is, squared) to give K_3:

$$K_3 = (K_3')^2 = (K_1K_2)^2 = 7.1 \times 10^{-19}$$

Consecutive Equilibria

Many real-world applications of chemistry and biochemistry involve fairly complex sets of reactions occurring in sequence and/or in parallel. Each of these individual reactions is governed by its own equilibrium constant. To describe the overall progress of the entire coupled set of reactions we write all the involved equilibrium expressions and treat them as a set of *simultaneous algebraic equations,* because the concentrations of various chemical species appear in several expressions in the set. Examination of relative values of equilibrium constants shows that some reactions dominate the overall coupled set of reactions, and this chemical insight enables mathematical simplifications in the simultaneous equations. We study coupled equilibria in considerable detail in Chapter 15 on acid–base equilibrium. In Section 14.6 we provide a brief introduction to this topic in the context of an important biological process.

14.5 EQUILIBRIUM CALCULATIONS FOR GAS-PHASE AND HETEROGENEOUS REACTIONS

Equilibrium calculations, used throughout the science of chemistry in both basic and applied work, involve specific procedures. The present section presents these problem-solving techniques in the context of gas-phase and heterogeneous reactions, but they are applicable in *all* equilibrium calculations. The strategy comprises three basic steps:

1. Always start by writing the balanced equation for the reaction being studied.
2. Visualize the reaction as proceeding through three steps:
   a. the reactants are brought together at their *initial partial pressures,* but not yet allowed to react;
   b. the reaction is initiated and causes *changes in partial pressures* of all products and reactants;

c. the reaction reaches equilibrium, and all products and reactants are present at their *equilibrium partial pressures*. (Note the similarity to the procedures described in Chapter 13 for initiating spontaneous processes by manipulating thermodynamic constraints.)

3. Develop approximation schemes when possible by neglecting a very small quantity when it is added to or subtracted from a much larger quantity.

We illustrate these calculation methods with several examples that fall into two broad classes: evaluating the equilibrium constant from reaction data, and calculating the amounts of products and reactants present at equilibrium when the equilibrium constant is known.

Evaluating Equilibrium Constants from Reaction Data

In Section 14.3 we showed how to evaluate K from calorimetric data on the pure reactants and products. Occasionally, these thermodynamic data may not be available for a specific reaction, or a quick estimate of the value of K may suffice. In these cases we can evaluate the equilibrium constant from measurements made directly on the reaction mixture. If we can measure the equilibrium partial pressures of all the reactants and products, we can evaluate the equilibrium constant by substituting these measured values (in units of atmospheres) into the equilibrium expression. In many cases it is not practical to measure directly the equilibrium partial pressure of each separate reactant and product. Nonetheless, the equilibrium constant can usually be derived from other available data, although the determination is less direct. We illustrate the method in the following two examples.

Phosgene, $COCl_2$, is a chemical intermediate used in making polyurethanes for foams and surface coatings.

EXAMPLE 14.8

Phosgene, $COCl_2$, forms from CO and Cl_2 according to the equilibrium

$$CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$$

At 600°C, a gas mixture of CO and Cl_2 is prepared that has initial partial pressures (before reaction) of 0.60 atm for CO and 1.10 atm for Cl_2. After the reaction mixture has reached equilibrium, the partial pressure of $COCl_2(g)$ at this temperature is measured to be 0.10 atm. Calculate the equilibrium constant for this reaction. The reaction is carried out in a vessel of fixed volume.

Solution

Only the equilibrium partial pressure of $COCl_2(g)$ and the *initial* partial pressures of the other two gases are given. To find the equilibrium constant, it is necessary to determine the equilibrium partial pressures of CO and Cl_2. To do this, we set up a simple table:

	$CO(g)$	+	$Cl_2(g)$	$\rightleftharpoons$	$COCl_2(g)$
Initial partial pressure (atm)	0.60		1.10		0
Change in partial pressure (atm)	?		?		+0.10
Equilibrium partial pressure (atm)	?		?		0.10

Note that the first two lines must add to give the third. We use the relationships built into the balanced chemical equation to fill in the blanks in the table. Because this is the only reaction taking place, every mole of $COCl_2$ produced consumes exactly 1 mol of CO and exactly 1 mol of Cl_2. According to the ideal gas equation, the partial pressures of gases are proportional to the number of moles of each gas present as long as the volume and temperature are held fixed. Therefore, the change in partial pressure of each gas

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

must be proportional to the change in its number of moles as the mixture goes toward equilibrium. If the partial pressure of $COCl_2$ *increases* by 0.10 atm through reaction, the partial pressures of CO and Cl_2 must each *decrease* by 0.10 atm. Inserting these values into the table gives

	$CO(g)$	+	$Cl_2(g)$	$\rightleftharpoons$	$COCl_2(g)$
Initial partial pressure (atm)	0.60		1.10		0
Change in partial pressure (atm)	−0.10		−0.10		+0.10
Equilibrium partial pressure (atm)	0.50		1.00		0.10

where the last line was obtained by adding the first two.

We now insert the equilibrium partial pressures into the equilibrium expression to calculate the equilibrium constant:

$$K = \frac{P_{COCl_2}}{(P_{CO})(P_{Cl_2})} = \frac{(0.10)}{(0.50)(1.00)} = 0.20$$

Related Problems: 21, 22, 23, 24

For a reaction in which some of the coefficients in the balanced equation are not equal to 1, deriving expressions for the changes in the partial pressures of the products and reactants requires care. Consider the combustion of ethane at constant volume:

$$2\ C_2H_6(g) + 7\ O_2(g) \rightleftharpoons 4\ CO_2(g) + 6\ H_2O(g)$$

If the initial partial pressures are all 1.00 atm and there is a net reaction from left to right in this equation, the table is

	$2\ C_2H_6(g)$	+	$7\ O_2(g)$	$\rightleftharpoons$	$4\ CO_2(g)$	+	$6\ H_2O(g)$
Initial partial pressure	1.00		1.00		1.00		1.00
Change in partial pressure	$-2y$		$-7y$		$+4y$		$+6y$
Equilibrium partial pressure	$1.00 - 2y$		$1.00 - 7y$		$1.00 + 4y$		$1.00 + 6y$

If the C_2H_6 partial pressure decreases by $2y$ atm, that of O_2 must decrease by $7y$, because the coefficients in the balanced equation are 2 and 7. The changes in partial pressures of products will have the opposite sign (positive instead of negative), because as reactants disappear, products appear. Their magnitudes are determined according to the coefficients in the balanced equation.

EXAMPLE 14.9

Graphite (a form of solid carbon) is added to a vessel that contains $CO_2(g)$ at a pressure of 0.824 atm at a certain high temperature. The pressure rises due to a reaction that produces $CO(g)$. The total pressure reaches an equilibrium value of 1.366 atm. (**a**) Write a balanced equation for the process. (**b**) Calculate the equilibrium constant.

Solution

(**a**) The reaction can only be the oxidation of C by CO_2 during which the CO_2 is itself reduced to CO. The reaction and its equilibrium expression are written as

$$C(s) + CO_2(g) \rightleftharpoons 2\ CO(g) \qquad \frac{(P_{CO})^2}{P_{CO_2}} = K$$

(b) To determine the equilibrium constant, we set up the standard table to describe reaction progress:

	C(*s*) +	$CO_2(g)$ $\rightleftharpoons$	2 CO(*g*)
Initial partial pressure (atm)		0.824	0
Change in partial pressure (atm)		$-x$	$+2x$
Equilibrium partial pressure (atm)		$0.824 - x$	$2x$

The total pressure at equilibrium is

$$P_{tot} = 0.824 \text{ atm} - x + 2x = 0.824 + x = 1.366 \text{ atm}$$

Solving for x gives

$$x = 1.366 - 0.824 = 0.542 \text{ atm}$$

The equilibrium partial pressures of the two gases are

$$P_{CO} = 2x = 1.084 \text{ atm}$$

$$P_{CO_2} = 0.824 - 0.542 = 0.282 \text{ atm}$$

The equilibrium constant for the reaction is therefore

$$K = \frac{(1.084)^2}{0.282} = 4.17$$

Related Problems: 25, 26

Calculating Equilibrium Compositions When *K* Is Known

The law of mass action relates the equilibrium composition to the equilibrium constant. We can use these expressions to predict the outcomes of chemical reactions. How to approach the problem depends on the type of experimental data available.

Suppose you are asked to determine the partial pressures of reactants and products at equilibrium, given initial partial pressures of the reactants. This is illustrated by the following example.

EXAMPLE 14.10

Suppose $H_2(g)$ and $I_2(g)$ are sealed in a flask at $T = 400$ K with partial pressures $P_{H_2} = 1.320$ atm and $P_{I_2} = 1.140$ atm. At this temperature H_2 and I_2 do not react rapidly to form HI(g), although after a long enough time they would produce HI(g) at its equilibrium partial pressure. Suppose, instead, that the gases are heated in the sealed flask to 600 K, a temperature at which they quickly reach equilibrium:

$$H_2(g) + I_2(g) \rightleftharpoons 2\ HI(g)$$

The equilibrium constant for the reaction is 92.6 at 600 K:

$$\frac{P_{HI}^2}{P_{H_2} P_{I_2}} = 92.6$$

(a) What are the equilibrium values of P_{H_2}, P_{I_2}, and P_{HI} at 600 K?

(b) What percentage of the I_2 originally present has reacted when equilibrium is reached?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

(a) Suppose H_2 and I_2 did *not* react at 600 K. From the ideal gas law at constant volume, their partial pressures would be

$$P^{\circ}_{H_2} = 1.320 \text{ atm} \times \left(\frac{600 \text{ K}}{400 \text{ K}}\right) = 1.980 \text{ atm}$$

$$P^{\circ}_{I_2} = 1.140 \text{ atm} \times \left(\frac{600 \text{ K}}{400 \text{ K}}\right) = 1.710 \text{ atm}$$

Of course, these gases *do* react, and the extent of the reaction can be calculated. To do this, set up a table as in Example 14.8:

	$H_2(g)$	+	$I_2(g)$	$\rightleftharpoons$	2 HI(g)
Initial partial pressure (atm)	1.980		1.710		0
Change in partial pressure (atm)	$-x$		$-x$		$+2x$
Equilibrium partial pressure (atm)	$1.980 - x$		$1.710 - x$		$2x$

If the partial pressure of H_2 decreases by x atm as the reaction proceeds, then the partial pressure of I_2 must also decrease by x atm because each mole of H_2 reacts with 1 mol of I_2. By similar reasoning, the partial pressure of HI increases by $2x$ atm: 2 mol of HI forms from each mole of H_2. Inserting the equilibrium partial pressures into the equilibrium expression results in the equation

$$\frac{(2x)^2}{(1.980 - x)(1.710 - x)} = 92.6$$

Multiplying and collecting terms gives

$$88.6x^2 - 341.694x + 313.525 = 0$$

Solving for x using the quadratic formula (see Appendix C) gives

$$x = \frac{-(-341.694) \pm \sqrt{(341.694)^2 - 4(88.6)(313.525)}}{2(88.6)}$$

$$= 1.5044 \text{ atm or } 2.3522 \text{ atm}$$

The second root is physically impossible because it leads to negative answers for the equilibrium partial pressures of the $H_2(g)$ and $I_2(g)$. Discarding it leaves

$$P_{HI} = 2 \times 1.5044 \text{ atm} = 3.0088 \text{ atm}$$

$$P_{H_2} = 1.980 \text{ atm} - 1.5044 \text{ atm} = 0.4756 \text{ atm}$$

$$P_{I_2} = 1.710 \text{ atm} - 1.5044 \text{ atm} = 0.2056 \text{ atm}$$

It is a good idea to check such results by inserting the calculated equilibrium partial pressures back into the equilibrium expression to make sure that the known value of K comes out.

$$\text{Check:} \quad \frac{(3.0088)^2}{(0.4756)(0.2056)} = 92.6$$

As the final step, round off each answer to the correct number of significant digits: $P_{HI} = 3.01$ atm, $P_{H_2} = 0.48$ atm, $P_{I_2} = 0.21$ atm. Rounding off sooner makes the K calculated in the check differ somewhat from 92.6.

(b) The fraction of I_2 that has *not* reacted is the ratio of the number of moles of I_2 present at the end to that present at the beginning. Because neither volume nor temperature changes during the reaction, this equals the ratio of the final partial pressure of I_2 (0.2056 atm) to its initial partial pressure (1.710 atm):

$$\text{percentage unreacted} = \frac{0.2056 \text{ atm}}{1.710 \text{ atm}} \times 100\% = 12\%$$

The percentage that *has* reacted is then 88%.

The concentrations of any products initially present must also be included in equilibrium calculations, as illustrated by the following example.

EXAMPLE 14.11

Hydrogen is made from natural gas (methane) for immediate consumption in industrial processes, such as ammonia production. The first step is called the "steam reforming of methane":

$$CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\,H_2(g)$$

The equilibrium constant for this reaction is 1.8×10^{-7} at 600 K. Gaseous CH_4, H_2O, and CO are introduced into an evacuated container at 600 K, and their initial partial pressures (before reaction) are 1.40 atm, 2.30 atm, and 1.60 atm, respectively. Determine the partial pressure of $H_2(g)$ that will result at equilibrium.

Solution

The equilibrium expression is

$$\frac{(P_{CO})(P_{H_2})^3}{(P_{CH_4})(P_{H_2O})} = K$$

Set up the table of partial pressures:

	$CH_4(g)$	+	$H_2O(g)$	$\rightleftharpoons$	$CO(g)$	+	$3\,H_2(g)$
Initial partial pressure	1.40		2.30		1.60		0
Change in partial pressure	$-y$		$-y$		$+y$		$+3y$
Equilibrium partial pressure	$1.40 - y$		$2.30 - y$		$1.60 + y$		$3y$

Insert the equilibrium partial pressures into the equilibrium expression:

$$\frac{(1.60 + y)(3y)^3}{(1.40 - y)(2.30 - y)} = 1.8 \times 10^{-7}$$

If we expand this equation by multiplying through by the denominator, a polynomial equation of fourth order in y would result, for which the quadratic formula from the preceding problem would be useless. How can we solve the equation?

The equilibrium constant in this case is quite small, so the extent of reaction will also be small. This suggests that y will be a small number relative to the partial pressures of the gases present initially. Let's try the approximation that y can be ignored where it is added to a number that is close to one; that is, let's replace $1.60 + y$ with 1.60 in the preceding equation, and make the same approximation for the two terms in the denominator. When y *multiplies* something, as in the $(3y)^3$ term, of course we cannot set it equal to zero. The result of these steps is the approximate equation

$$\frac{(1.60)(3y)^3}{(1.40)(2.30)} = 1.8 \times 10^{-7}$$

$$y^3 = 1.34 \times 10^{-8}$$

The cube roots of both sides give

$$y = 2.38 \times 10^{-3}$$

This value is indeed small compared with 1.60, 1.40, and 2.30, so our approximation of neglecting y relative to these numbers is justified. Finally, at equilibrium we have

$$P_{H_2} = 3y = 7.1 \times 10^{-3}\ \text{atm}$$

Suppose the data for a gas-phase equilibrium are given in terms of concentrations rather than partial pressures. In such cases we convert all concentrations to partial pressures before starting the calculations. Or, we can rewrite the equilibrium expression in terms of concentration variables. The concentration [A] of an ideal gas is related to its partial pressure P_A through

$$[A] = \frac{n_A}{V} = \frac{P_A}{RT}$$

which can be written

$$P_A = RT[A]$$

We can substitute such a relation for each species appearing in the equilibrium expression. It is best to put the factors of $P_{ref} = 1$ atm back into the equilibrium expression to examine the units of the resulting equations. For the general gas-phase reaction

$$aA(g) + bB(g) \rightleftharpoons cC(g) + dD(g)$$

the equilibrium expression is

$$\frac{(RT[C]/P_{ref})^c (RT[D]/P_{ref})^d}{(RT[A]/P_{ref})^a (RT[B]/P_{ref})^b} = K$$

Rearranging gives

$$\frac{[C]^c[D]^d}{[A]^a[B]^b} = K(RT/P_{ref})^{+a+b-c-d}$$

This expression relates concentrations of gas-phase species at equilibrium. If $a + b - c - d = 0$ (that is, if there is no change in the total number of moles of gases in the reaction mixture), the right side of the equilibrium expression reduces to K.

EXAMPLE 14.12

At elevated temperatures, PCl_5 dissociates extensively according to

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$$

At 300°C, the equilibrium constant for this reaction is $K = 11.5$. The concentrations of PCl_3 and Cl_2 at equilibrium in a container at 300°C are both 0.0100 mol L^{-1}. Calculate $[PCl_5]$.

Solution

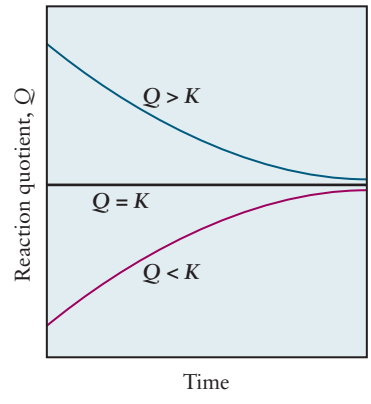
Two moles of gases are produced for each mole of gas consumed, so RT/P_{ref} must be raised to the power $1 - 2 = -1$. Hence,

$$\frac{[PCl_3][Cl_2]}{[PCl_5]} = K\left(\frac{RT}{P_{ref}}\right)^{-1} = K\left(\frac{P_{ref}}{RT}\right)$$

$$= 11.5 \times \frac{1 \text{ atm}}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(573 \text{ K})} = 0.245 \frac{\text{mol}}{\text{L}}$$

Solving this equation for $[PCl_5]$ gives

$$[PCl_5] = \frac{[PCl_3][Cl_2]}{0.245 \text{ mol L}^{-1}} = \frac{(0.0100 \text{ mol L}^{-1})(0.0100 \text{ mol L}^{-1})}{0.245 \text{ mol L}^{-1}}$$



$$= 4.08 \times 10^{-4} \text{ mol L}^{-1}$$

14.6 THE DIRECTION OF CHANGE IN CHEMICAL REACTIONS: EMPIRICAL DESCRIPTION

The specific examples in Section 14.5 illustrate how the law of mass action gives information about the nature of the equilibrium state. The law of mass action also explains and predicts the direction in which a reaction will proceed spontaneously when reactants and products are initially mixed together with arbitrary partial pressures or compositions. This requires a new concept, the reaction quotient Q, which is related to the equilibrium constant. Through the *principle of Le Châtelier* (described below), the mass action law also explains how a reaction in equilibrium responds to an external perturbation.

(a)

(b)

FIGURE 14.5 If nitrogen and hydrogen are mixed in 1:3 proportions together with some ammonia, they react according to the chemical equation

$$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$$

(a) If the initial reaction quotient Q_0 is less than K it increases with time; if it is greater than K, it decreases. (b) With three moles of H_2 available for each mole of N_2, a parabolic curve represents the partial pressures of ammonia and of hydrogen that coexist at equilibrium. From initial nonequilibrium conditions on either side, the partial pressures approach equilibrium along lines with slope −2/3, because three moles of H_2 are consumed to produce two moles of NH_3.

The Reaction Quotient

The **reaction quotient** Q for a general gas-phase reaction is defined as

$$Q = \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b}$$

where the partial pressures are the actual values measured at any point during the reaction, not just at equilibrium. The distinction between Q and K is crucial. The equilibrium constant K is determined by the partial pressures of reactants and products at equilibrium, and it is a constant, dependent only on the temperature. The reaction quotient Q depends on the actual instantaneous partial pressures, whatever they may be; thus, Q changes with time. As the reaction approaches equilibrium, Q approaches K. The initial partial pressures P_A°, P_B°, P_C°, and P_D° give an initial reaction quotient Q_0, whose magnitude relative to K determines the direction in which the reaction will proceed spontaneously toward equilibrium. If Q_0 is *less* than K, then Q must *increase* as time goes on. This requires an increase in the product partial pressures and a decrease in reactant partial pressures; in other words, the reaction proceeds from left to right. If Q_0 is *greater* than K, similar reasoning shows that the reaction will proceed from right to left, with Q *decreasing* with time until it becomes equal to K (Fig. 14.5).

EXAMPLE 14.13

The reaction between nitrogen and hydrogen to produce ammonia

$$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$$

is essential in making nitrogen-containing fertilizers. This reaction has an equilibrium constant equal to 1.9×10^{-4} at 400°C. Suppose that 0.10 mol of N_2, 0.040 mol of H_2, and 0.020 mol of NH_3 are sealed in a 1.00-L vessel at 400°C. In which direction will the reaction proceed?

Solution

The initial pressures $P_i = n_i RT/V$ are readily calculated to be

$$P_{N_2} = 5.5 \text{ atm} \qquad P_{H_2} = 2.2 \text{ atm} \qquad P_{NH_3} = 1.1 \text{ atm}$$

The initial numerical value of Q is therefore

$$Q_0 = \frac{(P_{NH_3}^\circ)^2}{P_{N_2}^\circ (P_{H_2}^\circ)^3} = \frac{(1.1)^2}{(5.5)(2.2)^3} = 2.1 \times 10^{-2}$$

Because $Q_0 > K$, the reaction will proceed from right to left and ammonia will dissociate until equilibrium is reached.

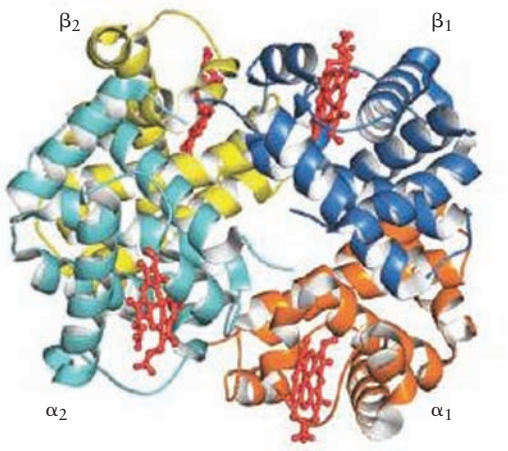
CONNECTION TO BIOLOGY

HEMOGLOBIN AND OXYGEN TRANSPORT



Humans and animals require oxygen for the aerobic metabolic processes that provide the energy necessary to sustain life. Food (a fuel) is oxidized in a series of enzyme-mediated reactions to produce energy; the products of the reactions being CO_2 and H_2O. Oxygen is carried from the lungs to tissues bound to the protein molecule hemoglobin (Hb), and it is stored in muscle by a related protein called myoglobin (Mb). Hemoglobin and myoglobin are both oxygen transport proteins in which O_2 is covalently bound to iron in an octahedral coordination complex built around the porphyrin molecule heme (see Section 8.3). Iron is coordinated to four nitrogen atoms in the planar porphyrin structure, leaving a fifth site available that binds the heme to the protein via the amino acid histidine, and a sixth site available to reversibly bind oxygen. The solubility of oxygen in whole blood can be as high as 10^{-2} mol L^{-1} only because it is chemically bound to hemoglobin. The solubility of O_2 in blood plasma, which contains no hemoglobin, is only about 10^{-4} mol L^{-1}, a value that is very close to its solubility in pure water (as determined by its Henry's Law constant, see Section 11.6). The partial pressure of O_2 in the lungs is about 100 torr, which is sufficiently high to saturate all of the available oxygen binding sites in hemoglobin. Highly oxygenated blood from the lungs is delivered throughout the body via the circulatory system, eventually reaching the capillaries, where the O_2 partial pressure is only about 40 torr. Hemoglobin releases a significant fraction of the bound oxygen under these low-pressure conditions; it can either be taken up and stored by myoglobin in muscle or transported directly to cells for their use in metabolism.

Why is oxygen bound so strongly by hemoglobin in the lungs and then released so readily to myoglobin through capillaries? The answer requires an understanding of the differences between the simple heterogeneous equilibrium established between oxygen and myoglobin and the more complicated set of simultaneous equilibria established between oxygen and hemoglobin. The differences arise as a consequence of the very different molecular structures of the two proteins. Myoglobin is a monomeric globular protein that contains 154 amino acids in a helical configuration (represented by the green ribbon structure) and a single heme group shown in red.

Myoglobin (Mb)

Hemoglobin, on the other hand, is a tetramer with two identical α subunits that each contains 141 amino acids and a single heme group, and two identical β subunits that each contains 146 amino acids and a single heme group. Each member of an identical pair of monomers is labeled by a number, and all four monomers are colored differently, for clarity.

Hemoglobin (Hb)

The uptake of oxygen by myoglobin follows the hyperbolic Michelis-Menten equation (see Section 18.8) as shown by the blue line in the adjacent graph, which is a plot of the **fractional saturation** versus the oxygen partial pressure. This behavior is characteristic of a simple enzyme/substrate equilibrium as represented by the following equation and equilibrium constant.

$$Mb(aq) + O_2(g) \rightleftharpoons Mb(O_2)(aq)$$

$$K = \frac{[Mb(O_2)]}{[Mb]P_{O_2}} = 271$$

The graph shows that binding saturates at very low oxygen partial pressures; half of the available sites are filled at $P_{O_2} = 1$ torr.

The experimental binding curve for hemoglobin is quite different, however. The S-shaped red curve shows that relatively few oxygen molecules are bound at low partial pressures but that the fractional saturation increases rapidly with increasing P_{O_2}; half saturation occurs at about 30 torr, a much higher pressure than for myoglobin. Curves of this type are characteristic of co-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

operative behavior. Binding the first O_2 molecule to one heme group in hemoglobin causes a conformational change that makes it easier to bind the second O_2 molecule to a different heme group and so forth until all four sites are occupied. Evidence for this conclusion is provided by comparing the values of the consecutive equilibrium constants, as shown below.

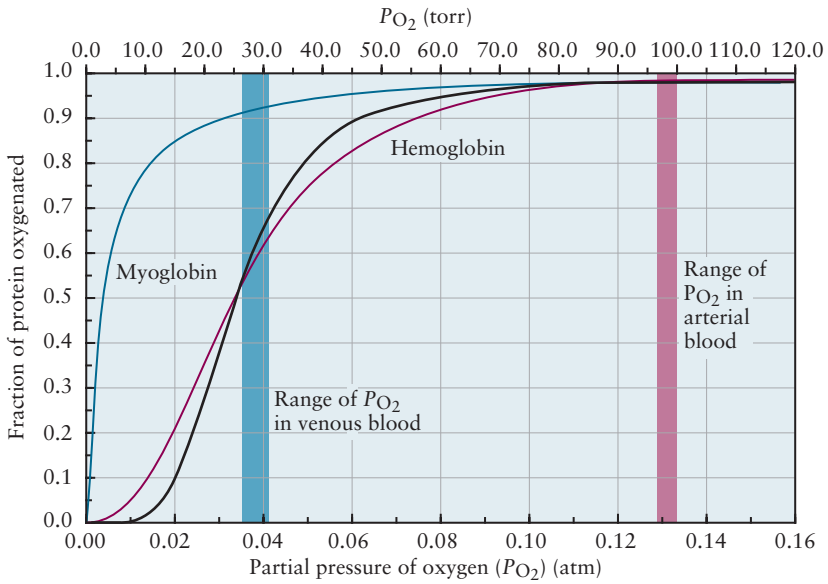
$$Hb(aq) + O_2(g) \rightleftharpoons Hb(O_2)(aq) \qquad K_1 = \frac{[Hb(O_2)]}{[Hb]P_{O_2}} = 4.88$$

$$Hb(O_2)(aq) + O_2(g) \rightleftharpoons Hb(O_2)_2(aq) \qquad K_2 = \frac{[Hb(O_2)_2]}{[HbO_2]P_{O_2}} = 15.4$$

$$Hb(O_2)_2(aq) + O_2(g) \rightleftharpoons Hb(O_2)_3(aq) \qquad K_3 = \frac{[Hb(O_2)_3]}{[Hb(O_2)_2]P_{O_2}} = 6.49$$

$$Hb(O_2)_3(aq) + O_2(g) \rightleftharpoons Hb(O_2)_4(aq) \qquad K_4 = \frac{[Hb(O_2)_4]}{[Hb(O_2)_3]P_{O_2}} = 1750$$

The four equilibrium constants are not equal to each other, and K_4 is much larger than the other three. Reducing P_{O_2} clearly reduces the fraction of bound oxygen (Le Châtelier's principle) for both proteins but the two molecules respond quite differently to decreasing oxygen partial pressures. Hemoglobin and myoglobin are both nearly saturated at partial pressures of 100 torr (in the lungs), but the fraction of oxygen bound to hemoglobin has dropped to 55% at 30 torr (in capillaries) while the fraction bound to myoglobin in muscle remains high at 90%. These different responses to changes in the oxygen partial pressure are responsible for transfer of O_2 from hemoglobin (in blood) to myoglobin (in muscle). See chart below.



Archibald Hill derived a simple model to account for the S-shaped curve observed that provides some physical insight into the nature of the cooperativity involved. Suppose, for example, that binding was an all or nothing event. The overall reaction and resulting equilibrium constant expression would be

$$Hb + 4O_2 \rightleftharpoons Hb(O_2)_4 \qquad K = \frac{[Hb][O_2]^+}{[Hb(O_2)_4]}$$

from which we express the fractional saturation as follows

$$X = \frac{[Hb(O_2)_4]}{[Hb(O_2)_4] + [Hb]} \qquad X = \frac{(P_{O_2})^+}{(P_{O_2})^+ + K}$$

which is plotted in black. The most general form proposed by Hill replaces the exponent 4 with a number n that is chosen to fit particular situations. $n = 1$ corresponds to the myoglobin case with no cooperativity, and a fit to the hemoglobin curve produces $n = 2.8$, which demonstrates a high degree of, but not perfect, cooperativity.

A plot of the fraction of the binding sites of hemoglobin (red) and myoglobin (blue) that are occupied as a function of the partial pressure of O_2. (Adapted from Reginald H. Garrett and Charles M. Grisham, *Biochemistry*. Boston: Brooks/Cole, Cengage Learning, 2010)

EXAMPLE 14.14

Solid ammonium chloride is in equilibrium with ammonia and hydrogen chloride gases:

$$NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g)$$

The equilibrium constant at 275°C is 1.04×10^{-2}.

We place 0.980 g of solid NH_4Cl into a closed vessel with volume 1.000 L and heat to 275°C. (**a**) In what direction does the reaction proceed? (**b**) What is the partial pressure of each gas at equilibrium? (**c**) What is the mass of solid NH_4Cl at equilibrium?

Solution

(**a**) We evaluate the reaction quotient

$$Q = P_{NH_3} P_{HCl}$$

Initially, $Q_0 = 0$ because neither gas is present. By comparison, $K = 1.04 \times 10^{-2}$. Because $Q < K$, the reaction will proceed spontaneously from left to right. Some of the solid NH_4Cl will decompose, and some gaseous NH_3 and HCl will appear in the vessel.

(**b**) We set up the standard table for the equilibrium calculation:

	$NH_4Cl(s)$	$\rightleftharpoons$	$NH_3(g)$	+	$HCl(g)$
Initial partial pressure (atm)			0		0
Change in partial pressure (atm)			$+x$		$+x$
Equilibrium partial pressure (atm)			$+x$		$+x$

Because NH_3 and HCl are formed in equimolar amounts, they will have the same partial pressure at equilibrium. The equilibrium expression is

$$P_{NH_3} P_{HCl} = K = 1.04 \times 10^{-2}$$

$$x^2 = 1.04 \times 10^{-2}$$

$$x = 0.102$$

At equilibrium, the partial pressures are

$$P_{NH_3} = P_{HCl} = 0.102 \text{ atm}$$

(**c**) The number of moles of NH_4Cl that decomposed is equal to the number of moles of each gas produced. We calculate this number, treating the gases as ideal

$$n_{NH_3} = n_{HCl} = \frac{(1.02 \times 10^{-1} \text{ atm})(1.000 \text{ L})}{(0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1})(548.2 \text{ K})} = 2.268 \times 10^{-3} \text{ mol}$$

The mass of NH_4Cl consumed is $(2.268 \times 10^{-3} \text{ mol})(53.49 \text{ g mol}^{-1}) = 0.121$ g. The remaining mass is 0.859 g. The percentage decomposition of the original sample is 12.4%.

External Effects on *K*: Principle of Le Châtelier

Suppose a system at equilibrium is perturbed by some external stress such as a change in volume or temperature or a change in the partial pressure or concentration of one of the reactants or products. How will the system respond? The qualitative answer is embodied in a principle stated by Henri Le Châtelier in 1884:

> *A system in equilibrium that is subjected to a stress will react in a way that tends to counteract the stress.*

Le Châtelier's principle provides a way to predict qualitatively the direction of change of a system under an external perturbation. It relies heavily on Q as a predictive tool.

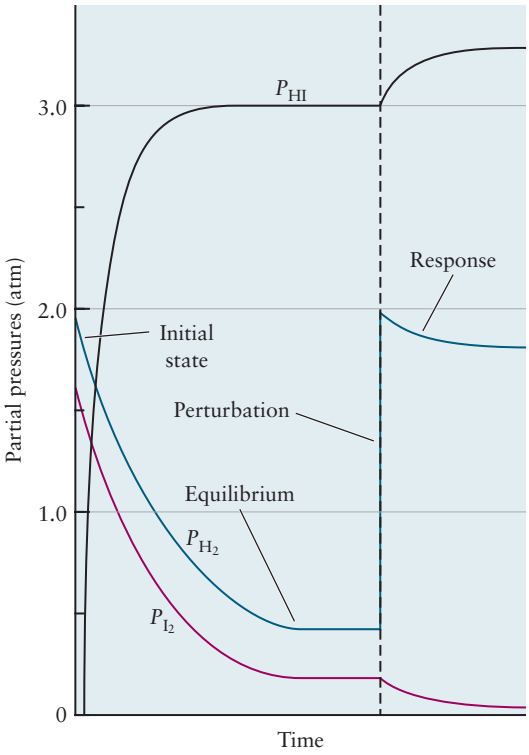

FIGURE 14.6 Partial pressures versus time for the equilibrium

$$H_2(g) + I_2(g) \rightleftharpoons 2\ HI(g)$$

The part of the graph to the left of the dashed vertical line shows the approach to equilibrium starting from the initial conditions specified in Example 14.10. Then the equilibrium state is abruptly perturbed by an increase in the partial pressure of H_2 to 2.000 atm. In accordance with Le Châtelier's principle, the system responds (Example 14.15) in such a way as to decrease the partial pressure of H_2—that is, to counteract the perturbation that moved it away from equilibrium in the first place.

Effects of Changing the Concentration of a Reactant or Product

As a simple example, consider what happens when a small quantity of a reactant is added to an equilibrium mixture. The addition of reactant lowers the reaction quotient Q below K and a net reaction takes place in the forward direction, partially converting reactants to products, until Q again equals K. The system partially counteracts the stress (the increase in the quantity of one of the reactants) and attains a new equilibrium state. If one of the *products* is added to an equilibrium mixture, Q temporarily becomes *greater* than K and a net *back* reaction occurs, partially counteracting the imposed stress by reducing the concentration of products (Fig. 14.6).

EXAMPLE 14.15

An equilibrium gas mixture of $H_2(g)$, $I_2(g)$, and $HI(g)$ at 600 K has

$$P_{H_2} = 0.4756 \text{ atm} \qquad P_{I_2} = 0.2056 \text{ atm} \qquad P_{HI} = 3.009 \text{ atm}$$

This is essentially the final equilibrium state of Example 14.10. Enough H_2 is added to increase its partial pressure to 2.000 atm at 600 K before any reaction takes place. The mixture then once again reaches equilibrium at 600 K. What are the final partial pressures of the three gases?

Solution

Set up the usual table, in which "initial" now means the moment after the addition of the new H_2 but before it reacts further.

	$H_2(g)$	+	$I_2(g)$	$\rightleftharpoons$	2 $HI(g)$
Initial partial pressure (atm)	2.000		0.2056		3.009
Change in partial pressure (atm)	$-x$		$-x$		$+2x$
Equilibrium partial pressure (atm)	$2.000 - x$		$0.2056 - x$		$3.009 + 2x$

From Le Châtelier's principle it follows that net reaction to consume H_2 will occur after addition of H_2, and this fact has been used in assigning a negative sign to the change in the partial pressure of H_2 in the table.

Substitution of the equilibrium partial pressures into the equilibrium law gives

$$\frac{(3.009 + 2x)^2}{(2.000 - x)(0.2056 - x)} = 92.6$$

Expansion of this expression results in the quadratic equation

$$88.60x^2 - 216.275x + 29.023 = 0$$

which can be solved to give

$$x = 0.1425 \text{ or } 2.299$$

The second root would lead to negative partial pressures of H_2 and I_2 and is therefore physically impossible. Substitution of the first root into the expressions from the table gives

$$P_{H_2} = 2.000 - 0.1425 = 1.86 \text{ atm}$$

$$P_{I_2} = 0.2056 = -0.1425 = 0.063 \text{ atm}$$

$$P_{HI} = 3.009 + 2(0.1425) = 3.29 \text{ atm}$$

$$\text{Check:} \quad \frac{(3.29)^2}{(1.86)(0.063)} = 92.4$$

HI is synthesized industrially by reacting elemental iodine with H_2. Because iodine is so much more expensive than hydrogen, the reaction conditions are chosen to maximize the conversion of iodine to product. This objective is accomplished by keeping hydrogen greatly in excess to drive the equilibrium to the right. The product is removed continuously to provide an additional thermodynamic driving force for conversion to product. Most industrial operations are designed in such a way that products can be removed continuously to achieve high overall yields, even for reactions with small equilibrium constants.

Effects of Changing the Volume

Le Châtelier's principle also predicts the effect of a change in volume on gas-phase equilibrium. We find it easier to think about changes in volume in terms of the changes in pressure they would produce and to see how the system can respond to these changes in pressure. Decreasing the volume of a gaseous system increases its total pressure, and the system responds, if possible, to reduce the total pressure. For example, in the equilibrium

$$2\ P_2(g) \rightleftharpoons P_4(g)$$

the reaction shifts in the forward direction when the volume is decreased. This occurs because every two molecules of P_2 consumed produce only one molecule of P_4, thus reducing the total pressure and partially compensating for the external stress caused by the change in volume. In contrast, an *increase* in volume favors reactants over products in this system, and some P_4 dissociates to form P_2 (Fig. 14.7). If there is no difference in the total numbers of gas-phase molecules on the two sides of the equation, then a change in volume has no effect on the equilibrium.

This effect of changing the volume of an equilibrium reacting mixture can also be understood by using the reaction quotient. For the phosphorus equilibrium just described, the reaction quotient is

$$Q = \frac{P_{P_4}}{(P_{P_2})^2}$$

Initially, Q_0 equals K. Suppose the volume is then decreased by a factor of 2; because the temperature is unchanged, this initially increases each partial pressure by

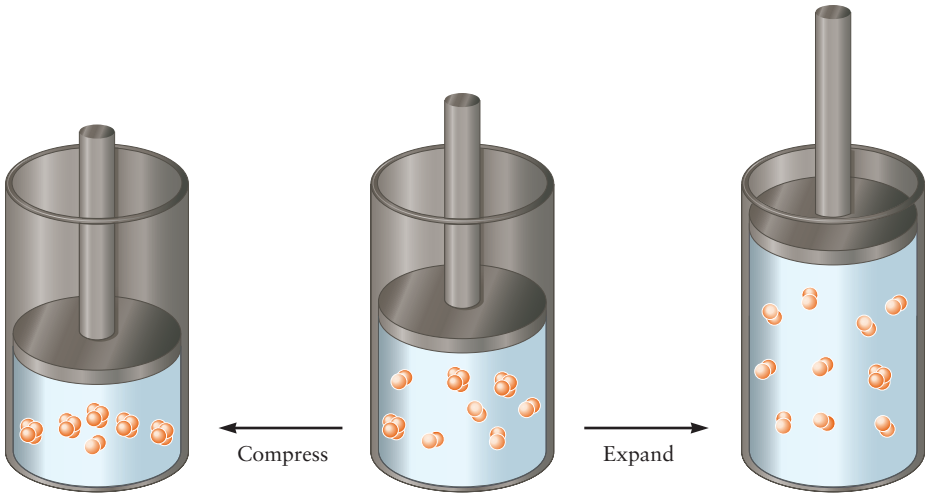

FIGURE 14.7 An equilibrium mixture of P_2 and P_4 (center) is compressed (left). Some P_2 molecules combine to give P_4 molecules, to reduce the total number of molecules and thus the total pressure. If the volume is increased (right), some P_4 molecules dissociate to pairs of P_2 molecules to increase the total number of molecules and the pressure exerted by those molecules.

a factor of 2. Because there are two powers of the pressure in the denominator and only one in the numerator, this decreases Q by a factor of 2, making it lower than K. Reaction must then occur in the forward direction until Q again equals K.

When the volume of a system is decreased, its total pressure increases. Another way to increase the total pressure is to add an inert gas such as argon to the reaction mixture without changing the total volume. In this case the effect on the equilibrium is entirely different. Because the partial pressures of the reactant and product gases are unchanged by an inert gas, adding argon at constant volume has no effect on the position of the equilibrium.

Effects of Changing the Temperature

Chemical reactions are either **endothermic** (taking up heat from the surroundings) or **exothermic** (giving off heat) (see Section 12.6). Raising the temperature of an equilibrium mixture by adding heat causes reactions to occur in such a way as to absorb some of the added heat. The equilibrium in an endothermic reaction shifts from left to right, while that in an exothermic reaction shifts from right to left, with "products" reacting to give "reactants." Equivalently, we can describe the shifts in terms of the effect of temperature on equilibrium constants. The equilibrium constant for an endothermic reaction increases with increasing temperature, while that for an exothermic reaction decreases with increasing temperature.

This effect is illustrated by the equilibrium between nitrogen dioxide (NO_2) and its dimer, dinitrogen tetraoxide (N_2O_4), briefly considered in Example 9.6, expressed by the chemical equation

$$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$$

Because NO_2 is a brown gas but N_2O_4 is colorless, the equilibrium between them can be studied by observing the color of a tube containing the two gases. At high temperatures, NO_2 predominates and a brown color results; as the temperature is lowered, the partial pressure of N_2O_4 increases and the color fades (Fig. 14.8).

The equilibrium expression for the N_2O_4–NO_2 equilibrium is

$$\frac{P_{N_2O_4}}{(P_{NO_2})^2} = K$$

K has the numerical value 8.8 at $T = 25°C$, provided the partial pressures of N_2O_4 and NO_2 are expressed in atmospheres. This reaction is exothermic ($\Delta H = -58.02$ kJ mol^{-1} at 298 K) because energy must be liberated when dimers are formed. Consequently, K decreases as the temperature T increases, so the amount of N_2O_4 present for a given partial pressure of NO_2 falls with increasing temperature as the dimer dissociates at elevated temperatures.

© Cengage Learning/Charles D. Winters

FIGURE 14.8 The equilibrium between N_2O_4 and NO_2 depends on temperature. The tube on the right, held in an ice bath at 0°C, contains mostly N_2O_4. Its color is pale because only NO_2 is colored. The deeper color in the tube on the left, which is held at 50°C, reflects the increased NO_2 present in equilibrium at the higher temperature. The tubes contain the same masses of substance, distributed in different ways between NO_2 and N_2O_4.

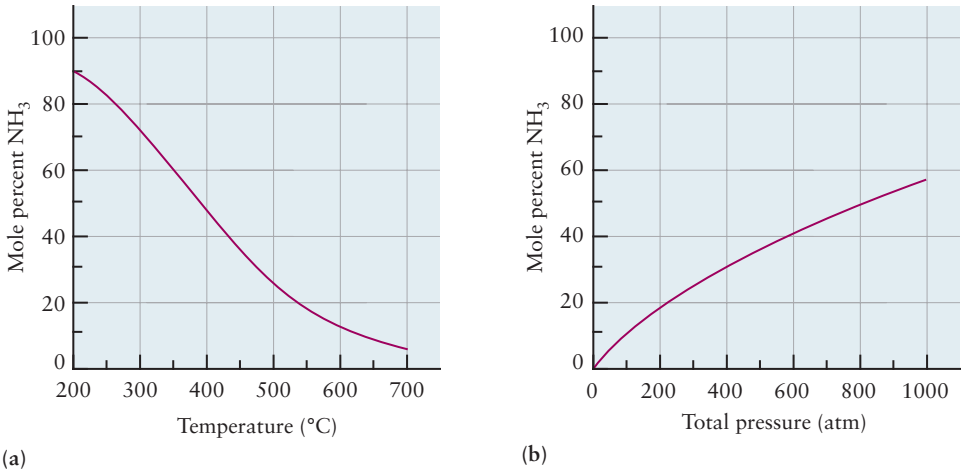

FIGURE 14.9 (a) The equilibrium mole percentage of ammonia in a 1:3 mixture of N_2 and H_2 varies with temperature; low temperatures favor high yields of NH_3. The data shown correspond to a fixed total pressure of 300 atm. (b) At a fixed temperature (here, 500°C), the yield of NH_3 increases with increasing total pressure.

Maximizing the Yield of a Reaction

As an application of Le Châtelier's principle, consider the reaction

$$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$$

which is the basis of the industrial synthesis of ammonia. Because this reaction is exothermic, the yield of ammonia is increased by working at as low a temperature as possible (Fig. 14.9a). At too low a temperature, the reaction is very slow, so a compromise temperature near 500°C is typically used. Because the number of moles of gas decreases as the reaction occurs, the yield of product is enhanced by decreasing the volume of the reaction vessel. Typically, total pressures of 150 to 300 atm are used (see Fig. 14.9b), although some plants work at up to 900 atm of pressure. Even at high pressures, the yield of ammonia is usually only 15% to 20% because the equilibrium constant is so small. To overcome this, ammonia plants operate in a cyclic process in which the gas mixture is cooled after ammonia is produced so that the ammonia liquefies (its boiling point is much higher than those of nitrogen and hydrogen) and is removed from the reaction vessel. Continuous removal of products helps drive the reaction to completion.

14.7 THE DIRECTION OF CHANGE IN CHEMICAL REACTIONS: THERMODYNAMIC EXPLANATION

The specific examples in Section 14.5 demonstrate that when $K \gg 1$ the reaction has progressed far toward products, and when $K \ll 1$ the reaction has remained near reactants. The empirical discussion in Section 14.6 shows how the reaction quotient Q and Le Châtelier's principle can predict the direction of spontaneous reaction and the response of an equilibrium state to an external perturbation. Here, we use the thermodynamic description of K from Section 14.3 to provide the thermodynamic basis for these results obtained empirically in Sections 14.5 and 14.6. We identify those thermodynamic factors that determine the magnitude of K. We also provide a thermodynamic criterion for predicting the direction in which a reaction proceeds from a given initial condition.

The Magnitude of the Equilibrium Constant

The expression connecting the standard Gibbs free energy change and the equilibrium constant can be rewritten as

$$\ln K = \frac{-\Delta G^\circ}{RT} = \frac{\Delta S^\circ}{R} - \frac{\Delta H^\circ}{RT}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

so that

$$K = \exp\left[\frac{-\Delta G^\circ}{RT}\right] = \exp\left[\frac{\Delta S^\circ}{R}\right] \exp\left[\frac{-\Delta H^\circ}{RT}\right]$$

Here K is large (favoring the products) if ΔS° is positive and large and ΔH° is negative and large. In other words, an increase in the number of microstates ($\Delta S^\circ > 0$) and a decrease in enthalpy ($\Delta H^\circ < 0$) both favor a large K. Thus, the same factors that favor reaction spontaneity by making ΔG° negative also favor a large K if they can make ΔG° large in magnitude as well as negative in sign. If ΔH° and ΔS° have the *same* sign, the value of K will be a compromise between one effect that raises K and another that lowers it.

Free Energy Changes and the Reaction Quotient

The direction in which a spontaneous chemical reaction proceeds after it is initiated with a given initial concentration of products and reactants is the direction in which $\Delta G < 0$. If the initial condition is "to the left" of the equilibrium state, products will be formed at the expense of reactants; if the initial condition is "to the right" of the equilibrium state, products will be converted back to reactants. This criterion can be made quantitative and expressed in terms of the initial concentrations as follows.

Proceeding as in Section 14.3, we find ΔG for the general gas-phase reaction

$$a\mathrm{A} + b\mathrm{B} \longrightarrow c\mathrm{C} + d\mathrm{D}$$

to be

$$\Delta G = \Delta G^\circ + RT \ln\left[\frac{(P_\mathrm{C}/P_\mathrm{ref})^c (P_\mathrm{D}/P_\mathrm{ref})^d}{(P_\mathrm{A}/P_\mathrm{ref})^a (P_\mathrm{B}/P_\mathrm{ref})^b}\right]$$

At equilibrium, where $\Delta G = 0$, the combination of partial pressures appearing inside the brackets becomes the equilibrium constant, K. Away from equilibrium, this combination of partial pressures is the reaction quotient Q, introduced in Section 14.6:

$$\Delta G = \Delta G^\circ + RT \ln Q$$

The equilibrium constant can be substituted for ΔG° in this equation to obtain a very useful relation between ΔG, K, and Q as follows:

$$\begin{aligned}\Delta G &= \Delta G^\circ + RT \ln Q = -RT \ln K + RT \ln Q \\ &= RT \ln (Q/K)\end{aligned} \qquad [14.10]$$

If the reaction quotient Q is *less* than K, $\Delta G < 0$ and the reaction will proceed spontaneously as written, from left to right. If $Q > K$, then $\Delta G > 0$ and the *reverse* reaction (right to left) will occur spontaneously until equilibrium is reached. These conditions are represented schematically in Figure 14.10. The second law of thermodynamics thus provides a very useful criterion for the direction of reaction in terms of the initial value of the reaction quotient.

There exists a deep relationship between Figure 14.5, which represents actual events occurring in the laboratory, and Figure 14.10, which represents the thermodynamic driving force (that is, the Gibbs free energy) governing these events. The function shown in Figure 14.10 is a thermodynamic potential function analogous to the mechanical potential functions we introduced in Chapter 3. The slope of this function at every point on the curve is the thermodynamic driving

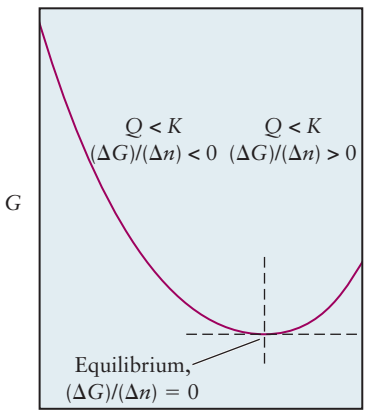

FIGURE 14.10 The free energy of a reaction system is plotted against its progress from pure reactants (left) to pure products (right). Equilibrium comes at the minimum of the curve. To the reactant side of equilibrium, $\Delta G < 0$ and $Q < K$. A reaction mixture with initial condition in this range will spontaneously move toward equilibrium by converting more reactants into products. To the product side of equilibrium, $\Delta G > 0$ and $Q > K$. A reaction mixture prepared in this range will spontaneously move toward equilibrium by converting products back into reactants.

$N_2(g) + 3\ H_2(g) \rightleftharpoons 2\ NH_3(g)$

Experimental data are shown by points.

force for the direction the reaction will take when the system has the composition described by that point.

Temperature Dependence of Equilibrium Constants

Le Châtelier's principle is a qualitative way of describing the *stability* of equilibrium states against sudden perturbations in concentration, pressure, and temperature. The responses of the system to all three effects can be described quantitatively by thermodynamics. Here we describe the effect of temperature, which is the most useful of these quantitative descriptions.

The temperature dependence of the equilibrium constant is determined by the equation

$$-RT \ln K = \Delta G^\circ \quad = \Delta H^\circ \quad - T\Delta S^\circ$$

If ΔH° and ΔS° are independent of temperature, then all the temperature dependence of K lies in the factor of T and the equation can be used to relate the values of K at two different temperatures, as follows. At least over a limited temperature range, ΔH° and ΔS° do not vary much with temperature. To the extent that their temperature dependence may be neglected, it is evident that $\ln K$ is a linear function of $1/T$ as shown in Figure 14.11.

$$\ln K = -\frac{\Delta G^\circ}{RT} = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \qquad [14.11]$$

A graph of $\ln K$ against $1/T$ is approximately a straight line with slope $-\Delta H^\circ/R$ and intercept $\Delta S^\circ/R$ (see Fig. 14.11). If the value of K is known for one temperature and ΔH° is also known, K can be calculated for other temperatures.

In addition to the graphical method, an equation can be obtained to connect the values of K at two different temperatures. Let K_1 and K_2 be the equilibrium constants for a reaction at temperatures T_1 and T_2, respectively. Then

$$\ln K_2 = -\frac{\Delta H^\circ}{RT_2} + \frac{\Delta S^\circ}{R}$$

$$\ln K_1 = -\frac{\Delta H^\circ}{RT_1} + \frac{\Delta S^\circ}{R}$$

Subtracting the second equation from the first gives

$$\ln\left(\frac{K_2}{K_1}\right) = -\frac{\Delta H^\circ}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right] \qquad [14.12]$$

This is known as the **van't Hoff equation** after the Dutch chemist Jacobus van't Hoff. Given ΔH° and K at one temperature, we can use the equation to calculate K at another temperature, within the approximation that ΔH° and ΔS° are independent of temperature. Alternatively, we can use the van't Hoff equation to determine ΔH° for reactions for which K is known at two or more temperatures. This approach is useful for finding enthalpy changes for reactions that might be difficult or inconvenient to measure directly by calorimetric methods.

The effect of a temperature change on the equilibrium constant depends on the sign of ΔH°. If ΔH° is negative (the reaction is exothermic, giving off energy as heat), then increasing the temperature *reduces* K. If ΔH° is positive (the reaction is endothermic, taking up energy as heat), then increasing the temperature *increases* K. These observations obtained from thermodynamics provide the quantitative basis for Le Châtelier's principle (Fig. 14.12).

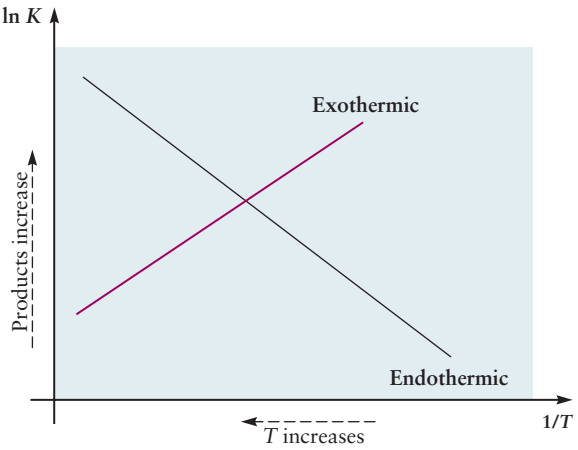

FIGURE 14.12 Sketch of ln *K* against 1/*T* for an exothermic reaction and for an endothermic reaction, as predicted by thermodynamics. Temperature increases to the left on this diagram. As *T* increases, *K* for the endothermic reaction increases and *K* for the exothermic reaction decreases in accordance with the principle of Le Châtelier.

EXAMPLE 14.16

Calculate *K* for the equilibrium of Example 14.4 at $T = 400$ K, assuming $\Delta H°$ to be approximately independent of temperature over the range from 298 to 400 K.

Solution

The first step is to calculate $\Delta H°$ for the reaction. Appendix D provides data to calculate

$$\Delta H° = -155.52 \text{ kJ}$$

From the van't Hoff equation,

$$\ln\left(\frac{K_{400}}{K_{298}}\right) = -\frac{\Delta H°}{R}\left[\frac{1}{400 \text{ K}} - \frac{1}{298 \text{ K}}\right]$$

$$= \frac{155{,}520 \text{ J mol}^{-1}}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}}\left[\frac{1}{400 \text{ K}} - \frac{1}{298 \text{ K}}\right] = -16.01$$

$$\frac{K_{400}}{K_{298}} = e^{-16.01} = 1.1 \times 10^{-7}$$

Taking K_{298} to be 1.8×10^{18} (from Example 14.4) gives

$$K_{400} = (1.8 \times 10^{18})(1.1 \times 10^{-7}) = 2.0 \times 10^{11}$$

Because the reaction is exothermic, an increase in temperature reduces the equilibrium constant.

An alternative way to do this calculation would be to determine both $\Delta H°$ and $\Delta S°$ and from them to calculate ΔG at 400 K.

Temperature Dependence of Vapor Pressure

Suppose pure liquid water is in equilibrium with its vapor at temperature *T*:

$$H_2O(\ell) \rightleftharpoons H_2O(g) \qquad P_{H_2O(g)} = K$$

The temperature dependence of *K* (and therefore of the vapor pressure $P_{H_2O(g)}$) can be described by the van't Hoff equation in the same way as chemical reactions. If ΔH_{vap} and ΔS_{vap} are approximately independent of temperature, then from the van't Hoff equation,

$$\ln\left(\frac{K_2}{K_1}\right) = \ln\left(\frac{P_2}{P_1}\right) = -\frac{\Delta H_{vap}}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

where P_2 and P_1 are the vapor pressures at temperatures T_2 and T_1. From this equation, the vapor pressure at any given temperature can be estimated if its value at some other temperature is known and if the enthalpy of vaporization is also known.

At the normal boiling point of a substance, T_b, the vapor pressure is 1 atm. If T_1 is taken to correspond to T_b and T_2 to some other temperature T, the van't Hoff equation is

$$\ln P = -\frac{\Delta H_{vap}}{R}\left[\frac{1}{T} - \frac{1}{T_b}\right] \qquad [14.13]$$

where P is the vapor pressure at temperature T, expressed in atmospheres.

EXAMPLE 14.17

The ΔH_{vap} for water is 40.66 kJ mol^{-1} at the normal boiling point, T_b = 373 K. Assuming ΔH_{vap} and ΔS_{vap} are approximately independent of temperature from 50°C to 100°C, estimate the vapor pressure of water at 50°C (323 K).

Solution

$$\ln P_{323} = \frac{-40660 \text{ J mol}^{-1}}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}}\left[\frac{1}{323 \text{ K}} - \frac{1}{373 \text{ K}}\right] = -2.03$$

$$P_{323} = 0.13 \text{ atm}$$

This differs slightly from the experimental value, 0.1217 atm, because ΔH_{vap} *does* change with temperature, an effect that was neglected in the approximate calculation.

14.8 DISTRIBUTION OF A SINGLE SPECIES BETWEEN IMMISCIBLE PHASES: EXTRACTION AND SEPARATION PROCESSES

An important type of heterogeneous equilibrium involves partitioning a solute species between two immiscible solvent phases. Such equilibria are used in many separation processes in chemical research and in industry.

Suppose two immiscible liquids, such as water and carbon tetrachloride, are put in a container. "Immiscible" means mutually insoluble; these liquids separate into two phases with the less dense liquid, in this case water, lying on top of the other liquid. A visible boundary, the meniscus, separates the two phases. If a solute such as iodine is added to the mixture and the vessel is shaken to distribute the iodine through the container (Fig. 14.13), the iodine is partitioned between the two phases at equilibrium with a characteristic concentration ratio, the **partition coefficient** K. This is the equilibrium constant for the process

$$I_2(aq) \rightleftharpoons I_2(CCl_4)$$

and can be written as

$$\frac{[I_2]_{CCl_4}}{[I_2]_{aq}} = K$$

in which $[I_2]_{CCl_4}$ and $[I_2]_{aq}$ are the concentrations (in moles per liter) of I_2 in the CCl_4 and aqueous phases, respectively. At 25°C, K has the value 85 for this equi-

Cengage Learning/Leon Lewandowski

FIGURE 14.13 Iodine is dissolved in water and poured on top of carbon tetrachloride in a separatory funnel (left). After the funnel is shaken (right), the iodine reaches a partition equilibrium between the upper (aqueous) phase and the lower (CCl_4) phase. The deeper color in the lower phase indicates that iodine dissolves preferentially in the denser CCl_4 phase.

librium. The fact that K is greater than 1 shows that iodine is more soluble in CCl_4 than in water. If iodide ion (I^-) is dissolved in the water, then it can react with iodine to form the triiodide ion I_3^-:

$$I_2(aq) + I^-(aq) \longrightarrow I_3^-(aq)$$

This consumes $I_2(aq)$ and, by Le Châtelier's principle, causes more I_2 in the first equilibrium to move from the CCl_4 phase to the aqueous phase.

Extraction Processes

Extraction takes advantage of the partitioning of a solute between two immiscible solvents to remove that solute from one solvent into another. Suppose iodine is present as a contaminant in water that also contains other solutes that are insoluble in carbon tetrachloride. In such a case, most of the iodine could be removed by shaking the aqueous solution with CCl_4, allowing the two phases to separate, and then pouring off the water layer from the heavier layer of carbon tetrachloride. The greater the equilibrium constant for the partition of a solute from the original solvent into the extracting solvent, the more complete such a separation will be.

EXAMPLE 14.18

An aqueous solution has an iodine concentration of 2.00×10^{-3} M. Calculate the percentage of iodine remaining in the aqueous phase after extraction of 0.100 L of this aqueous solution with 0.050 L of CCl_4 at 25°C.

Solution

The number of moles of I_2 present is

$$(2.00 \times 10^{-3} \text{ mol L}^{-1})(0.100\ L) = 2.00 \times 10^{-4} \text{ mol}$$

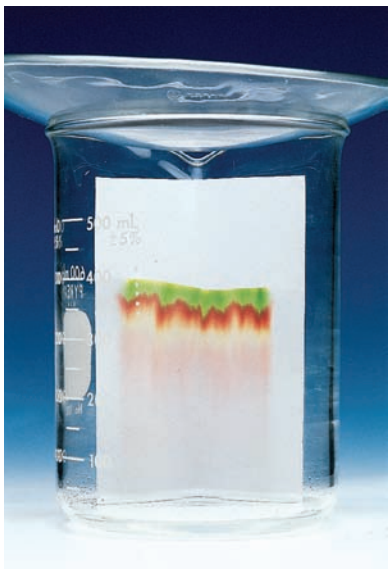
Suppose that y mol remains in the aqueous phase and $(2.00 \times 10^{-4} - y)$ mol passes into the CCl_4 phase. Then

$$\frac{[I_2]_{CCl_4}}{[I_2]_{aq}} = K = 85$$

$$= \frac{(2.00 \times 10^{-4} - y)/0.050}{y/0.100}$$

$$= \frac{2(2.00 \times 10^{-4} - y)}{y}$$

Note that the volumes of the two solvents used are unchanged because they are immiscible. Solving for y gives



$$y = 4.6 \times 10^{-6} \text{ mol}$$

The fraction remaining in the aqueous phase is $(4.6 \times 10^{-6})/(2.0 \times 10^{-4}) = 0.023$, or 2.3%. Additional extractions could be carried out to remove more of the I_2 from the aqueous phase.

Paper chromatography separates a line of ink, drawn across the bottom of the paper, into its component colors. As the water rises through the paper, the different components of the ink are attracted differently to the water and the paper and are separated.

monia phase in preference over the aqueous phase. The heavier aqueous phase is added to the top of an extraction vessel filled with ammonia, and equilibrium is reached as droplets of it settle through the ammonia phase to the bottom. This procedure reduces impurity concentrations in the sodium hydroxide solution to about 0.08% NaCl and 0.0002% $NaClO_3$.

Chromatographic Separations

Partition equilibria are the basis of an important class of separation techniques called **chromatography**. This word comes from the Greek root *chroma,* meaning "color," and was chosen because the original chromatographic separations involved colored substances. The technique can be applied to a variety of mixtures of substances.

Chromatography is a continuous extraction process in which solute species are exchanged between two phases. One, the mobile phase, moves with respect to the other, stationary phase. The partition ratio K of a solute A between the stationary and mobile phases is

$$\frac{[A]_{stationary}}{[A]_{mobile}} = K$$

As the mobile phase containing solute passes over the stationary phase, the solute molecules move between the two phases. True equilibrium is never fully established because the motion of the fluid phase continually brings fresh solvent into contact with the stationary phase. Nevertheless, the partition coefficient K provides a guide to the behavior of a particular solute. The greater K is, the more time the solute spends in the stationary phase and therefore the slower its progress through the separation system. Solutes with different values of K are separated by their different rates of travel.

Different types of chromatography use different mobile and stationary phases; Table 14.1 lists some of the most important. **Column chromatography** (Fig. 14.14) uses a tube packed with a porous material, often a silica gel on which water has been adsorbed. Water is therefore the stationary liquid phase in this case. Other solvents such as pyridine or benzene are used in the mobile phase; in some cases it is most efficient to use different solvents in succession to separate the components of a solute mixture. As the solute fractions reach the bottom of the column, they are separated for analysis or use. Column chromatography is important in industry because it is easily increased from laboratory to production scale.

Gas–liquid chromatography (Fig. 14.15) is one of the most important separation techniques for modern chemical research. The stationary phase is again a liquid

TABLE 14.1

Chromatographic Separation Techniques[†]

Name	Mobile Phase	Stationary Phase
Gas–liquid	Gas	Liquid adsorbed on a porous solid in a tube
Gas–solid	Gas	Porous solid in a tube
Column	Liquid	Liquid adsorbed on a porous solid in a tubular column
Paper	Liquid	Liquid held in the pores of a thick paper
Thin layer	Liquid	Liquid or solid; solid is held on glass plate and liquid may be adsorbed on it
Ion exchange	Liquid	Solid (finely divided ion-exchange resin) in a tubular column

[†]Adapted from D. A. Skoog and D. M. West, *Analytical Chemistry* (Saunders College Publishing, Philadelphia, 1980), Table 18-1.

adsorbed on a porous solid, but the mobile phase is now gaseous. The sample is vaporized and passes through the column, carried in a stream of an inert gas such as helium or nitrogen. The residence time in the column depends on the partition coefficient of the solute species, allowing an efficient separation of mixtures. The solute leaving the column at a given time can be detected by a variety of techniques that produce a **gas chromatogram** with a peak corresponding to each solute species in the mixture. Gas–liquid chromatography is widely used for separating the products of organic reactions. It can also be used to determine the purity of substances, because even very small amounts of impurities appear clearly as separate peaks in the chromatogram. The technique is important in the separation and identification of trace amounts of possibly toxic substances in environmental and biological samples. Amounts on the order of parts per trillion (10^{-12} g in a 1-g sample) can be detected and identified.

CHAPTER SUMMARY

Most chemical reactions do not go to completion. They arrive at the equilibrium state, after which there is no further net change in the amount of products or reactants. At the microscopic level, the reaction continues in both forward and reverse directions, at equal rates in these opposing directions. So, chemical equilibrium—which we measure at the macroscopic level—is characterized by a dynamical balance of events on the microscopic level. At the equilibrium state, concentrations of products and reactants always satisfy the mass action law, and so are related by the equilibrium constant. The equilibrium constant is a unique property of each chemical reaction. Knowledge of the equilibrium constant enables us to calculate the equilibrium concentrations of products and reactants that result from any set of initial concentrations for that reaction. Equilibrium calculations have enormous predictive power for interpreting and optimizing the outcome of chemical reactions. Thermodynamics explains all the empirical observations of chemical equilibrium and provides means for quantitative predictions. Thermodynamics explains the form of the mass action law, shows how to calculate the equilibrium constant from tabulations of Gibbs free energy for products and reactants, explains the temperature dependence of the equilibrium constant, and predicts the direction of change in response to any disturbance of the equilibrium state.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 14.1 – The Nature of Chemical Equilibrium

Describe the nature of the equilibrium state in chemical reactions.

- The equilibrium state shows no macroscopic evidence of change. On the microscopic level it is a dynamic balance between forward and reverse processes. The equilibrium state is reached through a spontaneous process. It is the same regardless of whether it is approached from the reactant side of the chemical equation or from the product side.

Section 14.2 – The Empirical Law of Mass Action

Set up the equilibrium expression for homogeneous reactions in the gas phase (Problems 1–6).

- Starting from the balanced equation for the reaction, place the partial pressure of each product in the numerator of the equilibrium expression and the partial pressure of each reactant in the denominator. Raise each of these to a power

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

equal to its stoichiometric coefficient in the balanced reaction equation. The result is

$$\frac{P_C^c P_D^d}{P_A^a P_B^b} = K$$

- Each partial pressure is expressed in units of atm, and is understood to be relative to a reference state with $P_{ref} = 1_{atm}$. Thus K is a dimensionless quantity.

Set up the equilibrium expression for homogeneous reactions in solution (Problems 7–8).

- Proceed as for the gas phase example. The result is

$$\frac{[C]^c[D]^d}{[A]^a[B]^c} = K$$

- Each concentration is expressed in units of moles per liter, and is understood to be relative to a reference state with $C_{ref} = 1\text{mole L}^{-1}$. Thus K is a dimensionless quantity.

Set up the equilibrium expression for heterogeneous reactions (Problems 9–12).

- Proceed as in the previous cases, but representing the concentration of each product or reactant as its activity. The result is

$$\frac{a_C^c a_D^d}{a_A^a a_B^b} = K$$

- Each activity is expressed relative to the proper standard state ($a = 1$) for that species, so K is a dimensionless quantity. For practical calculations involving dilute solutions and gases at low pressure, replace a for a gas with its limiting form of partial pressure in atm, a for a solute with its concentration in moles per liter, and a for a pure solid or liquid with its reference state value $a = 1$.

Section 14.3 – Thermodynamic Description of the Equilibrium State

Relate the equilibrium constant of a reaction to its change in standard Gibbs free energy (Problems 13–16).

- Calculate ΔG the change in Gibbs free energy for the reaction by a three-step process: ΔG_1 is the change for taking reactants from their initial conditions to standard state conditions. ΔG_2 is the change for converting reactants to products at standard state conditions. ΔG_3 is the change for taking products from standard state conditions to their final conditions. The equilibrium condition $\Delta G = 0$ leads to the relation $-\Delta G^o = RT \ln K(T)$ from which we calculate $K(T)$ by first calculating the change in standard Gibbs free energy. Pay careful attention to the reference state for each standard free energy value you use in these calculations.

Section 14.4 – The Law of Mass Action for Related and Simultaneous Equilibria

Combine the equilibrium constants for individual reactions to obtain net equilibrium constants for combined reactions (Problems 17–20).

- $K_{reverse} = 1/K_{forward}$
- K (equation multiplied by n) $= K^n$
- $K_3 = K_1 K_2 \ldots$ when a series of reactions is added to give an overall reaction.

Section 14.5 – Equilibrium Calculations for Gas-Phase and Heterogeneous Reactions

Calculate equilibrium constants from experimental measurements of partial and total pressures (Problems 21–26).

- Substitute experimental results measured at equilibrium into the equilibrium expression and evaluate K. If the equilibrium partial pressures are not known

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

directly, they can be calculated from other experimental data and then substituted into the equilibrium expression to determine K. The procedures are illustrated in Examples 14.9 and 14.10.

Calculate the equilibrium partial pressures of all species involved in a gas-phase or gas-solid reaction from the initial pressure(s) of the reactants (Problems 27–36).

- Assume that partial pressure of one of the species decreases by y atm while reaching the equilibrium state. Use the coefficients in the balanced reaction to write an equation for the partial pressure of each species at equilibrium in terms of y. Substitute these equilibrium partial pressures into the equilibrium relation, solve for y, and evaluate the partial pressure of each species at equilibrium.

Relate concentrations to partial pressures in equilibrium calculations (Problems 37–38).

- Define the concentration for each species A as the number of moles of A per unit volume, $[A] = n_A/V$, and relate this to the partial pressure of A through the ideal gas law $P_A = RT[A]$. Substitute the partial pressure for each species, divided by P_{ref}, into the equilibrium expression, insert the value of K, and solve to obtain the equilibrium concentration of each species.

Section 14.6 – The Direction of Change in Chemical Reactions: Empirical Description

Determine the direction in which a chemical reaction will proceed spontaneously by calculating its reaction quotient (Problems 45–46).

- Calculate the reaction quotient from the experimental data at a particular experimental condition. Compare the magnitude of Q at that condition to K and predict the direction of the reaction from the following guidelines:
- $Q = \dfrac{P_C^c P_D^d}{P_A^a P_B^b}$
- $Q < K \Rightarrow$ reaction moves to the right.
- $Q = K \Rightarrow$ system at equilibrium, no reaction.
- $Q > K \Rightarrow$ reaction moves to the left.

State Le Châtelier's principle and give several applications (Problems 47–58).

- Le Châtelier's Principle—A system in equilibrium that is subjected to a stress will react in a way to partially counteract the stress. Several specific cases are:
  - Stress 1: Increase concentration or pressure of species A.
  - Response 1: Reaction will move in appropriate direction to decrease A.
  - Stress 2: Increase pressure.
  - Response 2: Reaction will move in the direction that produces fewer molecules in order to decrease the pressure.
  - Stress 3: Decrease volume (same as increase pressure).
  - Response 3: Reaction moves in the direction that produces fewer molecules in order to decrease the pressure.
  - Stress 4: Increase temperature.
  - Response 4: Reaction moves in appropriate direction to absorb heat and decrease the temperature.

Section 14.7 – The Direction of Change in Chemical Reactions: Thermodynamics Explanation

Relate the temperature dependence of the equilibrium constant for a reaction to the standard enthalpy change for the reaction (Problems 59–70).

- Over temperature ranges where the standard enthalpy change of the reaction and the standard entropy change do not depend on temperature, the values of K at two different temperatures are related by the van't Hoff equation:

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

$$\ln\left(\frac{K_2}{K_1}\right) = -\frac{\Delta H^\circ}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right]$$

- This equation shows that K increases with temperature for endothermic reactions and decreases with T for exothermic reactions, as predicted by the principle of Le Châtelier.

Section 14.8 – Distribution of a Single Species between Immiscible Phases: Extraction and Separation Processes

Use the law of mass action to explain the distribution of a solute between two immiscible solvents (Problems 71–74).

- Distribution of a solute between immiscible phases is a concrete illustration of the spontaneous transfer of molecules across a boundary internal to the system, at fixed T and P, as described in Figure 13.7. The law of mass action characterizes the equilibrium state after such processes, giving the relative amounts of solute in the two phases. The partition coefficient, analogous to the chemical equilibrium constant, determines the distribution between phases.

Outline the basis for separation of compounds by partition chromatography.

- Partition chromatography relies on a mobile phase containing the solute flowing past a fresh solvent into which the solute is extracted. The effectiveness of the fresh solvent in extracting the solute is determined by the partition coefficient for the solute between the two immiscible solvents chosen for the process.

CUMULATIVE EXERCISE

Gunter Marx Photography/CORBIS

A stockpile of sulfur near chemical plants in Los Angeles.

This cumulative exercise is divided into two parts. Readers who have not yet studied thermodynamics should stop after Part 1; those who have studied thermodynamics should continue with Part 2.

Production of Sulfuric Acid—Part 1

Sulfuric acid is produced in larger volume than any other chemical and has a tremendous number of applications, ranging from fertilizer manufacture to metal treatment and chemical synthesis.

The modern industrial production of sulfuric acid involves three steps, for which the balanced chemical equations are:

1. $S(s) + O_2(g) \rightleftharpoons SO_2(g)$
2. $SO_2(g) + \frac{1}{2}O_2(g) \rightleftharpoons SO_3(g)$
3. $SO_3(g) + H_2O(\ell) \rightleftharpoons H_2SO_4(\ell)$

(a) Write an equilibrium expression for each of these steps, with equilibrium constants K_1, K_2, and K_3.

(b) If these reactions could be carried out at 25°C, the equilibrium constants would be 3.9×10^{52}, 2.6×10^{12}, and 2.6×10^{14}. Write a balanced equation for the overall reaction and calculate its equilibrium constant at 25°C.

(c) Although the products of all three equilibria are strongly favored at 25°C [See the data given in part (b)], reactions 1 and 2 occur too slowly to be practical; they must be carried out at elevated temperatures. At 700°C, the partial pressures of SO_2, O_2, and SO_3 in an equilibrium mixture are measured to be 2.23 atm, 1.14 atm, and 6.26 atm, respectively. Calculate K_2 at 700°C.

(d) At 300°C, K_2 has the value 1.3×10^4. Suppose some SO_3 is introduced into an evacuated vessel at an initial partial pressure of 0.89 atm. Calculate the partial pressure of SO_2 that will be reached at equilibrium, assuming that only reaction 2 takes place under these conditions. (*Hint:* K_2 is large enough that you can assume the fraction of SO_3 dissociated is very small.)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(e) Some SO_2 is placed in a flask and heated with oxygen to 600°C, at which point $K_2 = 9.5$. At equilibrium, 62% of it has reacted to give SO_3. Calculate the partial pressure of oxygen at equilibrium in this reaction mixture.

(f) Equal numbers of moles of SO_2, O_2, and SO_3 are mixed and heated to 600°C, where their total pressure before reaction is 0.090 atm. Will reaction 2 occur from right to left or from left to right? Will the total pressure increase or decrease during the course of the reaction?

(g) Reactions 1 and 3 are both exothermic. State the effects on equilibria 1 and 3 of increasing the temperature and of decreasing the volume. (*Note:* A change in volume has little effect on liquids and solids taking part in a reaction.)

Answers—Part 1

(a) $\dfrac{P_{SO_2}}{P_{O_2}} = K_1 \qquad \dfrac{P_{SO_3}}{P_{SO_2}P_{O_2}^{1/2}} = K_2 \qquad \dfrac{1}{P_{SO_3}} = K_3$

(b) $S(s) + \frac{3}{2}O_2(g) + H_2O(\ell) \rightleftharpoons H_2SO_4(\ell)$; $K = K_1K_2K_3 = 2.2 \times 10^{79}$

(c) K_2 is 2.63.

(d) The SO_2 partial pressure is 2.1×10^{-3} atm.

(e) The O_2 partial pressure is 0.029 atm.

(f) Left to right; pressure will decrease.

(g) Increasing the temperature will shift both equilibria to the left. Decreasing the volume will not affect equilibrium 1 and will shift equilibrium 3 to the right.

Production of Sulfuric Acid—Part 2

We continue with examination of reactions 1, 2, and 3 in the production of sulfuric acid.

(h) Calculate $\Delta G°$ for each reaction at 25°C. (Standard state of sulfur is rhombic.)

(i) Write a balanced equation for the overall reaction, and calculate its value of $\Delta G°$ at 25°C.

(j) Part (h) shows all three reactions are spontaneous at 25°C. Nonetheless, reactions 1 and 2 occur too slowly at 25°C to be practical; they must be carried out at higher temperatures. Calculate $\Delta G°$ for 1, 2, and 3 at 700°C.

(k) Determine the highest temperature at which all three reactions are spontaneous.

Answers—Part 2

(h) At 25°C: $\Delta G_1^\circ = -300.19$ kJ mol^{-1}; $\Delta G_2^\circ = -70.86$ kJ mol^{-1}; $\Delta G_3^\circ = -81.64$ kJ mol^{-1}

(i) $S(s) + \frac{3}{2}O_2(g) + H_2O(\ell) \rightleftharpoons H_2SO_4(\ell)$; $\Delta G_{net}^\circ = -452.89$ kJ mol^{-1}

(j) At 700° C: $\Delta G_1^\circ = -307.81$ kJ mol^{-1}; $\Delta G_2^\circ = -7.47$ kJ mol^{-1}; $\Delta G_3^\circ = +32.64$ kJ mol^{-1}

(k) Because reaction 1 has $\Delta H° < 0$ and $\Delta S° > 0$, it is spontaneous at all temperatures. Because both reaction 2 and reaction 3 have $\Delta H° < 0$ and $\Delta S° < 0$, each is spontaneous at temperatures below the temperature T^* at which $\Delta G = 0$. With the higher ratio of $\Delta S°$ to $\Delta H°$, reaction 3 is the first to become nonspontaneous, at $T^* = 508$°C.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

The Empirical Law of Mass Action

1. Write equilibrium expressions for the following gas-phase reactions.
(a) $2\ H_2(g) + O_2(g) \rightleftharpoons 2\ H_2O(g)$
(b) $Xe(g) + 3\ F_2(g) \rightleftharpoons XeF_6(g)$
(c) $2\ C_6H_6(g) + 15\ O_2(g) \rightleftharpoons 12\ CO_2(g) + 6\ H_2O(g)$

2. Write equilibrium expressions for the following gas-phase reactions.
(a) $2\ Cl_2(g) + O_2(g) \rightleftharpoons 2\ Cl_2O(g)$
(b) $N_2(g) + O_2(g) + Br_2(g) \rightleftharpoons 2\ NOBr(g)$
(c) $C_3H_8(g) + 5\ O_2(g) \rightleftharpoons 3\ CO_2(g) + 4\ H_2O(g)$

3. At a moderately elevated temperature, phosphoryl chloride ($POCl_3$) can be produced in the vapor phase from the gaseous elements. Write a balanced chemical equation and an equilibrium expression for this system. Note that gaseous phosphorus consists of P_4 molecules at moderate temperatures.

4. If confined at high temperature, ammonia and oxygen quickly react and come to equilibrium with their products, water vapor and nitrogen oxide. Write a balanced chemical equation and an equilibrium expression for this system.

5. An important step in the industrial production of hydrogen is the reaction of carbon monoxide with water:

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

(a) Use the law of mass action to write the equilibrium expression for this reaction.
(b) At 500°C, the equilibrium constant for this reaction is 3.9. Suppose that the equilibrium partial pressures of CO and H_2O are both 0.10 atm and that of CO_2 is 0.70 atm. Calculate the equilibrium partial pressure of $H_2(g)$.

6. Phosgene ($COCl_2$) is an important intermediate in the manufacture of certain plastics. It is produced by the reaction

$$CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$$

(a) Use the law of mass action to write the equilibrium expression for this reaction.
(b) At 600°C, the equilibrium constant for this reaction is 0.20. Calculate the partial pressure of phosgene in equilibrium with a mixture of CO (at 0.0020 atm) and Cl_2 (at 0.00030 atm).

7. N_2O_4 is soluble in the solvent cyclohexane; however, dissolution does not prevent N_2O_4 from breaking down to give NO_2 according to the equation

$$N_2O_{4(\text{cyclohexane})} \rightleftharpoons 2\ NO_{2(\text{cyclohexane})}$$

An effort to compare this solution equilibrium with the similar equilibrium in the gas gave the following actual experimental data at 20°C:

$[N_2O_4]$ (mol L^{-1})	$[NO_2]$ (mol L^{-1})
0.190×10^{-3}	2.80×10^{-3}
0.686×10^{-3}	5.20×10^{-3}
1.54×10^{-3}	7.26×10^{-3}
2.55×10^{-3}	10.4×10^{-3}
3.75×10^{-3}	11.7×10^{-3}
7.86×10^{-3}	17.3×10^{-3}
11.9×10^{-3}	21.0×10^{-3}

(a) Graph the *square* of the concentration of NO_2 versus the concentration of N_2O_4.
(b) Compute the average equilibrium constant of this reaction.

8. NO_2 is soluble in carbon tetrachloride (CCl_4). As it dissolves, it dimerizes to give N_2O_4 according to the equation

$$2\ NO_{2(CCl_4)} \rightleftharpoons N_2O_{4(CCl_4)}$$

A study of this equilibrium gave the following experimental data at 20°C:

$[N_2O_4]$ (mol L^{-1})	$[NO_2]$ (mol L^{-1})
0.192×10^{-3}	2.68×10^{-3}
0.721×10^{-3}	4.96×10^{-3}
1.61×10^{-3}	7.39×10^{-3}
2.67×10^{-3}	10.2×10^{-3}
3.95×10^{-3}	11.0×10^{-3}
7.90×10^{-3}	16.6×10^{-3}
11.9×10^{-3}	21.4×10^{-3}

(a) Graph the concentration of N_2O_4 versus the *square* of the concentration of NO_2.
(b) Compute the average equilibrium constant of this reaction.

9. Using the law of mass action, write the equilibrium expression for each of the following reactions.
(a) $8\ H_2(g) + S_8(s) \rightleftharpoons 8\ H_2S(g)$
(b) $C(s) + H_2O(\ell) + Cl_2(g) \rightleftharpoons COCl_2(g) + H_2(g)$
(c) $CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$
(d) $3\ C_2H_2(g) \rightleftharpoons C_6H_6(\ell)$

10. Using the law of mass action, write the equilibrium expression for each of the following reactions.
(a) $3\ C_2H_2(g) + 3\ H_2(g) \rightleftharpoons C_6H_{12}(\ell)$
(b) $CO_2(g) + C(s) \rightleftharpoons 2\ CO(g)$
(c) $CF_4(g) + 2\ H_2O(\ell) \rightleftharpoons CO_2(g) + 4\ HF(g)$
(d) $K_2NiF_6(s) + TiF_4(s) \rightleftharpoons K_2TiF_6(s) + NiF_2(s) + F_2(g)$

11. Using the law of mass action, write the equilibrium expression for each of the following reactions.
(a) $Zn(s) + 2\ Ag^+(aq) \rightleftharpoons Zn^{2+}(aq) + 2\ Ag(s)$
(b) $VO_4^{3-}(aq) + H_2O(\ell) \rightleftharpoons VO_3(OH)^{2-}(aq) + OH^-(aq)$
(c) $2\ As(OH)_6^{3-}(aq) + 6\ CO_2(g) \rightleftharpoons As_2O_3(s) + 6\ HCO_3^-(aq) + 3\ H_2O(\ell)$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

12. Using the law of mass action, write the equilibrium expression for each of the following reactions.
(a) $6\ I^-(aq) + 2MnO_4^-(aq) + 4\ H_2O(\ell) \rightleftharpoons 3\ I_2(aq) + 2\ MnO_2(s) + 8\ OH^-(aq)$
(b) $2\ Cu^{2+}(aq) + 4\ I^-(aq) \rightleftharpoons 2\ CuI(s) + I_2(aq)$
(c) $\frac{1}{2}\ O_2(g) + Sn^{2+}(aq) + 3\ H_2O(\ell) \rightleftharpoons SnO_2(s) + 2\ H_3O^+(aq)$

Thermodynamic Description of the Equilibrium State

13. Calculate $\Delta G°$ and the equilibrium constant K at 25°C for the reaction

$$2\ NH_3(g) + \tfrac{7}{2}\ O_2(g) \rightleftharpoons 2\ NO_2(g) + 3\ H_2O(g)$$

using data in Appendix D.

14. Write a reaction for the dehydrogenation of gaseous ethane (C_2H_6) to acetylene (C_2H_2). Calculate $\Delta G°$ and the equilibrium constant for this reaction at 25°C, using data from Appendix D.

15. Use the thermodynamic data from Appendix D to calculate the equilibrium constant at 25°C for the following reactions:
(a) $SO_2(g) + \frac{1}{2}\ O_2(g) \rightleftharpoons SO_3(g)$
(b) $3\ Fe_2O_3(s) \rightleftharpoons 2\ Fe_3O_4(s) + \frac{1}{2}\ O_2(g)$
(c) $CuCl_2(s) \rightleftharpoons Cu^{2+}(aq) + 2\ Cl^-(aq)$
Write the equilibrium expression for each reaction.

16. Use the thermodynamic data from Appendix D to calculate equilibrium constants at 25°C for the following reactions.
(a) $H_2(g) + N_2(g) + 2\ O_2(g) \rightleftharpoons 2\ HNO_2(g)$
(b) $Ca(OH)_2(s) \rightleftharpoons CaO(s) + H_2O(g)$
(c) $Zn^{2+}(aq) + 4\ NH_3(aq) \rightleftharpoons Zn(NH_3)_2^{2+}(aq)$
Write the equilibrium expression for each reaction.

The Law of Mass Action for Related and Simultaneous Equilibria

17. At a certain temperature, the value of the equilibrium constant for the reaction

$$CS_2(g) + 3\ O_2(g) \rightleftharpoons CO_2(g) + 2\ SO_2(g)$$

is K_1. How is K_1 related to the equilibrium constant K_2 for the related equilibrium

$$\tfrac{1}{3}\ CS_2(g) + O_2(g) \rightleftharpoons \tfrac{1}{3}\ CO_2(g) + \tfrac{2}{3}\ SO_2(g)$$

at the same temperature?

18. At 25°C, the equilibrium constant for the reaction

$$6\ ClO_3F(g) \rightleftharpoons 2\ ClF(g) + 4\ ClO(g) + 7\ O_2(g) + 2\ F_2(g)$$

is 32.6. Calculate the equilibrium constant at 25°C for the reaction

$$\tfrac{1}{3}\ ClF(g) + \tfrac{2}{3}\ ClO(g) + \tfrac{7}{6}\ O_2(g) + \tfrac{1}{3}\ F_2(g) \rightleftharpoons ClO_3F(g)$$

19. Suppose that K_1 and K_2 are the respective equilibrium constants for the two reactions

$$XeF_6(g) + H_2O(g) \rightleftharpoons XeOF_4(g) + 2\ HF(g)$$

$$XeO_4(g) + XeF_6(g) \rightleftharpoons XeOF_4(g) + XeO_3F_2(g)$$

Give the equilibrium constant for the reaction

$$XeO_4(g) + 2\ HF(g) \rightleftharpoons XeO_3F_2(g) + H_2O(g)$$

in terms of K_1 and K_2.

20. At 1330 K, germanium(II) oxide (GeO) and tungsten(VI) oxide (W_2O_6) are both gases. The following two equilibria are established simultaneously:

$$2\ GeO(g) + W_2O_6(g) \rightleftharpoons 2\ GeWO_4(g)$$

$$GeO(g) + W_2O_6(g) \rightleftharpoons GeW_2O_7(g)$$

The equilibrium constants for the two are respectively 7.0×10^3 and 38×10^3. Compute K for the reaction

$$GeO(g) + GeW_2O_7(g) \rightleftharpoons 2\ GeWO_4(g)$$

Equilibrium Calculations for Gas-Phase and Heterogeneous Reactions

21. At 454 K, $Al_2Cl_6(g)$ reacts to form $Al_3Cl_9(g)$ according to the equation

$$3\ Al_2Cl_6(g) \rightleftharpoons 2\ Al_3Cl_9(g)$$

In an experiment at this temperature, the equilibrium partial pressure of $Al_2Cl_6(g)$ is 1.00 atm and the equilibrium partial pressure of $Al_3Cl_9(g)$ is 1.02×10^{-2} atm. Compute the equilibrium constant of the preceding reaction at 454 K.

22. At 298 K, $F_3SSF(g)$ decomposes partially to $SF_2(g)$. At equilibrium, the partial pressure of $SF_2(g)$ is 1.1×10^{-4} atm and the partial pressure of F_3SSF is 0.0484 atm.
(a) Write a balanced equilibrium equation to represent this reaction.
(b) Compute the equilibrium constant corresponding to the equation you wrote.

23. The compound 1,3-di-*t*-butylcyclohexane exists in two forms that are known as the chair and boat conformations because their molecular structures resemble those objects. Equilibrium exists between the two forms, represented by the equation

$$\text{chair} \rightleftharpoons \text{boat}$$

At 580 K, 6.42% of the molecules are in the chair form. Calculate the equilibrium constant for the preceding reaction as written.

24. At 248°C and a total pressure of 1.000 atm, the fractional dissociation of $SbCl_5$ is 0.718 for the reaction

$$SbCl_5(g) \rightleftharpoons SbCl_3(g) + Cl_2(g)$$

This means that 718 of every 1000 molecules of $SbCl_5$ originally present have dissociated. Calculate the equilibrium constant.

25. Sulfuryl chloride (SO_2Cl_2) is a colorless liquid that boils at 69°C. Above this temperature, the vapors dissociate into sulfur dioxide and chlorine:

$$SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$$

This reaction is slow at 100°C, but it is accelerated by the presence of some $FeCl_3$ (which does not affect the final position of the equilibrium). In an experiment, 3.174 g of $SO_2Cl_2(\ell)$ and a small amount of solid $FeCl_3$ are put into an evacuated 1.000-L flask, which is then sealed and heated to 100°C. The total pressure in the flask at that temperature is found to be 1.30 atm.
(a) Calculate the partial pressure of each of the three gases present.
(b) Calculate the equilibrium constant at this temperature.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

26. A certain amount of NOBr(g) is sealed in a flask, and the temperature is raised to 350 K. The following equilibrium is established:

$$\mathrm{NOBr}(g) \rightleftharpoons \mathrm{NO}(g) + \tfrac{1}{2}\,\mathrm{Br_2}(g)$$

The total pressure in the flask when equilibrium is reached at this temperature is 0.675 atm, and the vapor density is 2.219 g L^{-1}.

(a) Calculate the partial pressure of each species.
(b) Calculate the equilibrium constant at this temperature.

27. The dehydrogenation of benzyl alcohol to make the flavoring agent benzaldehyde is an equilibrium process described by the equation

$$\mathrm{C_6H_5CH_2OH}(g) \rightleftharpoons \mathrm{C_6H_5CHO}(g) + \mathrm{H_2}(g)$$

At 523 K, the value of its equilibrium constant is $K = 0.558$.

(a) Suppose 1.20 g of benzyl alcohol is placed in a 2.00-L vessel and heated to 523 K. What is the partial pressure of benzaldehyde when equilibrium is attained?
(b) What fraction of benzyl alcohol is dissociated into products at equilibrium?

28. Isopropyl alcohol can dissociate into acetone and hydrogen:

$$(\mathrm{CH_3})_2\mathrm{CHOH}(g) \rightleftharpoons (\mathrm{CH_3})_2\mathrm{CO}(g) + \mathrm{H_2}(g)$$

At 179°C, the equilibrium constant for this dehydrogenation reaction is 0.444.

(a) If 10.00 g of isopropyl alcohol is placed in a 10.00-L vessel and heated to 179°C, what is the partial pressure of acetone when equilibrium is attained?
(b) What fraction of isopropyl alcohol is dissociated at equilibrium?

29. A weighed quantity of $PCl_5(s)$ is sealed in a 100.0-cm^3 glass bulb to which a pressure gauge is attached. The bulb is heated to 250°C, and the gauge shows that the pressure in the bulb rises to 0.895 atm. At this temperature, the solid PCl_5 is all vaporized and also partially dissociated into $Cl_2(g)$ and $PCl_3(g)$ according to the equation

$$\mathrm{PCl_5}(g) \rightleftharpoons \mathrm{PCl_3}(g) + \mathrm{Cl_2}(g)$$

At 250°C, $K = 2.15$ for this reaction. Assume that the contents of the bulb are at equilibrium and calculate the partial pressure of the three different chemical species in the vessel.

30. Suppose 93.0 g of HI(g) is placed in a glass vessel and heated to 1107 K. At this temperature, equilibrium is quickly established between HI(g) and its decomposition products, $H_2(g)$ and $I_2(g)$:

$$2\ \mathrm{HI}(g) \rightleftharpoons \mathrm{H_2}(g) + \mathrm{I_2}(g)$$

The equilibrium constant at 1107 K is 0.0259, and the total pressure at equilibrium is observed to equal 6.45 atm. Calculate the equilibrium partial pressures of HI(g), $H_2(g)$, and $I_2(g)$.

31. The equilibrium constant at 350 K for the reaction

$$\mathrm{Br_2}(g) + \mathrm{I_2}(g) \rightleftharpoons 2\ \mathrm{IBr}(g)$$

has a value of 322. Bromine at an initial partial pressure of 0.0500 atm is mixed with iodine at an initial partial pressure of 0.0400 atm and held at 350 K until equilibrium is reached. Calculate the equilibrium partial pressure of each of the gases.

32. The equilibrium constant for the reaction of fluorine and oxygen to form oxygen difluoride (OF_2) is 40.1 at 298 K:

$$\mathrm{F_2}(g) + \tfrac{1}{2}\,\mathrm{O_2}(g) \rightleftharpoons \mathrm{OF_2}(g)$$

Suppose some OF_2 is introduced into an evacuated container at 298 K and allowed to dissociate until its partial pressure reaches an equilibrium value of 1.00 atm. Calculate the equilibrium partial pressures of F_2 and O_2 in the container.

33. At 25°C, the equilibrium constant for the reaction

$$\mathrm{N_2}(g) + \mathrm{O_2}(g) \rightleftharpoons 2\ \mathrm{NO}(g)$$

is 4.2×10^{-31}. Suppose a container is filled with nitrogen (at an initial partial pressure of 0.41 atm), oxygen (at an initial partial pressure of 0.59 atm), and nitrogen oxide (at an initial partial pressure of 0.22 atm). Calculate the partial pressures of all three gases after equilibrium is reached at this temperature.

34. At 25°C, the equilibrium constant for the reaction

$$2\ \mathrm{NO_2}(g) \rightleftharpoons 2\ \mathrm{NO}(g) + \mathrm{O_2}(g)$$

is 5.9×10^{-13}. Suppose a container is filled with nitrogen dioxide at an initial partial pressure of 0.89 atm. Calculate the partial pressures of all three gases after equilibrium is reached at this temperature.

* **35.** The equilibrium constant for the synthesis of ammonia

$$\mathrm{N_2}(g) + 3\ \mathrm{H_2}(g) \rightleftharpoons 2\ \mathrm{NH_3}(g)$$

has the value $K = 6.78 \times 10^5$ at 25°C. Calculate the equilibrium partial pressures of $N_2(g)$, $H_2(g)$, and $NH_3(g)$ at 25°C if the total pressure is 1.00 atm and the H:N atom ratio in the system is 3:1. (*Hint:* Try the approximation that P_{N_2} and $P_{H_2} \ll P_{NH_3}$ and see if the resulting equations are simplified.)

* **36.** At 400°C, $K = 3.19 \times 10^{-4}$ for the reaction in problem 35. Repeat the calculation for P_{N_2}, P_{H_2}, and P_{NH_3} assuming the same total pressure and composition. (*Hint:* Try the approximation that $P_{NH_3} \ll P_{N_2}$ and P_{H_2} and see if the resulting equations are simplified.)

37. Calculate the concentration of phosgene ($COCl_2$) that will be present at 600°C in equilibrium with carbon monoxide (at a concentration of 2.3×10^{-4} mol L^{-1}) and chlorine (at a concentration of 1.7×10^{-2} mol L^{-1}). (Use the data of problem 6.)

38. The reaction

$$\mathrm{SO_2Cl_2}(g) \rightleftharpoons \mathrm{SO_2}(g) + \mathrm{Cl_2}(g)$$

has an equilibrium constant at 100°C of 2.40. Calculate the concentration of SO_2 that will be present at 100°C in equilibrium with SO_2Cl_2 (at a concentration of 3.6×10^{-4} mol L^{-1}) and chlorine (at a concentration of 6.9×10^{-3} mol L^{-1}).

39. At 298 K, the equilibrium constant for the reaction

$$\mathrm{Fe_2O_3}(s) + 3\ \mathrm{H_2}(g) \rightleftharpoons 2\ \mathrm{Fe}(s) + 3\ \mathrm{H_2O}(\ell)$$

is 4.0×10^{-6}, and that for

$$\mathrm{CO_2}(g) + \mathrm{H_2}(g) \rightleftharpoons \mathrm{CO}(g) + \mathrm{H_2O}(\ell)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is 3.2×10^{-4}. Suppose some solid Fe_2O_3, solid Fe, and liquid H_2O are brought into equilibrium with $CO(g)$ and $CO_2(g)$ in a closed container at 298 K. Calculate the ratio of the partial pressure of $CO(g)$ to that of $CO_2(g)$ at equilibrium.

40. A sample of ammonium carbamate placed in a glass vessel at 25°C undergoes the reaction

$$NH_4OCONH_2(s) \rightleftharpoons 2\ NH_3(g) + CO_2(g)$$

The total pressure of gases in equilibrium with the solid is found to be 0.115 atm.
(a) Calculate the partial pressures of NH_3 and CO_2.
(b) Calculate the equilibrium constant at 25°C.

41. The equilibrium constant for the reaction

$$NH_3(g) + HCl(g) \rightleftharpoons NH_4Cl(s)$$

at 340°C is $K = 4.0$.
(a) If the partial pressure of ammonia is $P_{NH_3} = 0.80$ atm and solid ammonium chloride is present, what is the equilibrium partial pressure of hydrogen chloride at 340°C?
(b) An excess of solid NH_4Cl is added to a container filled with ammonia at 340°C and a pressure of 1.50 atm. Calculate the pressures of $NH_3(g)$ and $HCl(g)$ reached at equilibrium.

42. The equilibrium constant for the reaction

$$H_2(g) + I_2(s) \rightleftharpoons 2\ HI(g)$$

at 25°C is $K = 0.345$.
(a) If the partial pressure of hydrogen is $P_{H_2} = 1.00$ atm and solid iodine is present, what is the equilibrium partial pressure of hydrogen iodide, P_{HI}, at 25°C?
(b) An excess of solid I_2 is added to a container filled with hydrogen at 25°C and a pressure of 4.00 atm. Calculate the pressures of $H_2(g)$ and $HI(g)$ reached at equilibrium.

43. Pure solid NH_4HSe is placed in an evacuated container at 24.8°C. Eventually, the pressure above the solid reaches the equilibrium pressure 0.0184 atm due to the reaction

$$NH_4HSe(s) \rightleftharpoons NH_3(g) + H_2Se(g)$$

(a) Calculate the equilibrium constant of this reaction at 24.8°C.
(b) In a different container, the partial pressure of $NH_3(g)$ in equilibrium with $NH_4HSe(s)$ at 24.8°C is 0.0252 atm. What is the partial pressure of $H_2Se(g)$?

44. The total pressure of the gases in equilibrium with solid sodium hydrogen carbonate at 110°C is 1.648 atm, corresponding to the reaction

$$2\ NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + H_2O(g) + CO_2(g)$$

($NaHCO_3$ is used in dry chemical fire extinguishers because the products of this decomposition reaction smother the fire.)
(a) Calculate the equilibrium constant at 110°C.
(b) What is the partial pressure of water vapor in equilibrium with $NaHCO_3(s)$ at 110°C if the partial pressure of $CO_2(g)$ is 0.800 atm?

The Direction of Change in Chemical Reactions: Empirical Description

45. Some Al_2Cl_6 (at a partial pressure of 0.473 atm) is placed in a closed container at 454 K with some Al_3Cl_9 (at a partial pressure of 1.02×10^{-2} atm). Enough argon is added to raise the total pressure to 1.00 atm.
(a) Calculate the initial reaction quotient for the reaction

$$3\ Al_2Cl_6(g) \rightleftharpoons 2\ Al_3Cl_9(g)$$

(b) As the gas mixture reaches equilibrium, will there be net production or consumption of Al_3Cl_9? (Use the data given in problem 21.)

46. Some SF_2 (at a partial pressure of 2.3×10^{-4} atm) is placed in a closed container at 298 K with some F_3SSF (at a partial pressure of 0.0484 atm). Enough argon is added to raise the total pressure to 1.000 atm.
(a) Calculate the initial reaction quotient for the decomposition of F_3SSF to SF_2.
(b) As the gas mixture reaches equilibrium, will there be net formation or dissociation of F_3SSF? (Use the data given in problem 22.)

47. The progress of the reaction

$$H_2(g) + Br_2(g) \rightleftharpoons 2\ HBr(g)$$

can be monitored visually by following changes in the color of the reaction mixture (Br_2 is reddish brown, and H_2 and HBr are colorless). A gas mixture is prepared at 700 K, in which 0.40 atm is the initial partial pressure of both H_2 and Br_2 and 0.90 atm is the initial partial pressure of HBr. The color of this mixture then fades as the reaction progresses toward equilibrium. Give a condition that must be satisfied by the equilibrium constant K (for example, it must be greater than or smaller than a given number).

48. Recall from our discussion of the NO_2–N_2O_4 equilibrium that NO_2 has a brownish color. At elevated temperatures, NO_2 reacts with CO according to

$$NO_2(g) + CO(g) \rightleftharpoons NO(g) + CO_2(g)$$

The other three gases taking part in this reaction are colorless. When a gas mixture is prepared at 500 K, in which 3.4 atm is the initial partial pressure of both NO_2 and CO, and 1.4 atm is the partial pressure of both NO and CO_2, the brown color of the mixture is observed to fade as the reaction progresses toward equilibrium. Give a condition that must be satisfied by the equilibrium constant K (for example, it must be greater than or smaller than a given number).

49. The equilibrium constant for the "water gas" reaction

$$C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g)$$

is $K = 2.6$ at a temperature of 1000 K. Calculate the reaction quotient Q for each of the following conditions, and state which direction the reaction shifts in coming to equilibrium.
(a) $P_{H_2O} = 0.600$ atm; $P_{CO} = 1.525$ atm; $P_{H_2} = 0.805$ atm
(b) $P_{H_2O} = 0.724$ atm; $P_{CO} = 1.714$ atm; $P_{H_2} = 1.383$ atm

50. The equilibrium constant for the reaction

$$H_2S(g) + I_2(g) \rightleftharpoons 2\ HI(g) + S(s)$$

at 110°C is equal to 0.0023. Calculate the reaction quotient Q for each of the following conditions and determine whether solid sulfur is consumed or produced as the reaction comes to equilibrium.
(a) $P_{I_2} = 0.461$ atm; $P_{H_2S} = 0.050$ atm; $P_{HI} = 0.0$ atm
(b) $P_{I_2} = 0.461$ atm; $P_{H_2S} = 0.050$ atm; $P_{HI} = 9.0$ atm

51. At $T = 1200$°C the reaction

$$P_4(g) \rightleftharpoons 2\ P_2(g)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

has an equilibrium constant $K = 0.612$.

(a) Suppose the initial partial pressure of P_4 is 5.00 atm and that of P_2 is 2.00 atm. Calculate the reaction quotient Q and state whether the reaction proceeds to the right or to the left as equilibrium is approached.
(b) Calculate the partial pressures at equilibrium.
(c) If the volume of the system is then increased, will there be net formation or net dissociation of P_4?

52. At $T = 100°C$ the reaction

$$SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$$

has an equilibrium constant $K = 2.4$.

(a) Suppose the initial partial pressure of SO_2Cl_2 is 1.20 atm, and $P_{SO_2} = P_{Cl_2} = 0$. Calculate the reaction quotient Q and state whether the reaction proceeds to the right or to the left as equilibrium is approached.
(b) Calculate the partial pressures at equilibrium.
(c) If the volume of the system is then decreased, will there be net formation or net dissociation of SO_2Cl_2?

53. Explain the effect of each of the following stresses on the position of the following equilibrium:

$$3\ NO(g) \rightleftharpoons N_2O(g) + NO_2(g)$$

The reaction as written is exothermic.

(a) $N_2O(g)$ is added to the equilibrium mixture without change of volume or temperature.
(b) The volume of the equilibrium mixture is reduced at constant temperature.
(c) The equilibrium mixture is cooled.
(d) Gaseous argon (which does not react) is added to the equilibrium mixture while both the total gas pressure and the temperature are kept constant.
(e) Gaseous argon is added to the equilibrium mixture without changing the volume.

54. Explain the effect of each of the following stresses on the position of the equilibrium

$$SO_3(g) \rightleftharpoons SO_2(g) + \tfrac{1}{2}\ O_2(g)$$

The reaction as written is endothermic.

(a) $O_2(g)$ is added to the equilibrium mixture without changing volume or temperature.
(b) The mixture is compressed at constant temperature.
(c) The equilibrium mixture is cooled.
(d) An inert gas is pumped into the equilibrium mixture while the total gas pressure and the temperature are kept constant.
(e) An inert gas is added to the equilibrium mixture without changing the volume.

55. In a gas-phase reaction, it is observed that the equilibrium yield of products is increased by lowering the temperature and by reducing the volume.

(a) Is the reaction exothermic or endothermic?
(b) Is there a net increase or a net decrease in the number of gas molecules in the reaction?

56. The equilibrium constant of a gas-phase reaction increases as temperature is increased. When the nonreacting gas neon is admitted to a mixture of reacting gases (holding the temperature and the total pressure fixed and increasing the volume of the reaction vessel), the product yield is observed to decrease.

(a) Is the reaction exothermic or endothermic?
(b) Is there a net increase or a net decrease in the number of gas molecules in the reaction?

57. The most extensively used organic compound in the chemical industry is ethylene (C_2H_4). The two equations

$$C_2H_4(g) + Cl_2(g) \rightleftharpoons C_2H_4Cl_2(g)$$

$$C_2H_4Cl_2(g) \rightleftharpoons C_2H_3Cl(g) + HCl(g)$$

represent the way in which vinyl chloride (C_2H_3Cl) is synthesized for eventual use in polymeric plastics (polyvinyl chloride, PVC). The byproduct of the reaction, HCl, is now most cheaply made by this and similar reactions, rather than by direct combination of H_2 and Cl_2. Heat is given off in the first reaction and taken up in the second. Describe how you would design an industrial process to maximize the yield of vinyl chloride.

58. Methanol is made via the exothermic reaction

$$CO(g) + 2\ H_2(g) \longrightarrow CH_3OH(g)$$

Describe how you would control the temperature and pressure to maximize the yield of methanol.

The Direction of Change in Chemical Reactions: Thermodynamic Explanation

59. One way to manufacture ethanol is by the reaction

$$C_2H_4(g) + H_2O(g) \rightleftharpoons C_2H_5OH(g)$$

The ΔH_f° of $C_2H_4(g)$ is 52.3 kJ mol^{-1}; of $H_2O(g)$, −241.8 kJ mol^{-1}; and of $C_2H_5OH(g)$, −235.3 kJ mol^{-1}. Without doing detailed calculations, suggest the conditions of pressure and temperature that will maximize the yield of ethanol at equilibrium.

60. Dimethyl ether (CH_3OCH_3) is a good substitute for environmentally harmful propellants in aerosol spray cans. It is produced by the dehydration of methanol:

$$2\ CH_3OH(g) \rightleftharpoons CH_3OCH_3(g) + H_2O(g)$$

Describe reaction conditions that favor the equilibrium production of this valuable chemical. As a basis for your answer, compute $\Delta H°$ and $\Delta S°$ of the reaction from the data in Appendix D.

61. The equilibrium constant at 25°C for the reaction

$$2\ NO_2(g) \rightleftharpoons N_2O_4(g)$$

is 6.8. At 200°C the equilibrium constant is 1.21×10^{-3}. Calculate the enthalpy change (ΔH) for this reaction, assuming that ΔH and ΔS of the reaction are constant over the temperature range from 25°C to 200°C.

62. Stearic acid dimerizes when dissolved in hexane:

$$2\ C_{17}H_{35}COOH(hexane) \rightleftharpoons (C_{17}H_{35}COOH)_2(hexane)$$

The equilibrium constant for this reaction is 2900 at 28°C, but it drops to 40 at 48°C. Estimate $\Delta H°$ and $\Delta S°$ for the reaction.

63. The equilibrium constant for the reaction

$$\tfrac{1}{2}\ Cl_2(g) + \tfrac{1}{2}\ F_2(g) \rightleftharpoons ClF(g)$$

is measured to be 9.3×10^9 at 298 K and 3.3×10^7 at 398 K.

(a) Calculate $\Delta G°$ at 298 K for the reaction.
(b) Calculate $\Delta H°$ and $\Delta S°$, assuming the enthalpy and entropy changes to be independent of temperature between 298 and 398 K.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

64. Stearic acid also dimerizes when dissolved in carbon tetrachloride:

$$2\ C_{17}H_{35}COOH(CCl_4) \rightleftharpoons (C_{17}H_{35}COOH)_2(CCl_4)$$

The equilibrium constant for this reaction is 2780 at 22°C, but it drops to 93.1 at 42°C. Estimate $\Delta H°$ and $\Delta S°$ for the reaction.

65. For the synthesis of ammonia from its elements,

$$3\ H_2(g) + N_2(g) \rightleftharpoons 2\ NH_3(g)$$

the equilibrium constant $K = 5.9 \times 10^5$ at 298 K, and $\Delta H° = -92.2\ \text{kJ mol}^{-1}$. Calculate the equilibrium constant for the reaction at 600 K, assuming no change in $\Delta H°$ and $\Delta S°$ between 298 K and 600 K.

66. The cumulative exercise at the end of Chapter 14 explored reaction steps in the manufacture of sulfuric acid, including the oxidation of sulfur dioxide to sulfur trioxide:

$$SO_2(g) + \tfrac{1}{2}\ O_2(g) \rightleftharpoons SO_3(g)$$

At 25°C the equilibrium constant for this reaction is 2.6×10^{12}, but the reaction occurs very slowly. Calculate K for this reaction at 550°C, assuming $\Delta H°$ and $\Delta S°$ are independent of temperature in the range from 25°C to 550°C.

67. The vapor pressure of ammonia at −50°C is 0.4034 atm; at 0°C, it is 4.2380 atm.

(a) Calculate the molar enthalpy of vaporization (ΔH_{vap}) of ammonia.

(b) Calculate the normal boiling temperature of $NH_3(\ell)$.

68. The vapor pressure of butyl alcohol (C_4H_9OH) at 70.1°C is 0.1316 atm; at 100.8°C, it is 0.5263 atm.

(a) Calculate the molar enthalpy of vaporization (ΔH_{vap}) of butyl alcohol.

(b) Calculate the normal boiling point of butyl alcohol.

69. Although iodine is not very soluble in pure water, it dissolves readily in water that contains $I^-(aq)$ ion, thanks to the reaction

$$I_2(aq) + I^-(aq) \rightleftharpoons I_3^-(aq)$$

The equilibrium constant of this reaction was measured as a function of temperature with these results:

T:	3.8°C	15.3°C	25.0°C	35.0°C	50.2°C
K:	1160	841	689	533	409

(a) Plot ln K on the y axis as a function of $1/T$, the reciprocal of the absolute temperature.

(b) Estimate the $\Delta H°$ of this reaction.

70. Barium nitride vaporizes slightly at high temperature as it undergoes the dissociation

$$Ba_3N_2(s) \rightleftharpoons 3\ Ba(g) + N_2(g)$$

At 1000 K the equilibrium constant is 4.5×10^{-19}. At 1200 K the equilibrium constant is 6.2×10^{-12}.

(a) Estimate $\Delta H°$ for this reaction.

(b) The equation is rewritten as

$$2\ Ba_3N_2(s) \rightleftharpoons 6\ Ba(g) + 2\ N_2(g)$$

Now the equilibrium constant is 2.0×10^{-37} at 1000 K and 3.8×10^{-23} at 1200 K. Estimate $\Delta H°$ of *this* reaction.

Distribution of a Single Species between Immiscible Phases: Extraction and Separation Processes

71. An aqueous solution, initially 1.00×10^{-2} M in iodine (I_2), is shaken with an equal volume of an immiscible organic solvent, CCl_4. The iodine distributes itself between the aqueous and CCl_4 layers, and when equilibrium is reached at 27°C, the concentration of I_2 in the aqueous layer is 1.30×10^{-4} M. Calculate the partition coefficient K at 27°C for the reaction

$$I_2(aq) \rightleftharpoons I_2(CCl_4)$$

72. An aqueous solution, initially 2.50×10^{-2} M in iodine (I_2), is shaken with an equal volume of an immiscible organic solvent, CS_2. The iodine distributes itself between the aqueous and CS_2 layers, and when equilibrium is reached at 25°C, the concentration of I_2 in the aqueous layer is 4.16×10^{-5} M. Calculate the partition coefficient K at 25°C for the reaction

$$I_2(aq) \rightleftharpoons I_2(CS_2)$$

73. Benzoic acid (C_6H_5COOH) dissolves in water to the extent of 2.00 g L^{-1} at 15°C and in diethyl ether to the extent of 6.6×10^2 g L^{-1} at the same temperature.

(a) Calculate the equilibrium constants at 15°C for the two reactions

$$C_6H_5COOH(s) \rightleftharpoons C_6H_5COOH(aq)$$

and

$$C_6H_5COOH(s) \rightleftharpoons C_6H_5COOH(ether)$$

(b) From your answers to part (a), calculate the partition coefficient K for the reaction

$$C_6H_5COOH(aq) \rightleftharpoons C_6H_5COOH(ether)$$

74. Citric acid ($C_6H_8O_7$) dissolves in water to the extent of 1300 g L^{-1} at 15°C and in diethyl ether to the extent of 22 g L^{-1} at the same temperature.

(a) Calculate the equilibrium constants at 15°C for the two reactions

$$C_6H_8O_7(s) \rightleftharpoons C_6H_8O_7(aq)$$

and

$$C_6H_8O_7(s) \rightleftharpoons C_6H_8O_7(ether)$$

(b) From your answers to part (a), calculate the partition coefficient K for the reaction

$$C_6H_8O_7(aq) \rightleftharpoons C_6H_8O_7(ether)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ADDITIONAL PROBLEMS

75. At 298 K, unequal amounts of $BCl_3(g)$ and $BF_3(g)$ were mixed in a container. The gases reacted to form $BFCl_2(g)$ and $BClF_2(g)$. When equilibrium was finally reached, the four gases were present in these relative chemical amounts: $BCl_3(90)$, $BF_3(470)$, $BClF_2(200)$, $BFCl_2(45)$.
(a) Determine the equilibrium constants at 298 K of the two reactions

$$2\ BCl_3(g) + BF_3(g) \rightleftharpoons 3\ BFCl_2(g)$$

$$BCl_3(g) + 2\ BF_3(g) \rightleftharpoons 3\ BClF_2(g)$$

(b) Determine the equilibrium constant of the reaction

$$BCl_3(g) + BF_3(g) \rightleftharpoons BFCl_2 + BClF_2(g)$$

and explain why knowing this equilibrium constant really adds nothing to what you knew in part (a).

76. Methanol can be synthesized by means of the equilibrium reaction

$$CO(g) + 2\ H_2(g) \rightleftharpoons CH_3OH(g)$$

for which the equilibrium constant at 225°C is 6.08×10^{-3}. Assume that the ratio of the pressures of $CO(g)$ and $H_2(g)$ is 1:2. What values should they have if the partial pressure of methanol is to be 0.500 atm?

77. At equilibrium at 425.6°C, a sample of *cis*-1-methyl-2-ethylcyclopropane is 73.6% converted into the *trans* form:

$$cis \rightleftharpoons trans$$

(a) Compute the equilibrium constant K for this reaction.
(b) Suppose that 0.525 mol of the *cis* compound is placed in a 15.00-L vessel and heated to 425.6°C. Compute the equilibrium partial pressure of the *trans* compound.

78. The equilibrium constant for the reaction

$$(CH_3)_3COH(g) \rightleftharpoons (CH_3)_2CCH_2(g) + H_2O(g)$$

is 2.42 at 450 K.
(a) A pure sample of the reactant, which is named "*t*-butanol," is confined in a container of fixed volume at a temperature of 450 K and at an original pressure of 0.100 atm. Calculate the fraction of this starting material that is converted to products at equilibrium.
(b) A second sample of the reactant is confined, this time at an original pressure of 5.00 atm. Again, calculate the fraction of the starting material that is converted to products at equilibrium.

79. At 627°C and 1 atm, SO_3 is partly dissociated into SO_2 and O_2:

$$SO_3(g) \rightleftharpoons SO_2(g) + \tfrac{1}{2}\ O_2(g)$$

The density of the equilibrium mixture is 0.925 g L^{-1}. What is the degree of dissociation of SO_3 under these circumstances?

80. Acetic acid in the vapor phase consists of both monomeric and dimeric forms in equilibrium:

$$2\ CH_3COOH(g) \rightleftharpoons (CH_3COOH)_2(g)$$

At 110°C the equilibrium constant for this reaction is 3.72.
(a) Calculate the partial pressure of the dimer when the total pressure is 0.725 atm at equilibrium.
(b) What percentage of the acetic acid is dimerized under these conditions?

* 81. Repeat the calculation of problem 36 with a total pressure of 100 atm. (*Note:* Here it is necessary to solve the equation by successive approximations. See Appendix C.)

82. At 900 K the equilibrium constant for the reaction

$$\tfrac{1}{2}\ O_2(g) + SO_2(g) \rightleftharpoons SO_3(g)$$

has the value $K = 0.587$. What will be the equilibrium partial pressure of $O_2(g)$ if a sample of SO_3 weighing 0.800 g is heated to 900 K in a quartz-glass vessel whose volume is 100.0 cm^3? (*Note:* Here it is necessary to solve the equation by successive approximations. See Appendix C.)

* 83. At 298 K chlorine is only slightly soluble in water. Thus, under a pressure of 1.00 atm of $Cl_2(g)$, 1.00 L of water at equilibrium dissolves just 0.091 mol of Cl_2.

$$Cl_2(g) \rightleftharpoons Cl_2(aq)$$

In such solutions the $Cl_2(aq)$ concentration is 0.061 M and the concentrations of $Cl^-(aq)$ and $HOCl(aq)$ are both 0.030 M. These two additional species are formed by the equilibrium

$$Cl_2(aq) + H_2O(\ell) \rightleftharpoons H^+(aq) + Cl^-(aq) + HOCl(aq)$$

There are no other Cl-containing species. Compute the equilibrium constants K_1 and K_2 for the two reactions.

84. At 400°C the reaction

$$BaO_2(s) + 4\ HCl(g) \rightleftharpoons BaCl_2(s) + 2\ H_2O(g) + Cl_2(g)$$

has an equilibrium constant equal to K_1. How is K_1 related to the equilibrium constant K_2 of the reaction

$$2\ Cl_2(g) + 4\ H_2O(g) + 2\ BaCl_2(s) \rightleftharpoons 8\ HCl(g) + 2\ BaO_2(s)$$

at 400°C?

85. Ammonium hydrogen sulfide, a solid, decomposes to give $NH_3(g)$ and $H_2S(g)$. At 25°C, some $NH_4HS(s)$ is placed in an evacuated container. A portion of it decomposes, and the total pressure at equilibrium is 0.659 atm. Extra $NH_3(g)$ is then injected into the container, and when equilibrium is reestablished, the partial pressure of $NH_3(g)$ is 0.750 atm.
(a) Compute the equilibrium constant for the decomposition of ammonium hydrogen sulfide.
(b) Determine the final partial pressure of $H_2S(g)$ in the container.

86. The equilibrium constant for the reaction

$$KOH(s) + CO_2(g) \rightleftharpoons KHCO_3(s)$$

is 6×10^{15} at 25°C. Suppose 7.32 g of KOH and 9.41 g of $KHCO_3$ are placed in a closed evacuated container and allowed to reach equilibrium. Calculate the pressure of $CO_2(g)$ at equilibrium.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

87. The equilibrium constant for the reduction of nickel(II) oxide to nickel at 754°C is 255.4, corresponding to the reaction

$$NiO(s) + CO(g) \rightleftharpoons Ni(s) + CO_2(g)$$

If the total pressure of the system at 754°C is 2.50 atm, calculate the partial pressures of $CO(g)$ and $CO_2(g)$.

88. Both glucose (corn sugar) and fructose (fruit sugar) taste sweet, but fructose tastes sweeter. Each year in the United States, tons of corn syrup destined to sweeten food are treated to convert glucose as fully as possible to the sweeter fructose. The reaction is an equilibrium:

$$\text{glucose} \rightleftharpoons \text{fructose}$$

(a) A 0.2564 M solution of pure glucose is treated at 25°C with an enzyme (catalyst) that causes the preceding equilibrium to be reached quickly. The final concentration of fructose is 0.1175 M. In another experiment at the same temperature, a 0.2666 M solution of pure fructose is treated with the same enzyme and the final concentration of glucose is 0.1415 M. Compute an average equilibrium constant for the preceding reaction.
(b) At equilibrium under these conditions, what percentage of glucose is converted to fructose?

89. At 300°C the equilibrium constant for the reaction

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$$

is $K = 11.5$.
(a) Calculate the reaction quotient Q if initially $P_{PCl_3} = 2.0$ atm, $P_{Cl_2} = 6.0$ atm, and $P_{PCl_5} = 0.10$ atm. State whether the reaction proceeds to the right or to the left as equilibrium is approached.
(b) Calculate P_{PCl_3}, P_{Cl_2}, and P_{PCl_5} at equilibrium.
(c) If the volume of the system is then increased, will the amount of PCl_5 present increase or decrease?

90. Although the process of dissolution of helium gas in water is favored in terms of energy, helium is only very slightly soluble in water. What keeps this gas from dissolving in great quantities in water?

91. The hydrogenation of pyridine to piperidine

$$C_5H_5N(g) + 3\ H_2(g) \rightleftharpoons C_5H_{11}N(g)$$

is an equilibrium process whose equilibrium constant is given by the equation

$$\log_{10} K = -20.281 + \frac{10.560\ \text{K}}{T}$$

(a) Calculate the value of K at $T = 500$ K.
(b) If the partial pressure of hydrogen is 1.00 atm, what fraction of the nitrogen is in the form of pyridine molecules at $T = 500$ K?

92. The breaking of the O—O bond in peroxydisulfuryl difluoride (FO_2SOOSO_2F) gives FO_2SO:

$$(FO_2SO)_2 \rightleftharpoons 2\ FO_2SO$$

The compound on the left of this equation is a colorless liquid that boils at 67.1°C. Its vapor, when heated to about 100°C, turns brown as the product of the reaction forms. Suppose that, in a sample of the vapor, the intensity of the brown color doubles between 100°C and 110°C and that the total pressure increases only by the 2.7% predicted for an ideal gas. Estimate $\Delta H°$ for the preceding reaction.

93. Polychlorinated biphenyls (PCBs) are a major environmental problem. These oily substances have many uses, but they resist breakdown by bacterial action when spilled in the environment and, being fat-soluble, can accumulate to dangerous concentrations in the fatty tissues of fish and animals. One little-appreciated complication in controlling the problem is that there are *209* different PCBs, all now in the environment. They are generally similar, but their solubilities in fats differ considerably. The best measure of this is K_{ow}, the equilibrium constant for the partition of a PCB between the fat-like solvent octanol and water.

$$PCB(aq) \rightleftharpoons PCB(octanol)$$

An equimolar mixture of PCB-2 and PCB-11 in water is treated with an equal volume of octanol. Determine the ratio between the amounts of PCB-2 and PCB-11 in the water at equilibrium. At room temperature, K_{ow} is 3.98×10^4 for PCB-2 and 1.26×10^5 for PCB-11.

94. Refer to the data in problems 73 and 74. Suppose 2.00 g of a solid consisting of 50.0% benzoic acid and 50.0% citric acid by mass is added to 100.0 mL of water and 100.0 mL of diethyl ether and the whole assemblage is shaken. When the immiscible layers are separated and the solvents are removed by evaporation, two solids result. Calculate the percentage (by mass) of the major component in each solid.

95. At 25°C the partition coefficient for the equilibrium

$$I_2(aq) \rightleftharpoons I_2(CCl_4)$$

has the value $K = 85$. To 0.100 L of an aqueous solution, which is initially 2×10^{-3} M in I_2, we add 0.025 L of CCl_4. The mixture is shaken in a separatory funnel and allowed to separate into two phases, and the CCl_4 phase is withdrawn.
(a) Calculate the fraction of the I_2 remaining in the aqueous phase.
(b) Suppose the remaining aqueous phase is shaken with another 0.025 L of CCl_4 and again separated. What fraction of the I_2 from the original aqueous solution is *now* in the aqueous phase?
(c) Compare your answer with that of Example 14.18, in which the same total amount of CCl_4 (0.050 L) was used in a *single* extraction. For a given total amount of extracting solvent, which is the more efficient way to remove iodine from water?

96. From the data in Appendix D calculate $\Delta H°$, $\Delta G°$, and K, for the following reaction at 298 K:

$$6\ CH_4(g) + \tfrac{9}{2}\ O_2(g) \rightleftharpoons C_6H_6(\ell) + 9\ H_2O(\ell)$$

CUMULATIVE PROBLEMS

97. The reaction

$$P_4(g) \rightleftharpoons 2\ P_2(g)$$

is endothermic and begins to occur at moderate temperatures.
(a) In which direction do you expect deviations to occur from Boyle's law, $P \propto 1/V$ (constant T), for gaseous P_4?
(b) In which direction do you expect deviations to occur from Charles's law, $V \propto T$ (constant P), for gaseous P_4?

98. A 4.72-g mass of methanol, CH_3OH, is placed in an evacuated 1.00-L flask and heated to 250°C. It vaporizes and then reaches the following equilibrium:

$$CH_3OH(g) \rightleftharpoons CO(g) + 2\ H_2(g)$$

A tiny hole forms in the side of the container, allowing a small amount of gas to effuse out. Analysis of the escaping gases shows that the rate of escape of the hydrogen is 33 times the rate of escape of the methanol. Calculate the equilibrium constant for the preceding reaction at 250°C.

99. The triple bond in the N_2 molecule is very strong, but at high enough temperatures even it breaks down. At 5000 K, when the total pressure exerted by a sample of nitrogen is 1.00 atm, $N_2(g)$ is 0.65% dissociated at equilibrium:

$$N_2(g) \rightleftharpoons 2\ N(g)$$

At 6000 K with the same total pressure, the proportion of $N_2(g)$ dissociated at equilibrium rises to 11.6%. Use the van't Hoff equation to estimate the ΔH of this reaction.

100. At 25°C the equilibrium constant for the reaction

$$CaSO_4(s) + 2\ H_2O(g) \rightleftharpoons CaSO_4{\cdot}2H_2O(s)$$

is 1.6×10^3. Over what range of relative humidities do you expect $CaSO_4(s)$ to be converted to $CaSO_4{\cdot}2H_2O$? (*Note:* The relative humidity is the partial pressure of water vapor divided by its equilibrium vapor pressure and multiplied by 100%. Use Table 10.3.)

101. Calculate the equilibrium pressure (in atmospheres) of $O_2(g)$ over a sample of pure $NiO(s)$ in contact with pure $Ni(s)$ at 25°C. The $NiO(s)$ decomposes according to the equation

$$NiO(s) \longrightarrow Ni(s) + \tfrac{1}{2}\ O_2(g)$$

Use data from Appendix D.

102. (a) From the values in Appendix D, find the enthalpy change and the Gibbs free energy change when one mole of benzene C_6H_6 is vaporized at 25°C.
(b) Calculate the vapor pressure of benzene at 25°C.
(c) Assuming that the enthalpy and entropy of vaporization are constant, estimate the normal boiling point of benzene.

103. Snow and ice sublime spontaneously when the partial pressure of water vapor is below the equilibrium vapor pressure of ice. At 0°C the vapor pressure of ice is 0.0060 atm (the triple-point pressure of water). Taking the enthalpy of sublimation of ice to be 50.0 kJ mol^{-1}, calculate the partial pressure of water vapor below which ice will sublime spontaneously at −15°C.

104. The sublimation pressure of solid NbI_5 is the pressure of gaseous NbI_5 present in equilibrium with the solid. It is given by the empirical equation

$$\log P = -6762/T + 8.566$$

The vapor pressure of liquid NbI_5, on the other hand, is given by

$$\log P = -4653/T + 5.43$$

In these two equations, T is the absolute temperature in kelvins and P is the pressure in atmospheres.
(a) Determine the enthalpy and entropy of sublimation of $NbI_5(s)$.
(b) Determine the enthalpy and entropy of vaporization of $NbI_5(\ell)$.
(c) Calculate the normal boiling point of $NbI_5(\ell)$.
(d) Calculate the triple-point temperature and pressure of NbI_5. (*Hint:* At the triple point of a substance, the liquid and solid are in equilibrium and must have the same vapor pressure. If they did not, vapor would continually escape from the phase with the higher vapor pressure and collect in the phase with the lower vapor pressure.)

105. In an extraction process, a solute species is partitioned between two immiscible solvents. Suppose the two solvents are water and carbon tetrachloride. State which phase will have the higher concentration of each of the following solutes: (a) CH_3OH, (b) C_2Cl_6, (c) Br_2, (d) NaCl. Explain your reasoning.

106. The gaseous compounds allene and propyne are isomers with formula C_3H_4. Calculate the equilibrium constant and the standard enthalpy change at 25°C for the isomerization reaction

$$\text{allene}(g) \rightleftharpoons \text{propyne}(g)$$

from the following data, all of which apply to 298 K:

	ΔH_f° (kJ mol^{-1})	ΔG_f° (kJ mol^{-1})
Allene	192	202
Propyne	185	194

107. (a) Calculate the standard free-energy change and the equilibrium constant for the dimerization of NO_2 to N_2O_4 at 25°C (see Appendix D).
(b) Calculate ΔG for this reaction at 25°C when the pressures of NO_2 and N_2O_4 are each held at 0.010 atm. Which way will the reaction tend to proceed?

108. There are two isomeric hydrocarbons with formula C_4H_{10}, butane and isobutane, which we denote here B and I. The standard enthalpies of formation for the gaseous species are −124.7 kJ mol^{-1} for B, −131.3 kJ mol^{-1} for I; the standard free energies of formation are −15.9 kJ mol^{-1} for B, −18.0 kJ mol^{-1} for I.
(a) Which is the more stable under standard conditions, and which has the higher entropy?
(b) The reaction B ⇌ I can occur in the presence of a catalyst. Calculate the equilibrium constant at 298 K for the conversion of B to I, and calculate the percentage of B in the equilibrium mixture.

109. At 3500 K the equilibrium constant for the reaction $CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g)$ is 8.28.
   (a) What is $\Delta G°(3500)$ for this reaction?
   (b) What is ΔG at 3500 K for transforming 1 mol CO_2 and 1 mol H_2, both held at 0.1 atm, to 1 mol CO and 1 mol H_2O, both held at 2 atm?
   (c) In which direction would this last reaction run spontaneously?

110. At 1200 K in the presence of solid carbon, an equilibrium mixture of CO and CO_2 (called "producer gas") contains 98.3 mol percent CO and 1.69 mol percent of CO_2 when the total pressure is 1 atm. The reaction is

$$CO_2(g) + C(graphite) \rightleftharpoons 2\ CO(g)$$

   (a) Calculate P_{CO} and P_{CO_2}.
   (b) Calculate the equilibrium constant.
   (c) Calculate $\Delta G°$ for this reaction.

111. (a) Formulate the equilibrium expression for the endothermic reaction

$$AgCl{\cdot}NH_3(s) \rightleftharpoons AgCl(s) + NH_3(g)$$

   (b) What is the effect on P_{NH_3} at equilibrium if additional AgCl(*s*) is added?
   (c) What is the effect on P_{NH_3} at equilibrium if additional $NH_3(g)$ is pumped into or out of the system, provided that neither of the two solid phases shown in the chemical equation is completely used up?
   (d) What is the effect on P_{NH_3} of lowering the temperature?

112. Solid ammonium carbonate decomposes according to the equation

$$(NH_4)_2CO_3(s) \rightleftharpoons 2\ NH_3(g) + CO_2(g) + H_2O(g)$$

At a certain elevated temperature the total pressure of the gases NH_3, CO_2, and H_2O generated by the decomposition of, and at equilibrium with, pure solid ammonium carbonate is 0.400 atm. Calculate the equilibrium constant for the reaction considered. What would happen to P_{NH_3} and P_{CO_2} if P_{H_2O} were adjusted by external means to be 0.200 atm without changing the relative amounts of $NH_3(g)$ and $CO_2(g)$ and with $(NH_4)_2CO_3(s)$ still being present?

Many naturally occurring dyes change color as the acidity of their surroundings changes. The compound cyanidin is blue in the basic sap of the cornflower and red in the acidic sap of the poppy. Such dyes can be used as indicators of the degree of acidity in a medium.

According to Section 11.3, an acid is a substance that upon dissolving in water increases the concentration of hydronium (H_3O^+) ions above the value found in pure water, and a base is a substance that increases the concentration of hydroxide (OH^-) ions above its value in pure water. Despite this carefully phrased definition, it is commonplace to describe acids as substances that dissociate to give protons (which upon hydration become hydronium ions) and bases as substances that dissociate to give hydroxide ions. If the dissociation is complete, we can easily calculate the concentration of hydronium and hydroxide ions in the solution and then calculate the yield of acid–base neutralization reactions, and acid–

base titrations, by the methods of stoichiometry in solution. But experience shows that many acid–base reactions do not go to completion. So, to predict the amount (or concentration) of their products, we have to use the ideas and methods of chemical equilibrium developed in Chapter 14. The present chapter deals with this fundamental aspect of acid–base chemistry which is key to its applications in the physical and biological sciences, in engineering, and in medicine: How far do acid–base reactions proceed before reaching equilibrium?

The reactions of acids and bases lie at the heart of nearly all branches of chemistry. Many acid–base reactions occur in the gaseous and solid states and in nonaqueous solutions. This chapter focuses on acid–base reactions in aqueous solutions, which play important roles in everyday life. Vinegar, orange juice, and battery fluid are familiar acidic aqueous solutions. Basic solutions are produced when such common products as borax, baking soda, and antacids are dissolved in water. Acid–base chemistry will appear many times throughout the rest of this book. We consider the effects of acidity on the dissolution of solids in Chapter 16, on redox reactions in electrochemical cells in Chapter 17, and on the rates of reaction in Chapter 18. At the end of this chapter we relate acid strength to molecular structure in organic acids, and in Chapter 23 we point out the central roles of amino acids and nucleic acids in biochemistry.

15.1 CLASSIFICATIONS OF ACIDS AND BASES

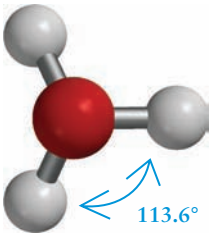

FIGURE 15.1 The structure of the hydronium ion (H_3O^+) in the gas phase.

Cengage Learning/Leon Lewandowski

As zinc dissolves in dilute hydrochloric acid, bubbles of hydrogen appear, and zinc chloride forms in solution.

Arrhenius Acids and Bases

In Section 11.3 we described the Arrhenius definition of acids and bases. An **acid** is a substance that when dissolved in water increases the concentration of hydronium ion (H_3O^+) above the value it takes in pure water. A **base** increases the concentration of hydroxide ion (OH^-). Arrhenius acids and bases release ions into the solution. Throughout this chapter, we will use the hydronium ion (Fig. 15.1) to represent the true nature of hydrogen ions in water. The hydronium ion may have as many as four molecules of water attached to it by hydrogen bonding. (See Section 10.3.) Depending upon the specific context we refer to this species as the hydrogen ion, the proton, or the hydronium ion in this chapter.

The Arrhenius model views acid–base neutralization as an exchange reaction in which the H^+ from the acid and the OH^- from the base separate from their original bonding partners and combine to form the neutral water molecule, and the original bonding partners combine to form a salt. (See Section 11.3.)

The Arrhenius model also describes other familiar reactions of the acids. Three broad types summarize the results of a very large number of reactions:

1. Acids react with carbonates and hydrogen carbonates such as Na_2CO_3 or $NaHCO_3$ to liberate gaseous CO_2 and produce a salt and water. An example reaction is

$$NaHCO_3(s) + HCl(aq) \longrightarrow NaCl(aq) + H_2O(\ell) + CO_2(g) \quad \text{(overall)}$$

$$NaHCO_3(s) + H_3O^+(aq) \longrightarrow Na^+(aq) + 2H_2O(\ell) + CO_2(g) \quad \text{(net ionic)}$$

2. Acids react with oxides of metals to form salts and water. An example reaction is

$$CuO(s) + H_2SO_4(aq) \longrightarrow CuSO_4(aq) + H_2O(\ell) \quad \text{(overall)}$$

$$CuO(s) + 2H_3O^+(aq) \longrightarrow Cu^{2+}(aq) + 3H_2O(\ell) \quad \text{(net ionic)}$$

3. Acids react with zinc, iron, and many metal elements to generate gaseous H_2 and form salts. An example reaction is

$$Zn(s) + 2HCl(aq) \longrightarrow ZnCl_2(aq) + H_2(g) \quad \text{(overall)}$$

$$Zn(s) + 2H_3O^+(aq) \longrightarrow Zn^{2+}(aq) + 3H_2(g) \quad \text{(net ionic)}$$

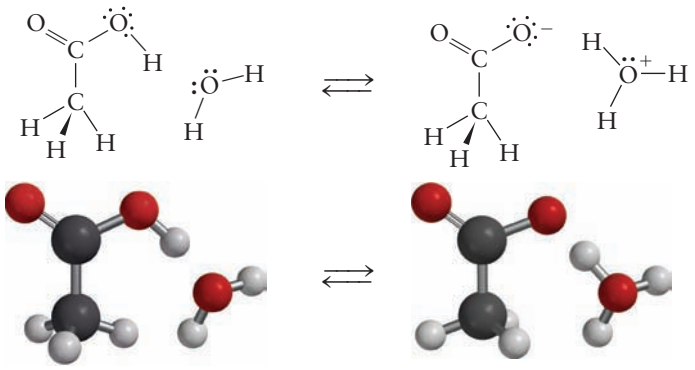
In the first example, hydrogen ions in the solution react with the carbonate or the hydrogen carbonate ions to form carbonic acid (H_2CO_3), which decomposes to produce water and carbon dioxide. The CO_2 has very limited solubility in water and escapes as gas bubbles.

In the second example, hydrogen ions in the solution are attracted to the negative charge on the oxide ions at the surface of the solid, and react with these ions to produce molecules of H_2O. The metal ions are freed from the solid into the solution.



In the third example, hydrogen ions are displaced from the solution by so-called "active metals." This reaction will be discussed in detail in Chapter 17.

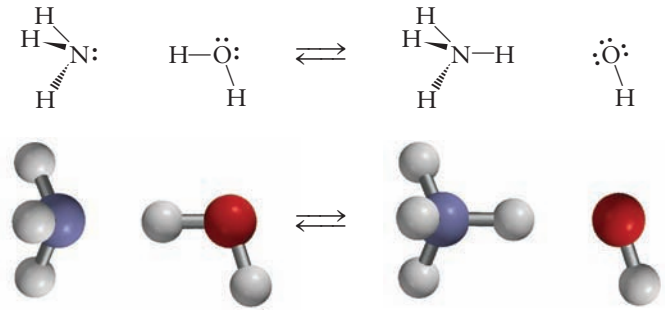
These examples illustrate the key aspect of acid–base reactions: A proton is transferred from a molecule defined to be the acid to an acceptor molecule. Proton transfer reactions in which the acceptor is some species other than OH^- are common throughout organic chemistry, inorganic chemistry, and biochemistry. Proton transfer reactions may occur in solvents other than water, and even in the gaseous and solid states. All these diverse reactions can be organized and discussed systematically by using generalized definitions of acids and bases, which include the Arrhenius definition as a limiting case. We describe these more general definitions as background for discussing acid–base equilibria for very broad classes of compounds. The first of these models was proposed independently by Johannes Brønsted and Thomas Lowry in 1923, and the second was introduced by G. N. Lewis in the same year.

Brønsted–Lowry Acids and Bases

A **Brønsted–Lowry acid** is defined as a substance that can *donate* a proton, and a **Brønsted–Lowry base** is a substance that can *accept* a proton. In a Brønsted–Lowry acid–base reaction, a proton is transferred from the acid to the base. For example, when acetic acid is dissolved in water, an acid–base reaction occurs in which protons are transferred from acetic acid molecules to water molecules:

$$\underset{\text{Acid}_1}{CH_3COOH(aq)} + \underset{\text{Base}_2}{H_2O(\ell)} \rightleftharpoons \underset{\text{Acid}_2}{CH_3COO^-(aq)} + \underset{\text{Base}_1}{H_3O^+(aq)}$$

The net result is the transfer of a proton from acetic acid to water to form the hydronium ion $H_3O^+(aq)$ (Fig. 15.1).



Examination of ball-and-stick models and Lewis electron diagrams for the molecules gives some sense of how this reaction occurs. Acetic acid molecules and water molecules experience numerous collisions while diffusing through solution. In some fraction of these collisions the molecules happen to be positioned so the O—H bond on the acetic acid and the O atom on the water molecule are nearly in a straight line. Some fraction of these specially aligned collisions occur with sufficient kinetic energy to push these three atoms and all their electrons quite close together, distort the structure of the molecules, and increase their potential energy.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

This highly energetic configuration of the two molecules can relax by rearranging the electron density around the nuclei to form a new stable state with lower potential energy, in which the bonds in the molecules have been rearranged. It appears that the oxygen atom in water donates a lone pair of electrons to the proton in the hydroxyl group (O—H) of acetic acid, forming a hydronium ion and freeing the bonding pair in the hydroxyl group to form the acetate ion. The net result of these electron pair redistributions is the transfer of a proton from acetic acid to water to form the hydronium ion $(H_3O^+)(aq)$. In fact we cannot claim to track the motions of any specific electron pairs during this reaction; we know from Chapters 4 through 6 that quantum mechanics does not allow us to know that level of detail. Nonetheless, the description of this reaction as the result of the redistribution of two electron pairs that breaks the O—H bond in acetic acid and forms a new O—H bond in the hydronium ion is a convenient, visual summary of the events that occur in the reaction.

Acids and bases occur as **conjugate acid–base pairs,** which are related by transfer of a proton. In an acid–base reaction, the acid donates a proton to the base and in the process is converted to its conjugate base. The base accepts the proton and is converted to its conjugate acid. In the preceding example, acetic acid CH_3COOH and the acetate anion CH_3COO^- form such a pair, in which CH_3COO^- is the conjugate base of CH_3COOH (equivalently, CH_3COOH is the conjugate acid of CH_3COO^-). In the same reaction, H_3O^+ and H_2O form a conjugate acid–base pair, where H_2O is the base and H_3O^+ is its conjugate acid. The equilibrium state of an acid–base reaction will include the acid and its conjugate base, as well as the base and its conjugate acid. It is useful to picture this equilibrium as the competition between two bases for hydrogen ions. For example, when ammonia is dissolved in water,

$$\underset{\text{Acid}_1}{H_2O(\ell)} + \underset{\text{Base}_2}{NH_3(aq)} \rightleftharpoons \underset{\text{Acid}_2}{NH_4^+(aq)} + \underset{\text{Base}_1}{OH^-(aq)}$$

the two bases NH_3 and OH^- compete for hydrogen ions to determine the equilibrium position of the reaction.

Unlike the Arrhenius definition, the Brønsted–Lowry definition has the advantage of not being limited to aqueous solutions, and is used to describe proton transfer reactions in nonaqueous solvents. An example with liquid ammonia as the solvent is

$$\underset{\text{Acid}_1}{HCl(\text{in } NH_3)} + \underset{\text{Base}_2}{NH_3(\ell)} \rightleftharpoons \underset{\text{Acid}_2}{NH_4^+(\text{in } NH_3)} + \underset{\text{Base}_1}{Cl^-(\text{in } NH_3)}$$

The NH_3 acts as both base and solvent, just as H_2O acts as both base and solvent in the proton transfer reaction with acetic acid discussed above.

Some molecules and ions function either as acids or bases depending on reaction conditions and are called **amphoteric.** The most common example is water itself. Water acts as an acid when donating a proton to NH_3 (the conjugate base of

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

water being OH^-) and as a base in accepting a hydrogen ion from CH_3COOH (the conjugate acid of water being H_3O^+). In the same way, the hydrogen carbonate ion can act as an acid

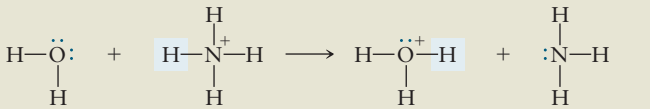
$$HCO_3^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CO_3^{2-}(aq)$$

or as a base:

$$HCO_3^-(aq) + H_2O(\ell) \rightleftharpoons H_2CO_3(aq) + OH^-(aq)$$

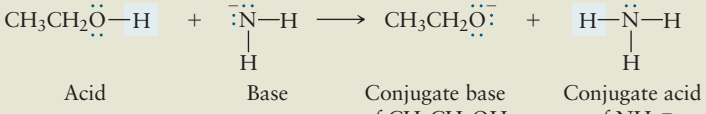
Many examples of proton transfer reactions found in organic chemistry and biochemistry are described by the Brønsted–Lowry model. The various organic functional groups defined in Chapter 7 can participate in these reactions. Ethane (CH_3CH_3) is an extremely weak acid (see later) that can donate a proton to form its conjugate base $CH_3CH_2^-$, an example of a carbanion, a species that plays an important role in organic reaction mechanisms. Ethanol (CH_3CH_2OH) can donate a proton to form its conjugate base $CH_3CH_2O^-$, another carbanion but one that is a much weaker base than the conjugate base of ethane. The carboxylic acids, of which acetic acid is an example, can give up the proton that is bonded to O (the so-called acidic proton) to form their anionic conjugated bases. Methylamine (CH_3NH_2) can accept a proton to form its conjugate acid the methylammonium ion ($CH_3NH_3^+$). The acid–base behavior of organic molecules is discussed in some detail in Section 15.8.

EXAMPLE 15.1



The following two reactions involve proton transfer. In each reaction, identify the acid and the base. Identify the conjugate base of the acid, and the conjugate acid of the base. Draw Lewis electron dot diagrams for each molecule, and describe the rearrangement of electrons in the reaction.

(a) $H_2O(\ell) + NH_4^+(aq) \longrightarrow H_3O^+(aq) + NH_3(aq)$



(b) $CH_3CH_2OH(aq) + NH_2^-(aq) \longrightarrow CH_3CH_2O^-(aq) + NH_3(aq)$

Solution

(a) The ammonium ion is the acid, and water is the base. An unshared pair of electrons on the oxygen atom in the water molecule is transferred to form a new covalent bond with one of the protons on the ammonium ion to form H_3O^+, the conjugate acid of water (the base). The reaction converts one of the remaining N—H bonding pairs into a lone (nonbonding) pair forming NH_3, the conjugate base of NH_4^+ (the acid).

(b) Ethanol is the acid and amide ion is the base. A lone pair of electrons on the amide ion is transferred to the proton in ethanol, producing ammonia (the conjugate base of the amide ion) and the ethoxide ion (the conjugate base of ethanol).

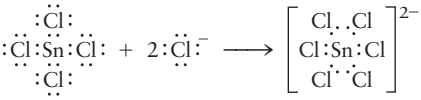
Lewis Acids and Bases

The Lewis model (Chapter 3), which focuses on the electron pair bond, provides a more general definition of acid–base behavior, of which the Arrhenius and Brønsted–Lowry definitions are special cases. Examination of the Lewis electron dot diagrams for molecules in a typical Brønsted–Lowry acid–base reaction shows that two bases compete for a proton by offering electron pairs that can be accepted by the proton to form new bonds.

$$\underset{\text{Acid}_1}{HF(aq)} + \underset{\text{Base}_2}{H_2O(\ell)} \rightleftharpoons \underset{\text{Acid}_2}{H_3O^+(aq)} + \underset{\text{Base}_1}{F^-(aq)}$$



A **Lewis base** is any species that donates lone-pair electrons, and a **Lewis acid** is any species that accepts such electron pairs. The Brønsted–Lowry acids and bases considered so far fit this description (with the Lewis acid, H^+, acting as an acceptor toward various Lewis bases such as NH_3 and OH^-, the electron pair donors). The Lewis acid–base model is much more general than the Brønsted–Lowry model because it applies to other reactions that do *not* involve hydrogen ion transfers. An example is the reaction between electron-deficient BF_3 and electron-rich NH_3.

Here ammonia, the Lewis base, donates lone-pair electrons to BF_3, the Lewis acid or electron acceptor. The pair of electrons donated by the Lewis base is not removed from its valence shell but instead is shared with the Lewis acid to form a new covalent bond. The bond that forms is called a **coordinate covalent bond** (or a **dative bond,** see Section 8.2) in which both electrons are provided by a lone pair on the Lewis base.

Octet-deficient compounds involving elements of Group III, such as boron and aluminum, are often strong Lewis acids because Group III atoms (electron pair acceptors) can achieve octet configurations by forming coordinate covalent bonds with electron pair donors such as atoms and ions from Groups V through VII. Compounds of main-group elements from the later periods can also act as Lewis acids because they can accept (or share) additional electrons through valence shell expansion (see Section 3.9). In such reactions the central atom accepts a share in additional lone pairs beyond the eight electrons needed to satisfy the octet rule. For example, $SnCl_4$ is a Lewis acid that accepts electron pairs from two chloride ions to form $SnCl_4$ as follows.

$$SnCl_4(\ell) + 2Cl^-(aq) \longrightarrow [SnCl_6]^{2-}(aq)$$

After the reaction, each tin atom is surrounded by twelve rather than eight valence electrons.

EXAMPLE 15.2

In the following reactions, identify the Lewis acid and the Lewis base.

(a) $AlCl_3(g) + Cl^-(g) \longrightarrow AlCl_4^-(g)$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(b) $CH_3COOH(aq) + NH_3(aq) \longrightarrow CH_3COO^-(aq) + NH_4^+(aq)$

(c) $Co^{3+}(aq) + 6F^-(aq) \longrightarrow [CoF_6]^{3-}(aq)$

Solution

(a) In $AlCl_3$ the Al atom has only six valence electrons. Thus $AlCl_3$ acts as a Lewis acid to accept electrons from the lone pairs on the Lewis base Cl^-.

(b) The Lewis base NH_3 donates a lone pair of electrons to form a coordinate covalent bond with the proton from acetic acid. The proton is the Lewis acid, not the acetic acid.

(c) The transition metal ion Co^{3+} is the Lewis acid, accepting electron pairs from the Lewis bases, the F^- ions, to form coordinate covalent bonds.

Related Problems: 5, 6, 7, 8

The Lewis definition systematizes the chemistry of a great many binary oxides, which can be considered to be anhydrides of acids or bases. An **acid anhydride** is obtained by removing water from an oxoacid (see Section 11.3) until only the oxide remains; thus, CO_2 is the anhydride of carbonic acid (H_2CO_3).

EXAMPLE 15.3

What is the acid anhydride of phosphoric acid (H_3PO_4)?

Solution

If the formula unit H_3PO_4 (which contains an odd number of hydrogen atoms) is doubled, $H_6P_2O_8$ is obtained. Subtraction of 3 H_2O from this gives P_2O_5, which is the empirical formula of tetraphosphorus decaoxide (P_4O_{10}). This compound is the acid anhydride of phosphoric acid.

Related Problems: 9, 10

The oxides of most of the nonmetals are acid anhydrides, which react with an excess of water to form acidic solutions. Examples include

$$N_2O_5(s) + H_2O(\ell) \longrightarrow 2HNO_3(aq) \longrightarrow 2H^+(aq) + 2\ NO_3^-(aq)$$

$$SO_3(g) + H_2O(\ell) \longrightarrow H_2SO_4(aq) \longrightarrow H^+(aq) + HSO_4^-(aq)$$

Silica (SiO_2) is the acid anhydride of the very weak silicic acid H_2SiO_3, a gelatinous material that is insoluble in water but readily dissolves in strongly basic aqueous solutions according to

$$H_2SiO_3(s) + 2OH^-(aq) \longrightarrow SiO_3^{2-}(aq) \longrightarrow 2H_2O(\ell)$$

Oxides of Group I and II metals are **base anhydrides,** obtained by removing water from the corresponding hydroxides. Calcium oxide, CaO, is the base anhydride of calcium hydroxide, $Ca(OH)_2$. The removal of water from $Ca(OH)_2$ is the reverse of the addition of water to the oxide:

$$CaO(s) + H_2O(\ell) \longrightarrow Ca(OH)_2(s)$$

$$Ca(OH)_2(s) \longrightarrow CaO(s) + H_2O(\ell)$$

The base anhydride of NaOH is Na_2O. Oxides of metals in the middle groups of the periodic table (III through V) lie on the border between ionic and covalent compounds and are frequently amphoteric. An example is aluminum oxide (Al_2O_3),

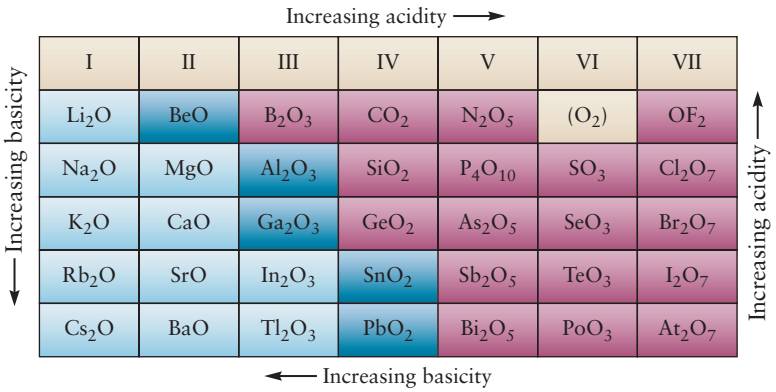

FIGURE 15.2 Among the oxides of the main-group elements, acidity tends to increase from left to right and from bottom to top in the periodic table. Oxygen difluoride is only weakly acidic, however. Oxides shown in light blue are derived from metals, those in dark blue from metalloids, and those in dark red from nonmetals.

which dissolves to only a limited extent in water but much more readily in either acids or bases:

$$\text{Acting as a base: } Al_2O_3(s) + 6H_3O^+(aq) \longrightarrow 2Al^{3+}(aq) + 9H_2O(\ell)$$

$$\text{Acting as an acid: } Al_2O_3(s) + 2OH^-(aq) + 3H_2O(\ell) \longrightarrow 2Al(OH^-)_4(aq)$$

Figure 15.2 summarizes the acid–base character of the main-group oxides in the first periods.

Although oxoacids and hydroxides are Arrhenius acids and bases (they release $H_3O^+(aq)$ or $OH^-(aq)$ into aqueous solution), acid and base anhydrides do not fall into this classification because they contain neither H^+ nor OH^- ions. Acid anhydrides are acids in the Lewis sense, (they accept electron pairs), and base anhydrides are bases in the Lewis sense, (their O^{2-} ions donate electron pairs). The reaction between an acid anhydride and a base anhydride is then a Lewis acid–base reaction. An example of such a reaction is

$$CaO(s) + CO_2(g) \longrightarrow CaCO_3(s)$$

Here, the Lewis base CaO donates an electron pair (one of the lone pairs of the oxygen atom) to the Lewis acid (CO_2) to form a coordinate covalent bond in the resulting ion. Similar Lewis acid–base reactions can be written for other acid–base anhydride pairs. Sulfur trioxide, for example, reacts with metal oxides to form sulfates:

$$MgO(s) + SO_3(g) \longrightarrow MgSO_4(s)$$

Note that these reactions are not redox reactions (oxidation numbers do not change), nor are they acid–base reactions in the Arrhenius or Brønsted–Lowry sense. But they are usefully classified as acid–base reactions in the Lewis sense.

Comparison of Arrhenius, Brønsted–Lowry, and Lewis Definitions

The neutralization reaction between HCl and NaOH

$$\underset{\text{Acid}}{HCl} + \underset{\text{Base}}{NaOH} \longrightarrow \underset{\text{Water}}{H_2O} + \underset{\text{Salt}}{NaCl}$$

introduced in Section 11.3 shows the progressive generality in these definitions. By the Arrhenius definition, HCl is the acid and NaOH is the base. By the Brønsted–Lowry definition, H_3O^+ is the acid and OH^- is the base. According to the Lewis model, H^+ is the acid and OH^- is the base, because the proton accepts the lone pair donated by hydroxide ion in the reaction

$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(\ell)$$

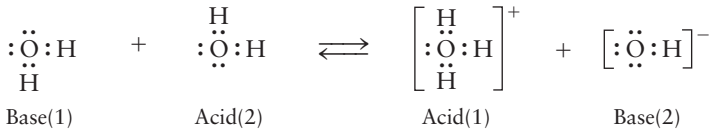
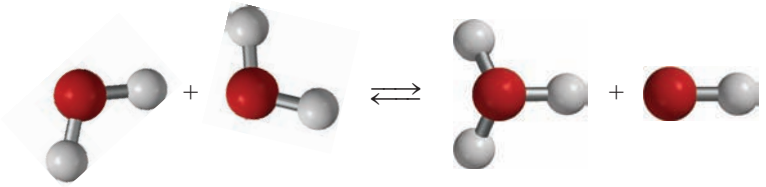
15.2 PROPERTIES OF ACIDS AND BASES IN AQUEOUS SOLUTIONS: THE BRØNSTED–LOWRY SCHEME

Chapters 10 and 11 describe the special properties of liquid water. Because of its substantial dipole moment, water is especially effective as a solvent, stabilizing both polar and ionic solutes. In acid–base reactions water is not only the solvent, but also participates as a reactant. Water plays an integral role in virtually all biochemical reactions essential to the survival of living organisms; these reactions involve acids, bases, and ionic species. In view of the wide-ranging importance of these reactions, we devote the remainder of this chapter to acid–base behavior and related ionic reactions in aqueous solution. The Brønsted–Lowry definition of acids and bases is especially well suited to describe these reactions.



Autoionization of Water



Water can act as both acid and base in the same reaction. The resulting equilibrium is

$$\underset{\text{Acid}_1}{H_2O(\ell)} + \underset{\text{Base}_2}{H_2O(\ell)} \rightleftharpoons \underset{\text{Acid}_2}{H_3O^+(aq)} + \underset{\text{Base}_1}{OH^-(aq)}$$

or

$$2\ H_2O(\ell) \rightleftharpoons H_3O^+(aq) + OH^-(aq)$$

This reaction is responsible for the **autoionization** of water, which leads to small but measurable concentrations of hydronium and hydroxide ions at equilibrium. The equilibrium expression for this reaction is

$$[H_3O^+][OH^-] = K_w \qquad [15.1]$$

The equilibrium constant for this particular reaction has a special symbol: K_w, and a special name, the **ion product constant for water;** its value is 1.0×10^{-14} at 25°C. Because the liquid water appears in this equilibrium reaction equation as a pure substance, it is considered already to be in its reference state, and therefore contributes only the factor 1 to the mass action law equilibrium expression. The reasons for this are discussed more fully in Sections 14.2 and 14.3. The temperature dependence of K_w is given in Table 15.1; all problems in this chapter are assumed to refer to 25°C unless otherwise stated.

TABLE 15.1

Temperature Dependence of K_w

T(°C)	K_w	pH of Water
0	0.114×10^{-14}	7.47
10	0.292×10^{-14}	7.27
20	0.681×10^{-14}	7.08
25	1.01×10^{-14}	7.00
30	1.47×10^{-14}	6.92
40	2.92×10^{-14}	6.77
50	5.47×10^{-14}	6.63
60	9.61×10^{-14}	6.51

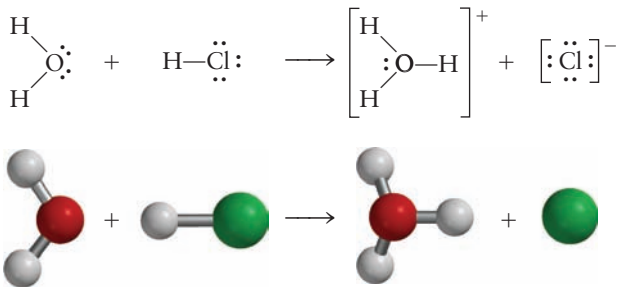
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Pure water contains no ions other than H_3O^+ and OH^-, and to maintain overall electrical neutrality, an equal number of ions of each type must be present. Putting these facts into the equilibrium expression Equation 15.1 gives

$$[H_3O^+] = [OH^-] = y$$
$$y^2 = 1.0 \times 10^{-14}$$
$$y = 1.0 \times 10^{-7}$$



so that in pure water at 25°C the concentrations of both H_3O^+ and OH^- are 1.0×10^{-7} M.

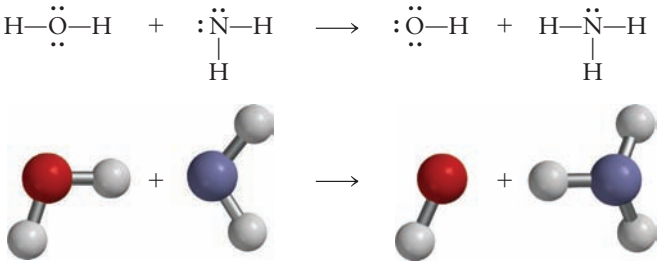
Strong Acids and Bases

An aqueous acidic solution contains an excess of H_3O^+ over OH^- ions. A **strong acid** is one that ionizes almost completely in aqueous solution. When the strong acid HCl (hydrochloric acid) is put in water, the reaction

$$H_2O(\ell) + HCl(aq) \longrightarrow H_3O^+(aq) + Cl^-(aq)$$

Base(2) Acid(1) Acid(2) Base(1)

occurs. A single rather than a double arrow indicates that the reaction is essentially complete. Another strong acid is perchloric acid ($HClO_4$). (See Table 11.1.) If 0.10 mol of either of these acids is dissolved in enough water to make 1.0 L of solution, 0.10 M concentration of $H_3O^+(aq)$ results. Because the acid–base properties of solutions are determined by their concentrations of $H_3O^+(aq)$, these two strong acids have the same effect in water despite differences we shall see shortly in their intrinsic abilities to donate hydrogen ions. Water is said to have a **leveling effect** on a certain group of acids (HCl, HBr, HI, H_2SO_4, HNO_3, and $HClO_4$) because they all behave as strong acids when water is the solvent. The reactions of these acids with water all lie so far to the right at equilibrium that the differences between the acids are negligible. The concentration of H_3O^+ in a 0.10 M solution of *any* strong acid that donates one hydrogen ion per molecule is simply 0.10 M. We use this result in Equation 15.1 to obtain the OH^- concentration



$$[OH^-] = \frac{K_w}{[H_3O^+]} = \frac{1.0 \times 10^{-14}}{0.10} = 1.0 \times 10^{-13} \text{ M}$$

In the same fashion, we define a **strong base** as one that reacts essentially completely to give $OH^-(aq)$ ion when put in water. The amide ion (NH_2^-) and the hydride ion (H^-) are both strong bases. For every mole per liter of either of these ions that is added to water, one mole per liter of $OH^-(aq)$ forms. Note that the other products in these reactions are gaseous NH_3 and H_2, respectively:

$$H_2O(\ell) + NH_2^-(aq) \longrightarrow OH^-(aq) + NH_3(aq)$$

Acid(1) Base(2) Base(1) Acid(2)

$$H_2O(\ell) + H^-(aq) \longrightarrow OH^-(aq) + H_2(aq)$$

Acid(1) Base(2) Base(1) Acid(2)

The important base sodium hydroxide, an ionic solid, increases the OH^- concentration in water when it dissolves:

$$NaOH(s) \longrightarrow Na^+(aq) + OH^-(aq)$$

For every mole of NaOH that dissolves in water, one mole of $OH^-(aq)$ forms, so NaOH is a strong base. Strong bases are leveled in aqueous solution in the same way that strong acids are leveled. If 0.10 mol of NaOH or NH_2^- or H^- is put into enough water to make 1.0 L of solution, then in every case

$$[OH^-] = 0.10 \text{ M}$$

$$[H_3O^+] = \frac{1.0 \times 10^{-14}}{0.10} = 1.0 \times 10^{-13} \text{ M}$$

The OH^- contribution from the autoionization of water is negligible here, as was the contribution of H_3O^+ from autoionization in the 0.10 M HCl and $HClO_4$ solutions. When only a very small amount of strong acid or base is added to pure water (for example, 10^{-7} mol L^{-1}), we have to include the autoionization of water to describe the concentration of hydronium and hydroxide ions accurately.

The pH Function

In aqueous solution the concentration of hydronium ion can range from 10 M to 10^{-15} M. It is convenient to compress this enormous range by introducing a logarithmic acidity scale, called **pH** and defined by

$$pH = -\log_{10} [H_3O^+] \qquad [15.2]$$

Pure water at 25°C has $[H_3O^+] = 1.0 \times 10^{-7}$ M, so

$$pH = -\log_{10} (1.0 \times 10^{-7}) = -(-7.00) = 7.00$$

FIGURE 15.3 A simple pH meter with a digital readout.

A 0.10 M solution of HCl has $[H_3O^+] = 0.10$ M, so

$$pH = -\log_{10}(0.10) = -\log_{10}(1.0 \times 10^{-1}) = -(-1.00) = 1.00$$

and at 25°C a 0.10 M solution of NaOH has

$$pH = -\log_{10}\left(\frac{1.0 \times 10^{-14}}{0.10}\right) = -\log_{10}(1.0 \times 10^{-13}) = -(-13.00) = 13.00$$

As these examples show, calculating the pH is especially easy when the concentration of H_3O^+ is exactly a power of 10, because the logarithm is then just the power to which 10 is raised. In other cases we need a calculator. When we know the pH, we calculate the concentration of H_3O^+ by raising 10 to the power $(-pH)$.

Because the most commonly encountered H_3O^+ concentrations are less than 1 M, the negative sign is put in the definition of the pH function to give a positive value in most cases. A *high* pH means a *low* concentration of H_3O^+ and vice versa. At 25°C,

$pH < 7$	Acidic solution	**[15.3a]**
$pH = 7$	Neutral solution	**[15.3b]**
$pH > 7$	Basic solution	**[15.3c]**

At other temperatures the pH of water differs from 7.00 (see Table 15.1). A change of one pH unit implies that the concentrations of H_3O^+ and OH^- change by a factor of 10 (that is, one order of magnitude). The pH is most directly measured with a **pH meter** (Fig. 15.3). The mechanism by which pH meters operate is described in Chapter 17. Figure 15.4 shows the pH values for several common fluids.

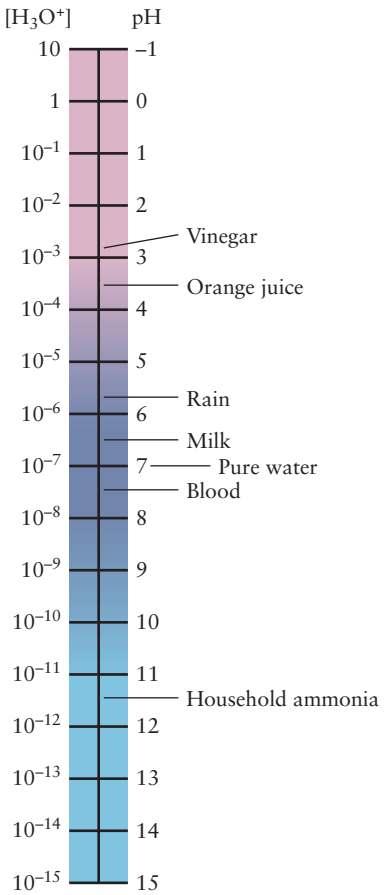

FIGURE 15.4 Many everyday materials are acidic or basic aqueous solutions with a wide range of pH values.

EXAMPLE 15.4

(a) A solution is prepared by dissolving 0.23 mol of NaH(*s*) in enough water to form 2.8 L of solution. Calculate its pH.

(b) The pH of some orange juice at 25°C is 2.85. Calculate $[H_3O^+]$ and $[OH^-]$.

Solution

(a) Because H^- is a strong base, it reacts to give 0.23 mol of OH^-:

$$NaH(s) + H_2O(\ell) \longrightarrow Na^+(aq) + OH^-(aq) + H_2(g)$$

The concentration is

$$[OH^-] = \frac{0.23 \text{ mol}}{2.8 \text{ L}} = 8.2 \times 10^{-2} \text{ M}$$

$$[H_3O^+] = \frac{1.0 \times 10^{-14}}{8.2 \times 10^{-2}} = 1.2 \times 10^{-13} \text{ M}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The pH is then

$$\text{pH} = -\log_{10}\,(1.22 \times 10^{-13}) = 12.91$$

(b)
$$\text{pH} = 2.85 = -\log_{10}\,[H_3O^+]$$
$$[H_3O^+] = 10^{-2.85}$$

This can be evaluated by using a calculator to give

$$[H_3O^+] = 1.4 \times 10^{-3}\ \text{M}$$
$$[OH^-] = \frac{1.0 \times 10^{-14}}{1.4 \times 10^{-3}} = 7.1 \times 10^{-12}$$

Related Problems: 13, 14, 15, 16

15.3 ACID AND BASE STRENGTH

Hydrogen cyanide, HCN, is a highly toxic gas that dissolves in water to form equally toxic solutions of hydrocyanic acid.

Acids are classified as strong or weak, depending on the extent to which they are ionized in solution. In a **weak acid** the transfer of hydrogen ions to water does not proceed to completion. A weak acid such as acetic acid is thus also a **weak electrolyte;** its aqueous solutions do not conduct electricity as well as a strong acid of the same concentration because fewer ions are present. A weak acid shows smaller values for colligative properties than a strong acid (recall the effect of dissolved acetic acid on the freezing point of water in Fig. 11.13).

The Brønsted–Lowry theory helps to establish a quantitative scale for acid strength. The ionization of an acid (symbolized by "HA") in aqueous solution can be written as

$$HA(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + A^-(aq)$$

where A^- is the conjugate base of HA. The equilibrium expression for this chemical reaction (see Section 14.2) is

$$\frac{[H_3O^+][A^-]}{[HA]} = K_a \qquad [15.4]$$

where the subscript "a" stands for "acid."[1] For example, if the symbol A^- refers to the cyanide ion (CN^-), we write

$$\frac{[H_3O^+][CN^-]}{[HCN]} = K_a$$

where K_a is the **acid ionization constant** for hydrogen cyanide in water and has a numerical value of 6.17×10^{-10} at 25°C. Table 15.2 gives values of K_a, and the useful quantity $pK_a = -\log_{10} K_a$, for a number of important acids. The acid ionization constant is a quantitative measure of the strength of the acid in a particular solvent (in the present case, water). Because a weak acid does not react completely with the solvent, the concentrations of the products are low at equilibrium, and K_a is small. A strong acid reacts nearly completely so the concentration of HA in the denominator is nearly 0, and K_a is large. Determining the value of K_a for strong acids is difficult because the concentration of HA is too small to be measured accurately. Relative acid strengths for such strong acids are estimated by using a solvent that is a weaker base than water. If the solvent is a sufficiently weak base (i.e., has significantly less tendency to accept H^+ than does H_2O), a relatively strong

[1] $H_2O(\ell)$ is in its reference state, so it contributes the factor 1 (see Sections 14.2 and 14.3).

TABLE 15.2

Ionization Constants of Acids in Water at 25°C

Acid	HA	A^-	K_a	pK_a
Hydroiodic	HI	I^-	$\sim 10^{11}$	~ -11
Hydrobromic	HBr	Br^-	$\sim 10^{9}$	~ -9
Perchloric	$HClO_4$	ClO_4^-	$\sim 10^{7}$	~ -7
Hydrochloric	HCl	Cl^-	$\sim 10^{7}$	~ -7
Chloric	$HClO_3$	ClO_3^-	$\sim 10^{3}$	~ -3
Sulfuric (1)	H_2SO_4	HSO_4^-	$\sim 10^{2}$	~ -2
Nitric	HNO_3	NO_3^-	~ 20	~ -1.3
Hydronium ion	H_3O^+	H_2O	1	0.0
Iodic	HIO_3	IO_3^-	1.6×10^{-1}	0.80
Oxalic (1)	$H_2C_2O_4$	$HC_2O_4^-$	5.9×10^{-2}	1.23
Sulfurous (1)	H_2SO_3	HSO_3^-	1.54×10^{-2}	1.81
Sulfuric (2)	HSO_4^-	SO_4^{2-}	1.2×10^{-2}	1.92
Chlorous	$HClO_2$	ClO_2^-	1.1×10^{-2}	1.96
Phosphoric (1)	H_3PO_4	$H_2PO_4^-$	7.52×10^{-3}	2.12
Arsenic (1)	H_3AsO_4	$H_2AsO_4^-$	5.0×10^{-3}	2.30
Chloroacetic	$CH_2ClCOOH$	CH_2ClCOO^-	1.4×10^{-3}	2.85
Hydrofluoric	HF	F^-	6.6×10^{-4}	3.18
Nitrous	HNO_2	NO_2^-	4.6×10^{-4}	3.34
Formic	HCOOH	$HCOO^-$	1.77×10^{-4}	3.75
Benzoic	C_6H_5COOH	$C_6H_5COO^-$	6.46×10^{-5}	4.19
Oxalic (2)	$HC_2O_4^-$	$C_2O_4^{2-}$	6.4×10^{-5}	4.19
Hydrazoic	HN_3	N_3^-	1.9×10^{-5}	4.72
Acetic	CH_3COOH	CH_3COO^-	1.76×10^{-5}	4.75
Propionic	CH_3CH_2COOH	$CH_3CH_2COO^-$	1.34×10^{-5}	4.87
Pyridinium ion	$HC_5H_5N^+$	C_5H_5N	5.6×10^{-6}	5.25
Carbonic (1)	H_2CO_3	HCO_3^-	4.3×10^{-7}	6.37
Sulfurous (2)	HSO_3^-	SO_3^{2-}	1.02×10^{-7}	6.91
Arsenic (2)	$H_2AsO_4^-$	$HAsO_4^{2-}$	9.3×10^{-8}	7.03
Hydrosulfuric	H_2S	HS^-	9.1×10^{-8}	7.04
Phosphoric (2)	$H_2PO_4^-$	HPO_4^{2-}	6.23×10^{-8}	7.21
Hypochlorous	HClO	ClO^-	3.0×10^{-8}	7.53
Hydrocyanic	HCN	CN^-	6.17×10^{-10}	9.21
Ammonium ion	NH_4^+	NH_3	5.6×10^{-10}	9.25
Carbonic (2)	HCO_3^-	CO_3^{2-}	4.8×10^{-11}	10.32
Arsenic (3)	$HAsO_4^{2-}$	AsO_4^{3}	3.0×10^{-12}	11.53
Hydrogen peroxide	H_2O_2	HO_2^-	2.4×10^{-12}	11.62
Phosphoric (3)	HPO_4^{2-}	PO_4^{3-}	2.2×10^{-13}	12.67
Water	H_2O	OH^-	1.0×10^{-14}	14.00

(1) and (2) indicate the first and second ionization constants, respectively.

acid may not dissociate completely. For example, in the solvent diethyl ether ($C_2H_5OC_2H_5$), HCl is a weaker proton donor than $HClO_4$. Therefore HCl is a weaker acid than $HClO_4$.

The strength of a base is inversely related to the strength of its conjugate acid; the weaker the acid, the stronger its conjugate base, and vice versa. This fact is demonstrated by the values in Figure 15.5. We can see the origin of this fact by writing the equation for the ionization of a base such as ammonia in water in the form

$$\underset{\text{Acid}_1}{H_2O(\ell)} + \underset{\text{Base}_2}{NH_3(aq)} \rightleftharpoons \underset{\text{Acid}_2}{NH_4^+(aq)} + \underset{\text{Base}_1}{OH^-(aq)}$$

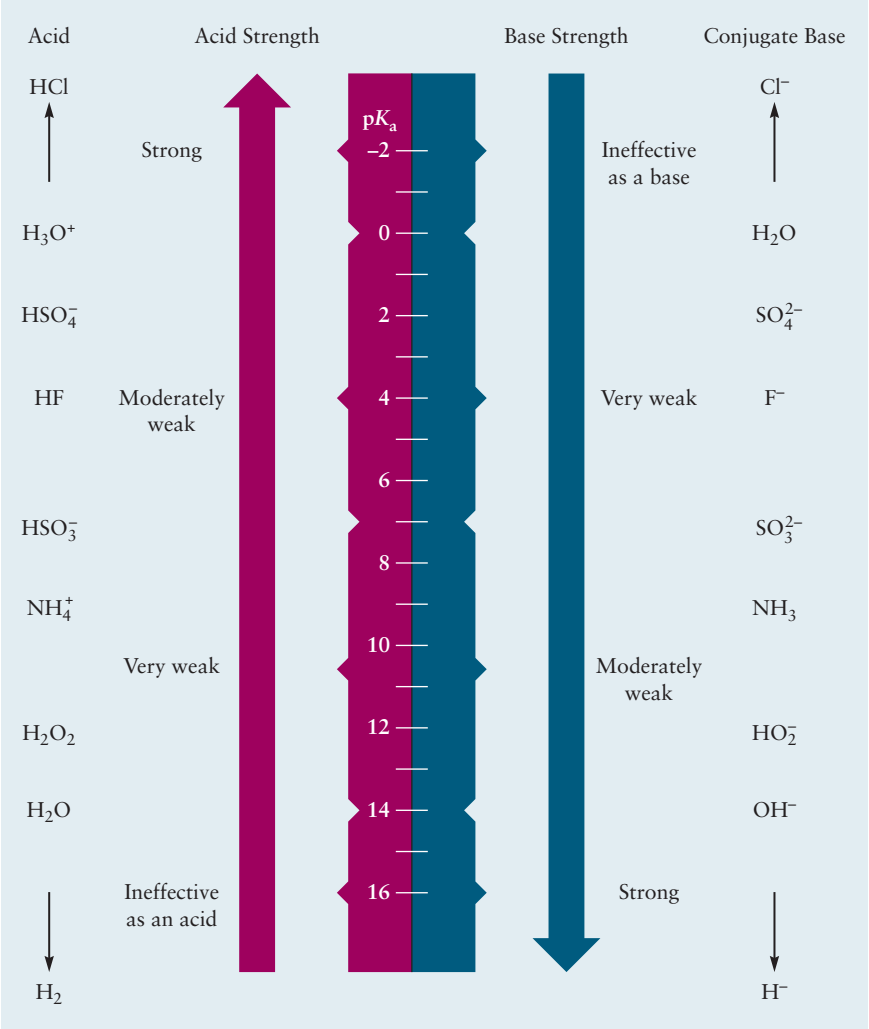

FIGURE 15.5 The relative strengths of some acids and their conjugate bases.

which gives an equilibrium expression of the form

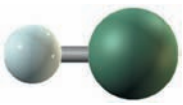
$$\frac{[NH_4^+][OH^-]}{[NH_3]} = K_b$$

where the subscript "b" on K_b stands for "base." Because $[OH^-]$ and $[H_3O^+]$ are related through the water autoionization equilibrium expression

$$[OH^-][H_3O^+] = K_w$$

the K_b expression can be written as

$$K_b = \frac{[NH_4^+]K_w}{[NH_3][H_3O^+]} = \frac{K_w}{K_a}$$



where K_a is the acid ionization constant for NH_4^+, the conjugate acid of the base NH_3. This general relationship between the K_b of a base and the K_a of its conjugate acid shows that K_b need not be tabulated separately from K_a, because the two are related through

$$K_w = K_a K_b \qquad [15.5]$$

Equation 15.5 is the basis of the inverse relationship between the strength of a base and its conjugate acid illustrated in Figure 15.5. Taking the logarithm of both sides of the equation and multiplying through by -1 shows that

$$pK_a + pK_b = pK_w$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Hydrogen fluoride, HF, is a colorless liquid that boils at 19.5°C. It dissolves in water to give solutions of hydrofluoric acid, a weak acid.

for a conjugate acid–base pair. This equation shows the inverse relationship in terms of pK values: the weaker the acid (pK_a large, K_a small), the stronger the conjugate base (pK_b small, K_b large). When values are needed for K_b or pK_b, they can be easily calculated from the tabulated values for K_a and pK_a. For example, we obtain the value of K_b for ammonia (NH_3) from the K_a value for the ammonium ion (NH_4^+) in Table 15.2:

$$K_b(NH_3) = \frac{K_w}{K_a(NH_4^+)} = \frac{1.0 \times 10^{-14}}{5.6 \times 10^{-10}} = 1.8 \times 10^{-5}$$

The ammonium ion is a very weak acid. Its conjugate base ammonia is a moderately weak base.

When two bases compete for protons, the stronger base dominates the equilibrium state in the sense that it holds the larger fraction of protons and is therefore present in a lesser amount in its basic form at equilibrium. The stronger acid donates hydrogen ions to the stronger base, producing a weaker acid and a weaker base at equilibrium. To see this consider the equilibrium

$$\underset{\text{Acid}_1}{HF(aq)} + \underset{\text{Base}_2}{CN^-(aq)} \rightleftharpoons \underset{\text{Acid}_2}{HCN(aq)} + \underset{\text{Base}_1}{F^-(aq)}$$

with equilibrium constant

$$\frac{[HCN][F^-]}{[HF][CN^-]} = K$$

The two bases F^- and CN^- compete for hydrogen ions. We can construct this net reaction by starting with one acid ionization reaction

$$HF(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + F^-(aq)$$
$$\frac{[H_3O^+][F^-]}{[HF]} = K_a = 6.6 \times 10^{-4}$$

and *subtracting* from it a second acid ionization reaction:

$$HCN(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CN^-(aq)$$
$$\frac{[H_3O^+][CN^-]}{[HCN]} = K_a' = 6.17 \times 10^{-10}$$

When the net reaction is the difference of two reactions, the equilibrium constant for the net reaction is the ratio of those for the separate reactions. (Section 14.4) The numerical value of K is

$$K = \frac{K_a}{K_a'} = \frac{6.6 \times 10^{-4}}{6.17 \times 10^{-10}} = 1.1 \times 10^6$$

Because HCN is a weaker acid than HF, K_a' is smaller than K_a, and K is larger than 1. The equilibrium described by K lies strongly to the right. Most of the hydrogen ions end up associated with $CN^-(aq)$, the stronger base, rather than with $F^-(aq)$, the weaker base. The dissolved species present in greatest amount at equilibrium are $HCN(aq)$, which is a weaker acid than $HF(aq)$, and $F^-(aq)$ which is a weaker base than $CN^-(aq)$.

Similar manipulations of chemical reaction equations and their associated equilibrium expressions predict the direction and extent of proton transfer in all Brønsted–Lowry acid–base reactions.

EXAMPLE 15.5

Predict the direction of proton transfer in the reaction of acetic acid and ammonia in aqueous solution. Describe qualitatively the extent of reaction and the composition of the equilibrium state.

$$CH_3COOH(aq) + NH_3(aq) \longrightarrow CH_3COO^-(aq) + NH_4^+(aq)$$

Solution
The equilibrium expression for this reaction is

$$\frac{[CH_3COO^-][NH_4^+]}{[CH_3COOH][NH_3]} = K$$

This reaction can be constructed by subtracting the second acid ionization from the first acid ionization below:

$$CH_3COOH(aq) + H_2O(aq) \longrightarrow CH_3COO^-(aq) + H_3O(aq)$$
$$\frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = K_{a1}$$
$$NH_4^+(aq) + H_2O(aq) \longrightarrow H_3O^+(aq) + NH_3(aq)$$
$$\frac{[H_3O^+][NH_3]}{[NH_4^+]} = K_{a2}$$

The equilibrium constant for the net reaction is the ratio of the equilibrium constants for the separate reactions. Inserting values from Table 15.2 gives the result

$$K = \frac{K_{a1}}{K_{a2}} = \frac{1.76 \times 10^{-5}}{5.6 \times 10^{-10}} = 3.1 \times 10^4$$

The equilibrium described by K lies strongly to the right. The net result is donation of H^+ by the stronger acid (CH_3COOH) (aq) to the stronger base (NH_3) (aq) to produce the weaker acid (NH_4^+)(aq) and the weaker base (CH_3COO^-)(aq). Most of the H^+ ends up associated with the NH_3 (aq) rather than the CH_3COO^-(aq). If the reaction begins with the same amounts of acetic acid and ammonia, the ratio of products to reactants in the equilibrium state is 30,000:1.

Related Problems: 23, 24

Molecular Structure and Acid Strength

The strength of an acid is determined by its tendency to lose a proton, converting it to its conjugate base, which is an anion. The more stable the anion, the further the reaction can proceed from left to right. Acid strength, therefore, depends on the ability of the anion to accommodate its negative charge, which increases with the electronegativity of the central atom in the anion.

Trends in the relative strength of oxoacids are explained by the influence of electronegativity and bond polarity on the ease of donating a proton. The protons donated by **oxoacids** in aqueous solution were previously bonded to oxygen atoms on the acid molecule. Examples include sulfuric acid (H_2SO_4), nitric acid (HNO_3), and phosphoric acid (H_3PO_4). If the central atom is designated X, then oxoacids have the structure

$$-X-O-H$$

where X can be bonded to additional $-OH$ groups, to oxygen atoms, or to hydrogen atoms. How does the strength of the oxoacid change as the electronegativity of X changes? Consider first the extreme case in which X is a highly electropositive element, such as an alkali metal. Of course, NaOH is not an acid at all, but a base. The sodium atom in $Na-O-H$ gives up a full electron to make Na^+ and OH^- ions. Because the $X-O$ bond here is almost completely ionic, the OH^- group has a net negative charge that holds the H^+ tightly to the oxygen and prevents formation of H^+ ions. The less electropositive alkaline-earth elements behave similarly. They form hydroxides, such as $Mg(OH)_2$, that are somewhat weaker bases than NaOH but in no way act as acids.

Now suppose the central atom X becomes more electronegative, reaching values between 2 and 3, as in the oxoacids of the elements B, C, P, As, S, Se, Br, and I. As

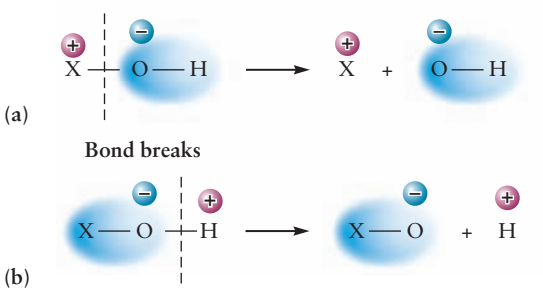
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



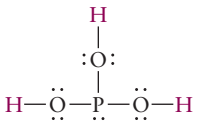


FIGURE 15.6 In part (a) the atom X is electropositive, so extra electron density (blue areas) accumulates on the OH group. The X—O bond then breaks easily, making the compound a base. In part (b) X is electronegative, so electron density is drawn from the H atom to the X—O bond. Now it is the O—H bond that breaks easily, and the compound is an acid.

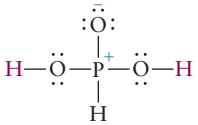

FIGURE 15.7 (a) The simplest Lewis diagram that can be drawn for H_3PO_3 gives an incorrect structure. This acid would be triprotic, like H_3PO_4. (b) The observed structure of H_3PO_3 requires assigning formal charge to the P atom and the lone O atom. The hydrogen atom attached to the P is not released into acid solution, so the acid is diprotic.

X becomes more effective at withdrawing electron density from the oxygen atom, the X—O bond becomes more covalent. This leaves less negative charge on the oxygen atom, and consequently the oxoacid releases H^+ more readily (Fig. 15.6). Other things being equal, acid strength should increase with increasing electronegativity of the central atom. This trend is observed among the oxoacids listed in Table 15.2.

The strength of oxoacids with a given central element X increases with the number of lone oxygen atoms attached to the central atom. If the formula of these acids is written as $XO_n(OH)_m$, the corresponding acid strengths fall into distinct classes according to the value of n, the number of lone oxygen atoms (see Table 15.3). Each increase of 1 in n increases the acid ionization constant K_a by a factor of about 10^5. Another way to describe this effect is to focus on the stability of the conjugate base, $XO_{n+1}(OH)^-_{m-1}$, of the oxoacid. The greater the number of lone oxygen atoms attached to the central atom, the more easily the net negative charge can be spread out over the ion, and therefore the more stable the base. This leads to a larger K_a.

An unusual and interesting structural result can be obtained from Table 15.3. Figure 15.7a shows the simplest Lewis diagram for phosphorous acid (H_3PO_3) in which each atom achieves an octet configuration. Such a diagram could also be written $P(OH)_3$ and would be analogous to $As(OH)_3$, which has no lone oxygen atoms bonded to the central atom ($n = 0$). On the basis of this analogy, we would expect the value of K_a for $P(OH)_3$ to be on the order of 10^{-9} (a very weak acid). But in fact, H_3PO_3 is only a moderately weak acid ($K_a = 1 \times 10^{-2}$) and fits better into the class of acids with one lone oxygen atom bonded to the central atom. X-ray diffraction measurements support this structural conclusion inferred from chemical behavior. So, the structure of H_3PO_3 is best represented by Figure 15.7b and cor-

responds either to a Lewis diagram with more than eight electrons around the central phosphorus atom or to one with formal charges on the central phosphorus and lone oxygen atoms. The formula of this acid is written as $HPO(OH)_2$ in Table 15.3. Unlike phosphoric acid (H_3PO_4), which is a triprotic acid, H_3PO_3 is a diprotic acid. The third hydrogen atom, the one directly bonded to the phosphorus atom, does not ionize even in strongly basic aqueous solution.

Indicators

An **indicator** is a soluble dye that changes color noticeably over a fairly narrow range of pH. The typical indicator is a weak organic acid that has a different color from its conjugate base (Fig. 15.8). Litmus changes from red to blue as its acid form is converted to base. Good indicators have such intense colors that only a few drops of a dilute indicator solution must be added to the solution being studied. The very low concentration of indicator molecules has almost no effect on the pH of solution. The color changes of the indicator reflect the effects of the *other* acids and bases present in the solution.

If the acid form of a given indicator is represented as HIn and the conjugate base form as In^-, their acid–base equilibrium is

$$HIn(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + In^-(aq)$$

$$\frac{[H_3O^+][In^-]}{[HIn]} = K_a$$

where K_a is the acid ionization constant for the indicator. This expression can be rearranged to give

$$\frac{[H_3O^+]}{K_a} = \frac{[HIn]}{[In^-]} \qquad [15.6]$$

If the concentration of hydronium ion $[H_3O^+]$ is large relative to K_a, this ratio is large, and [HIn] is large compared with $[In^-]$. The solution has the color of the acid form of the indicator because most of the indicator molecules are in the acid form. Litmus, for example, has a K_a near 10^{-7}. If the pH is 5, then

$$\frac{[H_3O^+]}{K_a} = \frac{10^{-5}}{10^{-7}} = 100$$

Thus, approximately 100 times as many indicator molecules are in the acid form as in the base form, and the solution is red.

As the concentration of hydronium ion is reduced, more molecules of acid indicator ionize to give the base form. When $[H_3O^+]$ is near K_a, almost equal amounts of the two forms are present, and the color is a mixture of the colors of the two indicator states (violet for litmus). A further decrease in $[H_3O^+]$ to a value much smaller than K_a then leads to a predominance of the base form, with the corresponding color being observed.

Different indicators have different values for K_a and thus show color changes at different pH values (Fig. 15.9). The weaker an indicator is as an acid, the higher the pH at which the color change takes place. Such color changes occur over a range of 1 to 2 pH units. Methyl red, for example, is red when the pH is below 4.8 and yellow above 6.0; shades of orange are seen at intermediate pH values. This limits the accuracy to which the pH can be determined through the use of indicators. Section 15.6 shows that this fact does not affect the analytical determination of acid or base concentrations through titration, provided that an appropriate indicator is used.

Many natural dyes found in fruits, vegetables, and flowers act as pH indicators by changing color with changes in acidity (Fig. 15.10). A particularly striking example is cyanidin, which is responsible both for the red color of poppies and the blue color of cornflowers. The sap of the poppy is sufficiently acidic to turn cyanidin red, but the sap of the cornflower is basic and makes the dye blue. (See the image on page 669.) Related natural dyes called anthocyanins contribute to the colors of raspberries, strawberries, and blackberries.

15.4 EQUILIBRIA INVOLVING WEAK ACIDS AND BASES

The reactions of weak acids and bases with water do not go to completion. So, to calculate the pH of their solutions, we use K_a or K_b and the laws of chemical equilibrium. The calculations follow the pattern of Example 14.10 for gas equilibria. In that case the initial gas-phase pressures $P°$ are known, and we calculate the pressures of products resulting from the incomplete reaction. Here we know the initial concentration of acid or base, and calculate the concentrations of products resulting from its partial reaction with water.

Weak Acids

A weak acid has a K_a smaller than 1. Values of the pK_a start at zero for the strongest weak acid and range upward for progressively weaker acids. (If the pK_a is greater than 14, the compound is ineffective as an acid in aqueous solution.) When a weak acid is dissolved in water, the original concentration of HA is almost always known, but partial reaction with water consumes some HA and generates A^- and H_3O^+:

$$HA(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + A^-(aq)$$

To calculate the amounts of H_3O^+, A^-, and HA at equilibrium, we use the methods of Chapter 14, with partial pressures replaced by concentrations. A new feature here is that one of the products (H_3O^+) can also come from a second source, the autoionization of the solvent, water. In most of the applications we study, this second effect is small and can be neglected in the equations. Even so, it is a good idea to verify at the end of each calculation that the $[H_3O^+]$ from the acid ionization alone exceeds 10^{-7} M by at least one order of magnitude. Otherwise, we have to use the more complete method of analysis given in Section 15.9.

EXAMPLE 15.6

Acetic acid (CH_3COOH) has a K_a of 1.76×10^{-5} at 25°C. Suppose 1.000 mol is dissolved in enough water to give 1.000 L of solution. Calculate the pH and the fraction of acetic acid ionized at equilibrium.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

The initial concentration of acetic acid is 1.000 M. If y mol L^{-1} ionizes, then

	$CH_3COOH(aq) + H_2O(\ell) \rightleftharpoons$	$H_3O^+(aq) +$	$CH_3COO^-(aq)$
Initial concentration (M)	1.000	≈0	0
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$1.000 - y$	y	y

Note that we ignored the H_3O^+ initially present from the ionization of water because we expect it to be smaller than y for all but the weakest acids or the most dilute solutions. Then, the equilibrium expression states that

$$\frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{y^2}{1.000 - y} = K_a = 1.76 \times 10^{-5}$$

This equation could be solved using the quadratic formula, as we did in Chapter 14, or by using a programmable calculator. But it is important to develop approximation methods that enable quick solutions and also develop chemical insight and intuition into the equilibrium process. These approximations are based on the fact that acetic acid is a weak acid, and therefore only a small fraction is ionized at equilibrium. Therefore it is reasonable to assume that y is small relative to 1.000 (that is, the final equilibrium concentration of CH_3COOH is close to its initial concentration). This gives

$$\frac{y^2}{1.000 - y} \approx \frac{y^2}{1.000} = 1.76 \times 10^{-5}$$

$$y = 4.20 \times 10^{-3}$$

so

$$[H_3O^+] = y = 4.20 \times 10^{-3} \text{ M}$$

Now we have to check whether the approximations are indeed valid. First, y is indeed much smaller than the original concentration of 1.000 M (by a factor of 200), so neglecting it in the denominator is justified. Second, the concentration of H_3O^+ from acetic acid (4.2×10^{-3} M) is large compared with 10^{-7} M, so neglecting the water ionization is also justified. Therefore,

$$\text{pH} = -\log_{10}(4.2 \times 10^{-3}) = 2.38$$

The fraction ionized is the ratio of the concentration of CH_3COO^- present at equilibrium to the concentration of CH_3COOH present in the first place:

$$\frac{y}{1.000} = y = 4.2 \times 10^{-3}$$

The percentage of the acetic acid that is ionized is 0.42%. Fewer than one in a hundred of the molecules of this typical weak acid dissociate in this solution.

Related Problems: 27, 28, 29, 30

Approximation methods of the type used in this example are also used in Example 14.10 and are discussed more extensively in Appendix C. As the solution of a weak acid becomes more dilute, a greater fraction of it ionizes, as shown by the following example.

EXAMPLE 15.7

Suppose that 0.00100 mol of acetic acid is used instead of the 1.000 mol in the preceding example. Calculate the pH and the percentage of acetic acid ionized.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

Once again we assume that the contribution of the ionization of water to $[H_3O^+]$ is negligible, and check the validity of the assumption at the end of the calculation. Hence,

$$[CH_3COOH] = 0.00100 - y$$

$$[CH_3COO^-] = [H_3O^+] = y$$

$$\frac{y^2}{0.00100 - y} = 1.76 \times 10^{-5}$$

In this case, y is *not* small relative to 0.00100 because a substantial fraction of the acetic acid molecules ionizes, so y cannot be neglected in the denominator. There are two alternatives for solving the problem in this case.

The first method is to solve the quadratic equation obtained by multiplying out the equilibrium expression:

$$y^2 + (1.76 \times 10^{-5})y - (1.76 \times 10^{-8}) = 0$$

Using the quadratic formula gives

$$y = 1.24 \times 10^{-4} \text{ M} = [H_3O^+] = [CH_3COO^-]$$

Because $y \gg 10^{-7}$ M, neglecting water ionization in setting up the problem is justified.

$$\text{pH} = -\log_{10} (1.24 \times 10^{-4}) = 3.91$$

$$\text{percentage ionized} = \frac{1.24 \times 10^{-4} \text{ M}}{0.00100 \text{ M}} \times 100\% = 12.4\%$$

The other approach to solving the problem is to use successive approximations (see Appendix C). Begin by neglecting y in the denominator (relative to 0.00100), which gives

$$\frac{y^2}{0.00100} = 1.76 \times 10^{-5}$$

$$y = 1.33 \times 10^{-4} \text{ M}$$

This is just what we do in Example 15.6. Now, continue by reinserting this *approximate* value of y into the *denominator* and then recalculate y:

$$\frac{y^2}{0.00100 - 0.00133} = 1.76 \times 10^{-5}$$

$$y^2 = 1.53 \times 10^{-8}$$

$$y = 1.33 \times 10^{-4} \text{ M}$$

If we insert this new value of y into the denominator and iterate the calculation once again, we obtain 1.24×10^{-4} M, the same value produced by the quadratic formula. We terminate the iteration process when two successive results for y agree to the desired number of significant figures.

Related Problems: 31, 32

The method of successive approximations is often faster to apply than the quadratic formula. Keep in mind that the accuracy of a result is limited both by the accuracy of the input data (values of K_a and initial concentrations) and by the fact that solutions are not ideal. It is pointless to calculate equilibrium concentrations to any degree of accuracy higher than 1% to 3%.

Weak Bases

There is a perfect parallel between the behavior of weak bases and weak acids. The definition and description of weak acids, the existence of K_a, and the production of $H_3O^+(aq)$ ion when they are dissolved in water can be applied directly to weak

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

bases, the existence of K_b, and the production of $OH^-(aq)$ ion. A **weak base** such as ammonia reacts only partially with water to produce $OH^-(aq)$:

$$H_2O(\ell) + NH_3(aq) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$$

$$\frac{[NH_4^+][OH^-]}{[NH_3]} = K_b = 1.8 \times 10^{-5}$$

The K_b of a weak base is smaller than 1, and the weaker the base, the smaller the K_b. If the K_b of a compound is smaller than 1×10^{-14}, that compound is ineffective as a base in aqueous solution.

The analogy to weak acids continues in the calculation of the aqueous equilibria of weak bases, as the following example shows.

EXAMPLE 15.8

Calculate the pH of a solution made by dissolving 0.0100 mol of NH_3 in enough water to give 1.000 L of solution at 25°C. The K_b for ammonia is 1.8×10^{-5}.

Solution

Set up the table of the changes in concentrations that occur as the reaction goes to equilibrium, neglecting the small contribution to $[OH^-]$ from the autoionization of water:

	$H_2O(\ell)$ + $NH_3(aq)$	$\rightleftharpoons NH_4^+(aq)$	+ $OH^-(aq)$
Initial concentration (M)	0.0100	0	≈0
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.100 - y$	y	y

Substitution into the equilibrium expression gives

$$\frac{y^2}{0.0100 - y} = K_b = 1.8 \times 10^{-5}$$

which can be solved for y by either the quadratic formula or the method of successive approximations to obtain:

$$y = 4.15 \times 10^{-4}\ \text{M} = [OH^-]$$

The product of $[H_3O^+]$ and $[OH^-]$ is always K_w. Hence,

$$[H_3O^+] = \frac{K_w}{[OH^-]} = \frac{1.0 \times 10^{-14}}{4.15 \times 10^{-14}} = 2.4 \times 10^{-11}$$

$$\text{pH} = -\log_{10}\ (2.4 \times 10^{-11}) = 10.62$$

The pH is greater than 7, as expected for a solution of a base.

Related Problems: 35, 36

Hydrolysis

Most of the acids considered up to now have been uncharged species with the general formula HA. In the Brønsted–Lowry picture there is no reason why the acid should be an electrically neutral molecule. When NH_4Cl, a salt, dissolves in water, NH_4^+ ions are present. Some of these ionize by transferring hydrogen ions to water in a straightforward Brønsted–Lowry acid–base reaction:

$$\underset{\text{Acid}_1}{NH_4^+(aq)} + \underset{\text{Base}_2}{H_2O(\ell)} \rightleftharpoons \underset{\text{Acid}_2}{H_3O^+(aq)} + \underset{\text{Base}_1}{NH_3(aq)}$$

$$\frac{[H_3O^+][NH_3]}{NH_4^+} = K_a = 5.6 \times 10^{-10}$$

(a) (b) (c)

Cengage Learning/Leon Lewandowski

FIGURE 15.11 Proof that ammonium chloride is an acid. (a) A solution of sodium hydroxide, with the pink color of phenolphthalein indicating its basic character. (b and c) As aqueous ammonium chloride is added, a neutralization reaction takes place and the solution turns colorless from the bottom up.

NH_4^+ acts as an acid here, just as acetic acid did in Examples 15.6 and 15.7. Because K_a is much smaller than 1, only a small amount of H_3O^+ is generated. NH_4^+ is a weak acid, but it is nonetheless an acid, and a solution of ammonium chloride has a pH below 7 (Fig. 15.11).

Hydrolysis is the label for the reaction of a substance with water. This term is applied especially to a reaction in which the pH changes from 7 upon dissolving a salt (in this case, NH_4Cl) in water. There is no need for any special description of hydrolysis. The hydrolysis reaction that takes place when NH_4Cl dissolves in water is completely described as a Brønsted–Lowry reaction in which water acts as a base and NH_4^+ acts as an acid to give a pH below 7. In parallel fashion, dissolving a salt whose anion is a weak base produces a basic solution. This too is a case of hydrolysis; it is simply another Brønsted–Lowry acid–base reaction, with water acting now as an acid (a hydrogen ion donor).

Two salts that give basic solutions are sodium acetate and sodium fluoride. When these salts dissolve in water, they furnish acetate (CH_3COO^-) and fluoride (F^-) ions, respectively, both of which act as Brønsted–Lowry bases,

$$H_2O(\ell) + CH_3COO^-(aq) \rightleftharpoons CH_3COOH(aq) + OH^-(aq)$$

$$H_2O(\ell) + F^-(aq) \rightleftharpoons HF(aq) + OH^-(aq)$$

causing the OH^- concentration to increase and give a pH above 7.

EXAMPLE 15.9

Suppose 0.100 mol of $NaCH_3COO$ is dissolved in enough water to make 1.00 L of solution. What is the pH of the solution?

Solution

The K_a for CH_3COOH, the conjugate acid of CH_3COO^-, is 1.76×10^{-5}. Therefore, K_b for the acetate ion is

$$\frac{[CH_3COOH][OH^-]}{[CH_3COO^-]} = K_b = \frac{K_w}{K_a} = 5.7 \times 10^{-10}$$

The equilibrium here is

$$H_2O(\ell) + CH_3COO^-(aq) \rightleftharpoons CH_3COOH(aq) + OH^-(aq)$$

Initial concentration (M)	0.100	0	≈0
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.100 - y$	y	y

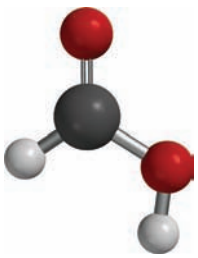
Substitution into the equilibrium expression gives

$$\frac{y^2}{0.100 - y} = K_b = 5.7 \times 10^{-10}$$

$$y = 7.5 \times 10^{-6} \text{ M} = [OH^-]$$

Note that y is small relative to 0.100 and fairly large relative to 10^{-7}.

$$[H_3O^+] = \frac{K_w}{[OH^-]} = \frac{1.0 \times 10^{-14}}{7.5 \times 10^{-6}} = 1.3 \times 10^{-9} \text{ M}$$



$$\text{pH} = 8.89$$

Related Problems: 41, 42

Hydrolysis does not occur with all ions, only with those that are conjugate acids of weak bases or conjugate bases of weak acids. Chloride ion is the conjugate base of the strong acid HCl and consequently is ineffective as a base, unlike $F^-(aq)$ and $CH_3COO^-(aq)$. Its interaction with water would therefore scarcely change the $OH^-(aq)$ concentration. So, a solution of NaCl is neutral, whereas a solution of NaF is slightly basic.

15.5 BUFFER SOLUTIONS

A **buffer solution** maintains approximately constant pH upon small additions of acid or base. Typically, a buffer solution contains a weak acid and its conjugate weak base in approximately equal concentrations. Buffer solutions play important roles in controlling the solubility of ionic compounds in solution (see Chapter 16) and in maintaining the pH in biochemical and physiological processes. Many life processes are sensitive to pH and require regulation within a small range of H_3O^+ and OH^- concentrations. Organisms have built-in buffers to protect them against large changes in pH. Human blood has a pH near 7.4, which is maintained by a combination of carbonate, phosphate, and protein buffer systems. Conditions that drive blood pH below 7.0 or above 7.8 lead quickly to death.

Formic acid, HCOOH, is the simplest carboxylic acid, with only a hydrogen atom attached to the —COOH group.

Calculations of Buffer Action

Consider a typical weak acid, formic acid (HCOOH), and its conjugate base, formate ion ($HCOO^-$). The latter can be obtained by dissolving a salt such as sodium formate (NaHCOO) in water. The acid–base equilibrium established between these species is given by

$$HCOOH(aq) + H_2O(\ell) \longrightarrow H_3O^+(aq) + HCOO^-(aq)$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

with an acid ionization constant

$$\frac{[H_3O^+][HCOO^-]}{[HCOOH]} = K_a = 1.77 \times 10^{-4}$$

Section 15.2 describes the pH of a solution containing only a weak acid (such as HCOOH) or only a weak base (such as $HCOO^-$). Suppose now that the weak acid and its conjugate base are *both* present initially. The resulting calculations resemble closely the calculation of Example 14.15, in which equilibrium was established from an initial mixture containing both reactants and products.

EXAMPLE 15.10

Suppose 1.00 mol of HCOOH and 0.500 mol of NaHCOO are added to water and diluted to 1.00 L. Calculate the pH of the solution.

Solution

	$HCOOH(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HCOO^-(aq)$		
Initial concentration (M)	1.00	≈0	0.500
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$1.00 - y$	y	$0.500 + y$

The equilibrium expression is

$$\frac{y(0.500 + y)}{1.00 - y} = K_a = 1.77 \times 10^{-4}$$

Because y is likely to be small relative to 1.00 and to 0.500, we write the approximate expression

$$\frac{y(0.500)}{1.00} \approx 1.77 \times 10^{-4}$$

$$y \approx 3.54 \times 10^{-4} \text{ M} = [H_3O^+]$$

A glance verifies that y is indeed small relative to 1.00 and 0.500. Then

$$\text{pH} = -\log_{10}(3.54 \times 10^{-4}) = 3.45$$

Related Problems: 43, 44

To understand how buffer solutions work, let's write the equilibrium expression for the ionization of a weak acid HA in the form

$$[H_3O^+] = K_a \frac{[HA]}{[A^-]}$$

The concentration of hydronium ion depends on the ratio of the concentration of the weak acid to the concentration of its conjugate base. The key to effective buffer action is to keep these concentrations nearly equal and fairly large. Adding a small amount of base to an effective buffer takes away only a few percent of the HA molecules by converting them into A^- ions and adds only a few percent to the amount of A^- originally present. The ratio $[HA]/[A^-]$ decreases, but only very slightly. Added acid consumes a small fraction of the base A^- to generate a bit more HA. The ratio $[HA]/[A^-]$ now increases, but again the change is only slight. Because the concentration of H_3O^+ is tied directly to this ratio, it changes only slightly. The following example illustrates buffer action quantitatively.

EXAMPLE 15.11

Suppose 0.10 mol of a strong acid such as HCl is added to the solution in Example 15.10. Calculate the pH of the resulting solution.

Solution

The strong acid HCl ionizes essentially completely in dilute aqueous solution. Initially assume that *all* the hydrogen ions from HCl are taken up by formate ions to produce formic acid, some of which ionizes back to formate ion and H_3O^+. This is simply a way of describing one possible route by which equilibrium is approached and does not define the sequence of reactions that actually occurs. The position of the final equilibrium does not depend on the route by which it is attained.

Because 0.10 mol of HCl reacts with an equal number of moles of $HCOO^-$, the concentrations of $HCOO^-$ and HCOOH *before* ionization are

$$[HCOO^-]_0 = 0.50 - 0.10 = 0.40 \text{ M}$$

$$[HCOOH]_0 = 1.00 + 0.10 = 1.10 \text{ M}$$

The table to calculate the concentrations at equilibrium is

	$HCOOH(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HCOO^-(aq)$		
Initial concentration (M)	1.10	≈0	0.40
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$1.10 - y$	y	$0.40 + y$

The equilibrium expression then becomes

$$\frac{y(0.40 + y)}{1.10 - y} = 1.77 \times 10^{-4}$$

Because y is again likely to be small relative to both 0.40 and 1.10,

$$y \approx \left(\frac{1.10}{0.40}\right)(1.77 \times 10^{-4}) = 4.9 \times 10^{-4}$$

$$\text{pH} = 3.31$$

Even though 0.10 mol of a strong acid was added, the pH changed only slightly, from 3.45 to 3.31. In contrast, the same amount of acid added to a liter of pure water would change the pH from 7 to 1.

Related Problems: 45, 46

Note that we solved this problem by first performing a stoichiometric (limiting reactant) calculation and then an equilibrium calculation. A similar strategy works if a strong base such as OH^- is added instead of a strong acid. The base reacts with formic acid to produce formate ions. Adding 0.10 mol of OH^- to the $HCOOH/HCOO^-$ buffer of Example 15.10 increases the pH only to 3.58. In the absence of the buffer system, the same base would raise the pH to 13.00.

In any buffer there is competition between the tendency of the acid to donate hydrogen ions to water (increasing the acidity) and the tendency of the base to accept hydrogen ions from water (increasing the basicity). The resulting pH depends on the magnitude of K_a. If K_a is large relative to 10^{-7}, the acid ionization will win out and acidity will increase, as in the $HCOOH/HCOO^-$ buffer. A basic buffer (with pH > 7) can be prepared by working with an acid–base pair with K_a smaller than 10^{-7}. In this case the net reaction produces OH^-, and we must use K_b to determine the equilibrium state. A typical example is the NH_4^+/NH_3 buffer prepared by mixing ammonium chloride with ammonia.

EXAMPLE 15.12

Calculate the pH of a solution made by adding 0.100 mol of NH_4Cl and 0.200 mol of NH_3 to water and diluting to 1.000 L. K_a for NH_4^+ is 5.6×10^{-10}.

Solution

Because $K_a \ll 10^{-7}$ for NH_4^+ (equivalently, $K_b \gg 10^{-7}$ for NH_3), the net reaction is production of OH^- ions. Therefore, the equilibrium is written to show the net transfer of hydrogen ions from water to NH_3:

	$H_2O(\ell)$ +	$NH_3(aq)$ ⇌	$NH_4^+(aq)$ +	$OH^-(aq)$
Initial concentration (M)		0.200	0.100	0
Change in concentration (M)		$-y$	$+y$	$+y$
Equilibrium concentration (M)		$0.200 - y$	$0.100 + y$	y

The equilibrium expression is

$$\frac{y(0.100 + y)}{0.200 - y} = K_b = \frac{K_w}{K_a} = 1.8 \times 10^{-5}$$

If y is small relative to the original concentrations of both NH_3 and NH_4^+, then

$$\frac{y(0.100)}{0.200} \approx 1.8 \times 10^{-5}$$

$$y \approx \left(\frac{0.200}{0.100}\right)(1.8 \times 10^{-5}) = 3.6 \times 10^{-5} \ll 0.100,\ 0.200$$

$$[H_3O^+] = \frac{1.0 \times 10^{-14}}{[OH^-]} = \frac{1.0 \times 10^{-14}}{3.6 \times 10^{-5}} = 2.8 \times 10^{-10}\ \text{M}$$

$$\text{pH} = -\log_{10}(2.8 \times 10^{-10}) = 9.55$$

Designing Buffers

Control of pH is vital in synthetic and analytical chemistry, just as it is in living organisms. Procedures that work well at a pH of 5 may fail when the concentration of hydronium ion in the solution is raised tenfold to make the pH 4. Fortunately, it is possible to prepare buffer solutions that maintain the pH close to any desired value by the proper choice of a weak acid and the ratio of its concentration to that of its conjugate base. Let's see how to choose the best conjugate acid–base system and how to calculate the required acid–base ratio.

In Examples 15.10, 15.11, and 15.12, the equilibrium concentrations of acid and base in the buffer systems were close to the initial concentrations. When this is the case, the calculation of pH is simplified greatly, because for either an acidic *or* a basic buffer,

$$K_a = \frac{[H_3O^+][A^-]}{[HA]} \approx \frac{[H_3O^+][A^-]_0}{[HA]_0}$$

$$[H_3O^+] \approx \frac{[HA]_0}{[A^-]_0} K_a$$

and the pH is given by

$$\text{pH} \approx \text{p}K_a - \log_{10} \frac{[HA]_0}{[A^-]_0} \qquad [15.7]$$

We obtained Equation 15.7 by taking the logarithm and changing sign. It is easy to verify that this simple equation gives the correct result for the three preceding ex-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

amples. However, it must be used with some care because it is only approximate. It is valid only when *both* $[H_3O^+]$ and $[OH^-]$ are small relative to $[HA]_0$ and $[A^-]_0$; this means the extent of ionization must be small.

We can use this expression relating pH to pK_a to design buffers with a specific value of pH. In an optimal buffer the acid and its conjugate base are purposely very nearly equal in concentration; if the difference in concentrations is too great, the buffer is less resistant to the effects of adding acid or base. To select a buffer system, we choose an acid with a pK_a as close as possible to the desired pH. Then we adjust the concentrations of acid and conjugate base to give exactly the desired pH.

EXAMPLE 15.13

Design a buffer system with pH 4.60.

Solution

From Table 15.2, the pK_a for acetic acid is 4.75, so the CH_3COOH/CH_3COO^- buffer is a suitable one. The concentrations required to give the desired pH are related by

$$\text{pH} = 4.60 = pK_a - \log_{10} \frac{[CH_3COOH]_0}{[CH_3COO^-]_0}$$

$$\log_{10} \frac{[CH_3COOH]_0}{[CH_3CHOO^-]_0} = pK_a - \text{pH} = 4.75 - 4.60 = 0.15$$

$$\frac{[CH_3COOH]_0}{[CH_3COO^-]_0} = 10^{0.15} = 1.4$$

We can establish this ratio by dissolving 0.100 mol of sodium acetate and 0.140 mol of acetic acid in water and diluting to 1.00 L, or 0.200 mol of $NaCH_3COO$ and 0.280 mol of CH_3COOH in the same volume, and so on. As long as the ratio of the concentrations is 1.4, the solution will be buffered at approximately pH 4.60.

Related Problems: 47, 48, 49, 50

The preceding example shows that the *absolute* concentrations of acid and conjugate base in a buffer are much less important than is their ratio in determining the pH. Nonetheless, the absolute concentrations do affect the capacity of the solution to resist changes in pH when acid or base is added. The higher the concentrations of buffering species, the smaller the change in pH when a fixed

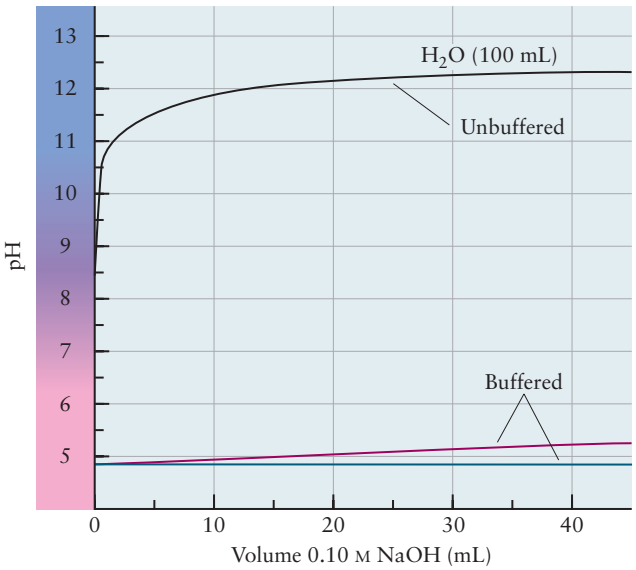

FIGURE 15.12 Addition of a given volume of base to buffered and unbuffered solutions causes a much greater change in the pH of the unbuffered solution. Of the two buffered solutions, the one with higher buffer concentration resists pH changes more effectively. The red line represents 100 mL of a buffer that is 0.1 M in both CH_3COOH and CH_3COO^-; the blue line represents the same volume of a buffer that is 1.0 M in both components.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

amount of a strong acid or base is added. In Example 15.10 a change in buffer concentrations from 1.00 M and 0.500 M to 0.500 M and 0.250 M does not alter the original pH of 3.45 because the ratio of acid to base concentrations is unchanged. The pH after 0.100 mol of HCl is added does change to the value 3.15 rather than 3.31. The buffer at lower concentration is less resistant to pH change (Fig. 15.12). The buffering capacity of *any* buffer solution is exhausted if enough strong acid (or strong base) is added to use up the original amount of weak base (or weak acid) through chemical reaction.

15.6 ACID–BASE TITRATION CURVES

Section 11.3 describes an acid–base titration as the addition of carefully metered volumes of a basic solution of known concentration to an acidic solution of unknown concentration—or the addition of acid to base—to reach an *endpoint* at which the unknown solution has been completely neutralized. The endpoint is signaled by the color change of an indicator or by a sudden rise or fall in pH. The pH of the reaction mixture changes continuously over the course of an acid–base titration, but changes abruptly only near the end point. A graph of the pH versus the volume V of titrating solution added is a **titration curve.** Its shape depends on the value of K_a and on the concentrations of the acid and base reacting. The concepts and tools of acid–base equilibria predict the exact shapes of titration curves when these quantities are all known. The same concepts allow K_a and the concentration of the unknown solution to be calculated from an experimental titration curve. Here we examine three categories of titration and determine the titration curve for each: strong acid reacting with strong base, weak acid reacting with strong base, and strong acid reacting with weak base. Titrations of a weak acid with a weak base (and the reverse) are not useful for analytical purposes.

Titration of a Strong Acid with a Strong Base

The addition of a strong base to a strong acid (or the reverse) is the simplest type of titration. The chemical reaction is the neutralization:

$$H_3O^+(aq) + OH^-(aq) \longrightarrow 2\,H_2O(\ell)$$

Suppose a solution of 100.0 mL (0.1000 L) of 0.1000 M HCl is titrated with 0.1000 M NaOH. What does the titration curve look like? The curve can be measured experimentally, and the result is shown in Figure 15.13. We can also construct the curve theoretically by calculating the pH of the reaction mixture at many different points during the addition of the NaOH solution and plotting the results. The following example illustrates the theoretical procedure.

1. **V = 0 mL NaOH added**
   Initially, $[H_3O^+] = 0.1000$ M, so the pH is 1.000. The number of moles of H_3O^+ present initially is

$$n_{H_3O^+} = [H_3O^+](\text{volume}) = (0.1000 \text{ mol L}^{-1})(0.1000 \text{ L})$$
$$= 1.000 \times 10^{-2} \text{ mol}$$

2. **V = 30.00 mL NaOH added**
   30.00 mL of 0.1000 M NaOH solution contains

$$(0.1000 \text{ mol L}^{-1})(0.03000 \text{ L}) = 3.000 \times 10^{-3} \text{ mol OH}^-$$

   This reacts with (and neutralizes) an equal number of moles of the H_3O^+ ion present initially and reduces $n_{H_3O^+}$ to

$$n_{H_3O^+} = (1.000 \times 10^{-2} - 3.000 \times 10^{-3})\text{mol} = 7.00 \times 10^{-3} \text{ mol}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

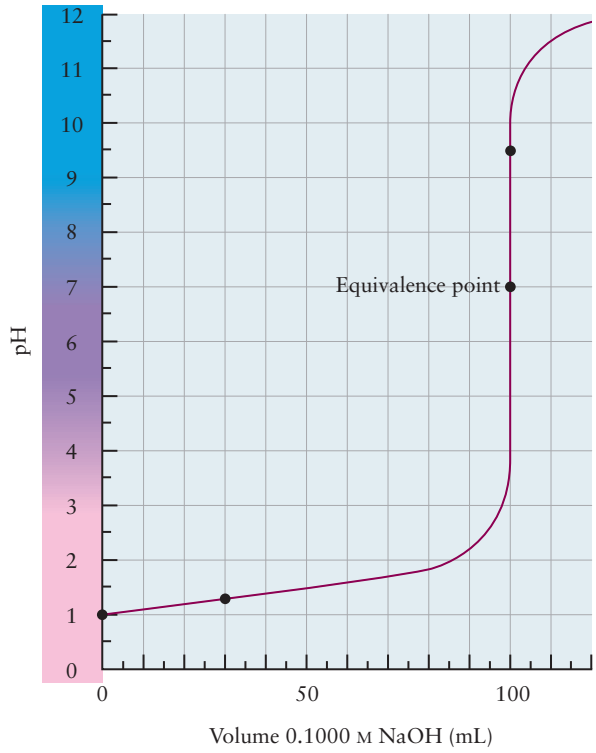

FIGURE 15.13 A titration curve for the titration of a strong acid by a strong base. The curve shown is for 100.0 mL of 0.1000 M HCl titrated with 0.1000 M NaOH.

In addition—and this is very important to remember—the volume of the titration mixture has increased from 100.0 to 130.0 mL (that is, from 0.1000 to 0.1300 L). The concentration of H_3O^+ at this point in the titration is

$$[H_3O^+] = \frac{n_{H_3O^+}}{V_{tot}} = \frac{7.00 \times 10^{-3} \text{ mol}}{0.1300 \text{ L}} = 0.0538 \text{ M}$$

$$\text{pH} = 1.27$$

3. **V = 100.00 mL NaOH added**
This is called the **equivalence point,** that point in the titration at which the number of moles of base added equals the number of moles of acid originally present. The volume of base added up to the equivalence point is the **equivalent volume,** V_e. At the equivalence point in the titration of a strong acid with a strong base, the concentrations of OH^- and H_3O^+ must be equal and the pH 7.0 due to the autoionization of water. At this point the solution is simply a nonhydrolyzing salt (in this case, NaCl) in water. The pH is 7 at the equivalence point only in the titration of a strong acid with a strong base (or vice versa). The pH at the equivalence point differs from 7 if the titration involves a weak acid or weak base.

4. **V = 100.05 mL NaOH added**
Beyond the equivalence point, OH^- is added to a neutral unbuffered solution. The OH^- concentration can be found from the number of moles of OH^- added after the equivalence point has been reached. The volume beyond the equivalence point at this stage is 0.05 mL, or 5×10^{-5} L. (This is the volume of approximately one drop of solution added from the buret.) The number of moles of OH^- in this volume is

$$(0.1000 \text{ mol L}^{-1})(5 \times 10^{-5} \text{ L}) = 5 \times 10^{-6} \text{ mol}$$

Meanwhile, the total volume of the titration mixture is

$$0.1000 \text{ L HCl solution} + 0.10005 \text{ L NaOH solution} = 0.20005 \text{ L solution}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Therefore, the concentration of OH^- is

$$[OH^-] = \frac{\text{moles } OH^-}{\text{total volume}} = \frac{5 \times 10^{-5} \text{ mol}}{0.2005 \text{ L}} = 2.5 \times 10^{-5} \text{ M}$$

$$[H_3O^+] = 4 \times 10^{-10} \text{ M}; \text{ pH} = 9.4$$

As the titration curve shows (see Fig. 15.13), the pH increases dramatically in the immediate vicinity of the equivalence point: $[H_3O^+]$ changes by four orders of magnitude between 99.98 mL and 100.02 mL NaOH! Any indicator whose color changes between pH = 5.0 and pH = 9.0 therefore signals the endpoint of the titration to an accuracy of ±0.02 mL in 100.0 mL, or ±0.02%. The titration **endpoint,** the experimentally measured volume at which the indicator changes color, is then almost identical to the equivalence point, the theoretical volume at which the chemical amount of added base equals that of acid present originally.

The titration of a strong base by a strong acid is entirely parallel. In this case the pH starts at a higher value and *drops* through a pH of 7 at the equivalence point. The roles of acid and base, and of H_3O^+ and OH^-, are reversed in the equations already given.

Titration of a Weak Acid with a Strong Base

We turn now to the titration of a weak acid with a strong base (the titration of a weak base with a strong acid is analogous). The equivalence point has the same meaning as for a strong acid titration. At the equivalence point, the number of moles of base added (in volume V_e) is equal to the number of moles of acid originally present (in volume V_0). So, once again

$$c_0 V_0 = c_t V_e$$

where c_0 is the original weak acid concentration and c_t is the OH^- concentration in the titrating solution.

The calculation of the titration curve differs from the strong acid–strong base case in that now equilibrium (reflected in the K_a of the weak acid) enters the picture. As an example, consider the titration of 100.0 mL of a 0.1000 M solution of acetic acid (CH_3COOH) with 0.1000 M NaOH. For this titration,

$$V_e = \frac{c_0}{c_t} V_0 = \left(\frac{0.1000 \text{ M}}{0.1000 \text{ M}}\right)(100.0 \text{ mL})$$

$$= 100.0 \text{ mL}$$

There are four distinct ranges in the titration; each corresponds to a type of calculation that we have illustrated already. Figure 15.14 shows pH versus volume for this titration, and the following paragraphs outline the calculation of four typical points on the curve.

1. **V = 0 mL NaOH added**
   At the beginning of the titration—before any NaOH is added—the problem is simply the ionization of a weak acid, considered in Section 15.4. A calculation analogous to those of Examples 15.6 and 15.7 gives a pH of 2.88.
2. **$0 < V < V_e$**
   In this range the acid has been partially neutralized by added NaOH solution. Because OH^- is a stronger base than acetate ion, it reacts almost completely with the acid originally present:

$$CH_3COOH(aq) + OH^-(aq) \rightleftharpoons H_2O(\ell) + CH_3COO^-(aq)$$

$$K = \frac{1}{K_b} = \frac{K_a}{K_w} = 2 \times 10^9 \gg 1$$

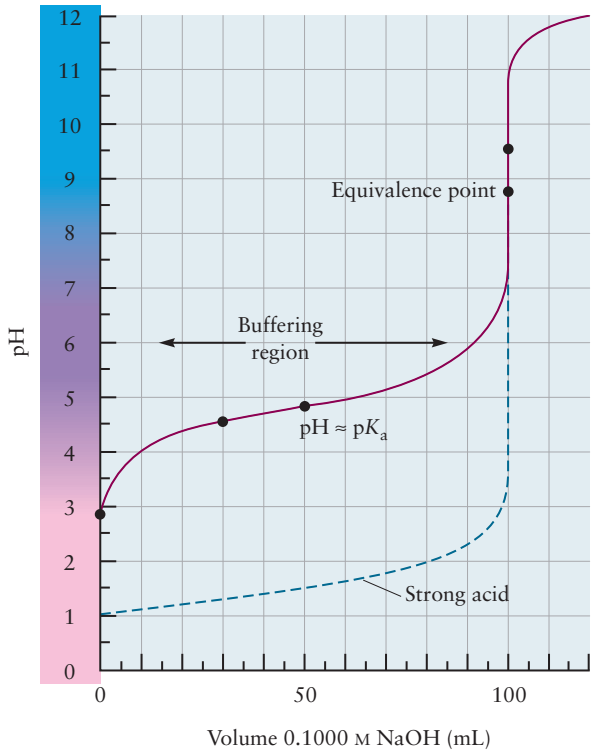

FIGURE 15.14 A titration curve for the titration of a weak acid by a strong base. The curve shown in red is for 100.0 mL of 0.1000 M CH_3COOH titrated with 0.1000 M NaOH. For comparison, the dashed blue line shows the titration curve for a strong acid of the same amount and concentration as presented in Figure 15.13.

As a specific example, suppose that 30.00 mL of 0.1000 M NaOH has been added. The 30.00 mL NaOH contains

$$(0.1000 \text{ mol L}^{-1})(0.03000 \text{ L}) = 3.000 \times 10^{-3} \text{ mol OH}^-$$

and the original solution contained

$$(0.1000 \text{ mol L}^{-1})(0.1000 \text{ L}) = 1.000 \times 10^{-2} \text{ mol } CH_3COOH$$

The neutralization reaction generates one CH_3COO^- ion for every OH^- ion added. Hence, 3.000×10^{-3} mol of CH_3COO^- ions is generated. The amount of acetic acid that remains unreacted is

$$1.000 \times 10^{-2} - 3.000 \times 10^{-3} = 7.00 \times 10^{-3} \text{ mol}$$

Because the total volume is now 130.0 mL (or 0.1300 L), the nominal concentrations after reaction are

$$[CH_3COOH] \approx \frac{7.00 \times 10^{-3} \text{ mol}}{0.1300 \text{ L}} = 5.38 \times 10^{-2} \text{ M}$$

$$[CH_3COO^-] \approx \frac{3.00 \times 10^{-3} \text{ mol}}{0.1300 \text{ L}} = 2.31 \times 10^{-2} \text{ M}$$

This is merely a buffer solution containing acetic acid at a concentration of 5.38×10^{-2} M and sodium acetate at a concentration of 2.31×10^{-2} M. Because the K_a for acetic acid is larger than 10^{-7}, hydronium ion (not hydroxide ion) predominates, and this is an acidic buffer. The pH can be found from the procedure used in Example 15.10 or, more approximately from Equation 15.7:

$$\text{pH} \approx \text{p}K_a - \log_{10} \frac{[CH_3COOH]_0}{[CH_3COO^-]_0} = 4.75 - \log_{10} \frac{5.38 \times 10^{-2}}{2.31 \times 10^{-2}} = 4.38$$

This region of the titration shows clearly the buffering action of a mixture of a weak acid with its conjugate base. At the half-equivalence point $V = V_e/2$,

$[CH_3COOH]_0 = [CH_3COO^-]_0$, which corresponds to an equimolar buffer; at this point pH ≈ pK_a. On either side of this point the pH rises relatively slowly as the NaOH solution is added.

3. $V = V_e$
At the equivalence point, $c_t V_e$ mol of OH^- has been added to the same number of moles of CH_3COOH. An identical solution could have been prepared simply by adding $c_t V_e = 1.000 \times 10^{-2}$ mol of the base CH_3COO^- (in the form of $NaCH_3COO$) to 0.2000 L of water. The pH at the equivalence point corresponds to the hydrolysis of CH_3COO^-:

$$H_2O(\ell) + CH_3COO^-(aq) \rightleftharpoons CH_3COOH(aq) + OH^-(aq)$$

as considered in Example 15.9. At the equivalence point the pH is 8.73.

Note that in the titration of a weak acid by a strong base the equivalence point comes not at pH 7 but at a higher (more basic) value. By the same token, the equivalence point in the titration of a weak base by a strong acid occurs at a pH lower than 7.

4. $V > V_e$
Beyond the equivalence point, $OH^-(aq)$ is added to a solution of the base CH_3COO^-. The $[OH^-]$ comes almost entirely from the hydroxide ion added beyond the equivalence point; very little comes from the reaction of the CH_3COO^- with water. Beyond V_e, the pH for the titration of a weak acid by a strong base is very close to that for a strong acid by a strong base.

The equivalent volume V_e is readily determined in the laboratory by using an indicator that changes color near pH 8.7, the pH at the equivalence point of the acetic acid titration. A suitable choice would be phenolphthalein, which changes from colorless to red over a pH range from 8.2 to 10.0. The slope of pH versus volume of strong base is less steep near the equivalence point for a weak acid than it is for a strong acid, so determination of the equivalent volume—and of the unknown weak acid concentration—is somewhat less accurate.

The following example shows how to determine concentrations and ionization constants for unknown acids and bases from titrations.

EXAMPLE 15.14

A volume of 50.00 mL of a weak acid of unknown concentration is titrated with a 0.1000 M solution of NaOH. The equivalence point is reached after 39.30 mL of NaOH solution has been added. At the half-equivalence point (19.65 mL) the pH is 4.85. Calculate the original concentration of the acid and its ionization constant K_a.

Solution

The number of moles of acid originally present, $c_0 V_0$, is equal to the number of moles of base added at the equivalence point, $c_t V_e$, so

$$c_0 = \frac{V_e}{V_0} c_t = \frac{39.50 \text{ mL}}{50.00 \text{ mL}} \times 0.100 \text{ M} = .0786 \text{ M}$$

This is the original concentration of acid.

At the half-equivalence point,

$$\text{pH} = 4.85 \approx \text{p}K_a$$

$$K_a = 10^{-4.85} = 1.4 \times 10^{-5}$$

The unknown acid could be propionic acid, CH_3CH_2COOH (see Table 15.2).

15.7 POLYPROTIC ACIDS

So far, we have considered only **monoprotic acids,** whose molecules can donate only a single hydrogen ion to acceptor molecules. **Polyprotic acids** can donate two or more hydrogen ions to acceptors. Sulfuric acid is a familiar and important example. It reacts in two stages; first

$$H_2SO_4(aq) + H_2O(\ell) \longrightarrow H_3O^+(aq) + HSO_4^-(aq)$$

to give the hydrogen sulfate ion, and then

$$HSO_4^-(aq) + H_2O(\ell) \longrightarrow H_3O^+(aq) + SO_4^{2-}(aq)$$

The hydrogen sulfate ion is amphoteric, meaning that it is a base in the first reaction (with conjugate acid H_2SO_4) and an acid in the second (with conjugate base SO_4^{2-}). In its first ionization H_2SO_4 is a strong acid, but the product of that ionization (HSO_4^-) is a weak acid. So, the H_3O^+ produced in a solution of H_2SO_4 comes primarily from the first ionization, and the solution has a pH close to that of a monoprotic strong acid of the same concentration. But when this solution reacts with a strong base, its neutralizing power is twice that of a monoprotic acid of the same concentration, because each mole of sulfuric acid can react with and neutralize two moles of hydroxide ion.

Weak Polyprotic Acids

Weak polyprotic acids ionize in two or more stages. Examples are carbonic acid (H_2CO_3), formed from solvated CO_2 (carbonated water; Fig. 15.15), and phosphoric acid (H_3PO_4). Carbonic acid can give up one hydrogen ion to form HCO_3^- (hydrogen carbonate ion) or two hydrogen ions to form CO_3^{2-} (carbonate ion). Phosphoric acid ionizes in three stages, giving successively $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}.

Two simultaneous equilibria are involved in the ionization of a diprotic acid such as H_2CO_3:[2]

$$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HCO_3^-(aq)$$

$$\frac{[H_3O^+][HCO_3^-]}{[H_2CO_3]} = K_{a1} = 4.3 \times 10^{-7}$$

and

$$HCO_3^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CO_3^{2-}(aq)$$

$$\frac{[H_3O^+][CO_3^{2-}]}{[HCO_3^-]} = K_{a2} = 4.8 \times 10^{-11}$$

We emphasize two important points at the outset:

1. The $[H_3O^+]$ in the two ionization equilibria are one and the same.
2. K_{a2} is invariably smaller than K_{a1} because the negative charge left behind by the loss of a hydrogen ion in the first ionization causes the second hydrogen ion to be more tightly bound.

© Cengage Learning/Charles D. Winters

FIGURE 15.15 The indicator phenolphthalein is pink in basic solution *(left).* When dry ice (solid carbon dioxide) is placed in the bottom of the beaker *(right),* it dissolves to form carbonic acid. This neutralizes the base in solution, and causes the indicator to change to its colorless form characteristic of an acid solution.

[2]An accurate description of carbonic acid and solvated CO_2 is somewhat more complicated than indicated here. In fact, most of the dissolved CO_2 remains as $CO_2(aq)$, and only a small fraction actually reacts with water to give $H_2CO_3(aq)$. However, we will indicate by $[H_2CO_3]$ the total concentration of both of these species. Approximately 0.034 mol of CO_2 dissolves per liter of water at 25°C and atmospheric pressure.

Exact calculations of simultaneous equilibria can be complicated. They simplify considerably when the original acid concentration is not too small and the ionization constants K_{a1} and K_{a2} differ substantially in magnitude (by a factor of 100 or more). The latter condition is almost always satisfied. Under such conditions, the two equilibria can be treated sequentially, as in the following example.

EXAMPLE 15.15

Calculate the equilibrium concentrations of H_2CO_3, HCO_3^-, CO_3^{2-}, and H_3O^+ in a saturated aqueous solution of CO_2, in which the original concentration of H_2CO_3 is 0.034 M.

Solution

The H_3O^+ arises both from the ionization of H_2CO_3 and from the subsequent ionization of HCO_3^-, but because $K_{a1} \gg K_{a2}$ it is reasonable to ignore the contribution of $[H_3O^+]$ from the second ionization (as well as from the autoionization of water). These approximations will be checked later in the calculation.

If y mol L^{-1} of H_2CO_3 ionizes, the following approximations apply:

	$H_2CO_3(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HCO_3^-(aq)$		
Initial concentration (M)	0.034	≈0	0
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.034 - y$	y	y

where equating both $[HCO_3^-]$ and $[H_3O^+]$ to y involves the assumption that the subsequent ionization of HCO_3^- has only a small effect on its concentration. Then the first ionization equilibrium can be written as

$$\frac{[H_3O^+][HCO_3^-]}{[H_2CO_3]} = K_{a1}$$

$$\frac{y^2}{0.034 - y} = 4.3 \times 10^{-7}$$

Solving this equation for y gives

$$y = 1.2 \times 10^{-4}\ \text{M} = [H_3O^+] = [HCO_3^-]$$

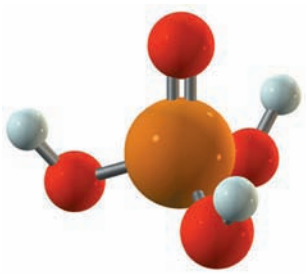
$$[H_2CO_3] = 0.034 - y = 0.034\ \text{M}$$

The second equilibrium can be written as

$$\frac{[H_3O^+][CO_3^{2-}]}{[HCO_3^-]} = K_{a2} = \frac{(1.2 \times 10^{-4})[CO_3^{2-}]}{1.2 \times 10^{-4}} = 4.8 \times 10^{-11}$$

$$[CO_3^{2-}] = 4.8 \times 10^{-11}\ \text{M}$$

The concentration of the base produced in the second ionization, $[CO_3^{2-}]$, is numerically equal to K_{a2}.



Now we must check the validity of the assumptions. Because

$$[CO_3^{2-}] = 4.8 \times 10^{-11}\ \text{M} \ll 1.2 \times 10^{-4}\ \text{M} = [HCO_3^-]$$

we were justified in ignoring the effect of the second ionization on the concentrations of HCO_3^- and H_3O^+. The additional concentration of H_3O^+ furnished by HCO_3^- is only 4.8×10^{-11} M. Finally, $[H_3O^+]$ is much larger than 10^{-7} M, so neglecting the water autoionization was also justified.

Phosphoric acid, H_3PO_4, is a triprotic acid that is used in the manufacture of phosphate fertilizers and in the food industry.

For a triprotic acid such as H_3PO_4, the concentration of the base (PO_4^{3-}) resulting from the third ionization could have been calculated in a similar manner.

An analogous procedure applies to the reactions of a base that can accept two or more hydrogen ions. In a solution of sodium carbonate (Na_2CO_3), the carbonate ion reacts with water to form first HCO_3^- and then H_2CO_3:

$$H_2O(\ell) + CO_3^{2-}(aq) \rightleftharpoons HCO_3^-(aq) + OH^-(aq)$$

$$\frac{[OH^-][HCO_3^-]}{[CO_3^{2-}]} = K_{b1} = \frac{K_w}{K_{a2}} = 2.1 \times 10^{-4}$$

$$H_2O(\ell) + HCO_3^-(aq) \rightleftharpoons H_2CO_3(aq) + OH^-(aq)$$

$$\frac{[OH^-][H_2CO_3]}{[HCO_3^-]} = K_{b2} = \frac{K_w}{K_{a1}} = 2.3 \times 10^{-8}$$

In this case $K_{b1} \gg K_{b2}$, so essentially all the OH^- arises from the first reaction.

The ensuing calculation of the concentrations of species present is just like that in Example 15.15.

Effect of pH on Solution Composition

Changing the pH of a solution shifts the positions of all acid–base equilibria, including those involving polyprotic acids. Acid–base equilibrium expressions and equilibrium constants are used to calculate the amount of the change. For example, the two equilibria that apply to solutions containing H_2CO_3, HCO_3^-, and CO_3^{2-} can be written as

$$\frac{[HCO_3^-]}{[H_2CO_3]} = \frac{K_{a1}}{[H_3O^+]} \qquad \frac{[CO_3^{2-}]}{[HCO_3^-]} = \frac{K_{a2}}{[H_3O^+]}$$

At a given pH, the right sides are known and the relative amounts of the three carbonate species can be calculated. This is illustrated by the following example.

EXAMPLE 15.16

Calculate the fraction of carbonate present as H_2CO_3, HCO_3^-, and CO_3^{2-} at pH 10.00.

Solution

At this pH, $[H_3O^+] = 1.0 \times 10^{-10}$ M, and the values of K_{a1} and K_{a2} for the preceding equations are used to find

$$\frac{[HCO_3^-]}{[H_2CO_3]} = \frac{4.3 \times 10^{-7}}{1.0 \times 10^{-10}} = 4.3 \times 10^3$$

$$\frac{[CO_3^{2-}]}{[HCO_3^-]} = \frac{4.8 \times 10^{-11}}{1.0 \times 10^{-10}} = 0.48$$

It is most convenient to rewrite these ratios with the same species (say, HCO_3^-) in the denominator. The first equation becomes

$$\frac{[H_2CO_3]}{[HCO_3^-]} = \frac{1}{4.3 \times 10^3} = 2.3 \times 10^{-4}$$

The fraction of each species present is obtained by dividing the concentration of each species by the sum of the three concentrations. For H_2CO_3 this gives

$$\text{fraction } H_2CO_3 = \frac{[H_2CO_3]}{[H_2CO_3] + [HCO_3^-] + [CO_3^{2-}]}$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

This can be simplified by dividing numerator and denominator by $[HCO_3^-]$ and substituting the ratios that have already been calculated:

$$\text{fraction } H_2CO_3 = \frac{[H_2CO_3]/[HCO_3^-]}{([H_2CO_3]/[HCO_3^-]) + 1 + ([CO_3^{2-}]/[HCO_3^-])}$$

$$= \frac{2.3 \times 10^{-4}}{2.3 \times 10^{-4} + 1 + 0.48} = 1.6 \times 10^{-4}$$

In the same way the fractions of HCO_3^- and CO_3^{2-} present are calculated to be 0.68 and 0.32, respectively.

Related Problems: 67, 68

Repeating the calculation of Example 15.16 at a series of different pH values gives the graph shown in Figure 15.16. At high pH, CO_3^{2-} predominates, and at low pH, H_2CO_3 is the major species. At intermediate pH (near pH 8, the approximate pH of seawater), the hydrogen carbonate ion HCO_3^- is most prevalent. The variation in composition of sedimentary rocks from different locations can be traced back to the effect of pH on solution composition. Sediments containing carbonates were formed from alkaline (high-pH) lakes and oceans in which CO_2 was present mainly as CO_3^{2-} ion. Sediments deposited from waters with intermediate pH are hydrogen carbonates or mixtures between carbonates and hydrogen carbonates. An example of the latter is trona ($2Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$), an ore from the western United States that is an important source of both carbonates of sodium. Acidic waters did not deposit carbonates, but instead released $CO_2(g)$ to the atmosphere.

CONNECTION TO BIOLOGY

Buffered Blood Plasma

Both the interiors of cells and the fluids that surround them must be maintained at relatively constant pH because the activities of enzymes (biological catalysts, see Section 18.8) are markedly pH dependent. The phosphate buffer system ($HPO_4^{2-}/H_2PO_4^-$) is one of the systems that stabilize pH within cells whereas the bicarbonate buffer system (HCO_3^-/H_2CO_3) stabilizes pH in fluids, including blood. The bicarbonate buffer system in blood is particularly interesting for a number of reasons. First, the pK_a of carbonic acid is 3.57 at physiological temperatures (37 °C), which is far removed from the desired pH of 7.4, so it would appear that it would be a poor choice for this application. What makes it work is the tight coupling of the buffer system with the dissolution equilibrium of CO_2 in plasma. Not only does this coupling provide an additional source of carbonic acid but it also provides a mechanism for the dynamic regulation of a number of metabolic reactions through changes in respiration rates. Finally, both pH and the concentration of dissolved CO_2 enhance and regulate the delivery of O_2 from the lungs to tissues via the capillaries. Let's examine each of these issues in turn.

We can use Equation 15.7 (often called the Henderson–Hasselbalch equation in biochemistry) to calculate the buffering capacity (the quantity of acid or base added that changes the pH by 1 unit) of the bicarbonate system in plasma

$$\text{pH} = 7.4 = 3.57 - \log \frac{[H_2CO_3]}{[HCO_3^-]}$$

so the ratio of bicarbonate to carbonic acid is about 6800 in plasma under normal physiological conditions. The concentration of bicarbonate in blood is one of several indicators of acid–base imbalance and it is generally measured as part of an electrolyte panel in routine blood tests; a typical value is 20 mM. The carbonic acid concentration under these conditions is only about 3 μM. Using the approach developed in Example 15.8, we calculate the buffering capacity of this system to be only 2.7 μM with respect to added OH^-, which is a typical OH^- concentration in plasma. The system would have essentially no buffering capacity were it not coupled to the equilibrium established between gas phase and dissolved CO_2 as represented by the following reactions

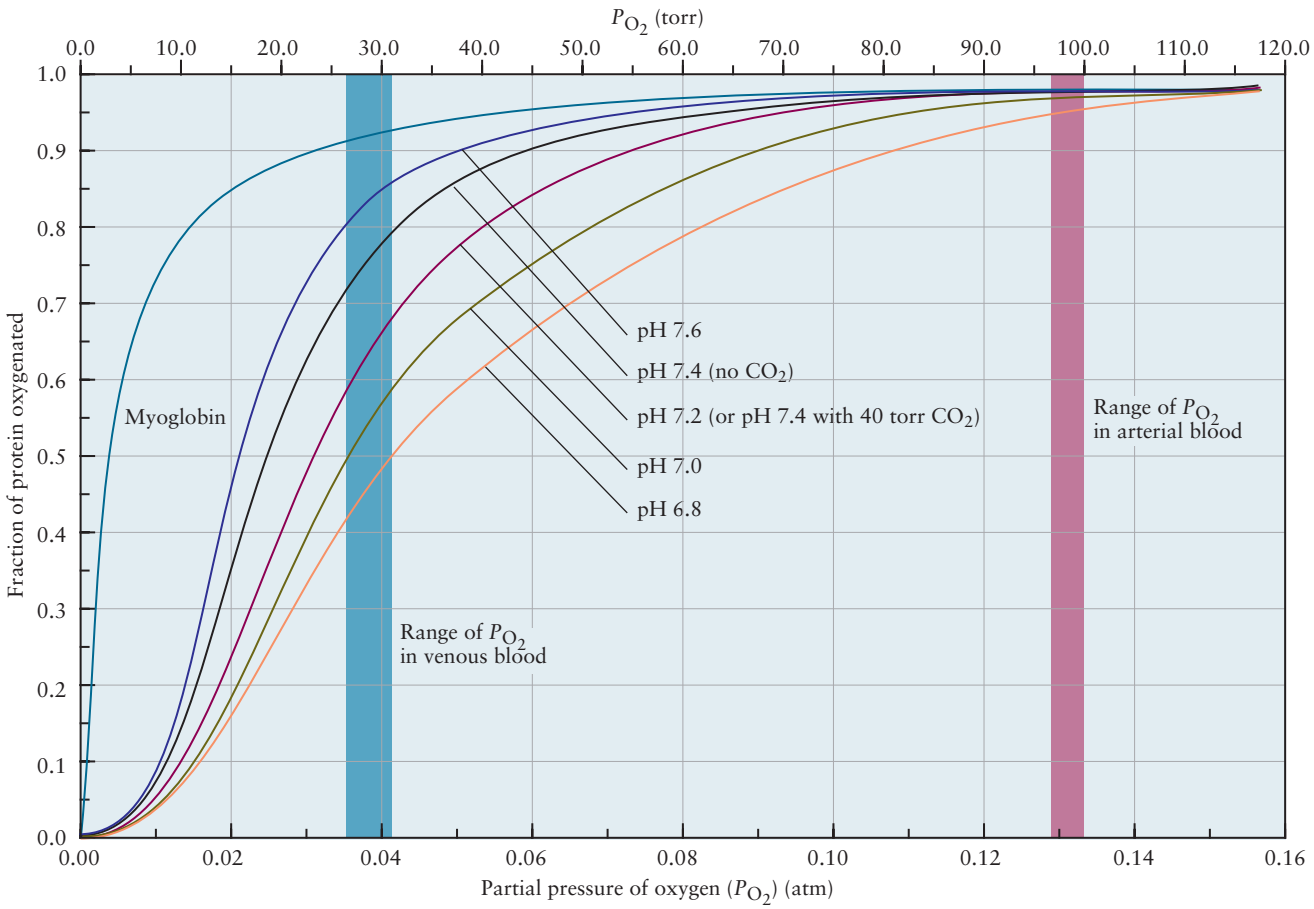
$$CO_2(g) \rightleftharpoons CO_2(aq)$$
$$CO_2(aq) + H_2O(\ell) \overset{K_h}{\rightleftharpoons} H_2CO_3(aq)$$
$$H_2CO_3(aq) \overset{K_a}{\rightleftharpoons} H^+(aq) + HCO_3^-(aq)$$

in which *(aq)* refers to the plasma phase. The equilibrium constant for the second reaction is rather small under normal physiological conditions (in mammals) but it provides the additional source of carbonic acid needed to make a viable buffer system. We can combine the equilibrium constants for the simultaneous reactions using the method developed in Section 14.4 to get

$$K_aK_h = \frac{[H^+][HCO_3^-]}{[CO_2(aq)]} = \frac{[H^+][HCO_3^-]}{(pCO_2)/K}$$

in which P_{CO_2} and K are the partial pressure and Henry's law constant of CO_2. We can rearrange this equation to get

$$\text{pH} = pK_apK_h + \frac{K[HCO_3^-]}{(pCO_2)}$$



$pK_a = 3.57$ and $pK_h = 2.52$ so the first two terms in the Henderson–Hasselbalch equation for the coupled reactions yield an initial pH = 6.1, which is still much lower than the desired value of 7.4 but within the range considered acceptable, and certainly much better than what could be accomplished using the bicarbonate buffer system alone. This coupled buffer system is an open system in which the total carbonic acid pool available for buffering is largely provided by dissolved CO_2. The Henry's law constant for CO_2 in plasma at 37°C is about 2 L atm mol^{-1} so the concentration of dissolved CO_2 at the typical partial pressure found in the lungs (40 torr) is about 1.2 mM, which provides an adequate concentration of acid to ensure sufficient buffering capacity.

Rapidly metabolizing tissues, such as muscle, produce large quantities of CO_2 and hydrogen ions, which are both heterotropic effectors that promote the release of oxygen from the oxygenated form of hemoglobin. One of the mechanisms by which this occurs is through the formation of salt bridges, ionic bonds between amino acids that stabilize certain protein structures over others. Low pH leads to the formation of salt bridges by protonating the side chain of the amino acid histidine, which binds electrostatically to the deprotonated carboxylate group of the amino acid aspartate in the same chain, resulting in a conformational change that favors the quaternary structure (see Section 7.6) of deoxyhemoglobin, thus promoting the release of O_2. CO_2 produces a similar effect, though indirectly, through the second and third reactions listed above. The regulation of O_2 binding through these mechanisms is referred to as the **Bohr effect** (named after Christian Bohr, the father of Neils Bohr), which has at least two important

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

physiological consequences. First, it enhances the total fraction of bound oxygen that can be delivered by hemoglobin as it moves from $P_{O_2} \approx 100$ torr in the lungs to $P_{O_2} \approx 30$ in tissues. Only about 66% of the oxygen stored in hemoglobin is available to be transferred if the pH is the same in both environments. This fraction increases to 77% at pH 7.2 (characteristic of actively metabolizing tissues) with no CO_2 present, and to 88% at pH 7.2 with a CO_2 partial pressure of 40 torr. In addition to increasing the overall quantity of O_2 available, heterotropic regulation provides a mechanism to respond differentially to cells undergoing metabolism at different rates. The figure shows that lowering the pH dramatically increases the amount of oxygen transferred. The curves all shift to the right, indicating a smaller fraction of bound oxygen at typical partial pressures found in venous blood. Increasing the partial pressure of CO_2 has the same effect as shown by the pair of curves labeled pH 7.4 (no CO_2) and pH 7.4 (40 torr CO_2).

Regulating pH is vital to all cells because many cellular processes are catalyzed by enzymes, the activities of which depend strongly on pH. Coupling of the bicarbonate buffer system in blood to CO_2 provides a mechanism for controlling pH through respiration. Increases in the plasma hydrogen ion concentration shift the equilibrium toward carbonic acid, which ultimately produces gaseous CO_2 in the reverse of the series of reactions listed earlier. pH can be restored to the desired value by increasing the rate of respiration, which removes $CO_2(g)$ and shifts the equilibria back to the right. It is possible to overdo it, however. Hyperventilation (breathing faster and/or deeper than normal) can remove such large amounts of CO_2 that the pH rises to unhealthy levels, causing symptoms such as dizziness or fainting. Sudden exposure to high altitudes, for example during skiing and mountain climbing, can also cause hyperventilation. Adaptation to high altitudes is accomplished, in part, by excreting bicarbonate through the kidneys, thus shifting the equilibria to the right and increasing pH.

15.8 ORGANIC ACIDS AND BASES: STRUCTURE AND REACTIVITY

One of the goals of chemistry is to understand the relationship between *structure* and *function*. How does the molecular structure of a compound (including its attached functional groups) affect its chemical reactivity? As an example of the exploration of structure–function relationships, we consider here the trends in acid strength in organic compounds. This extends the earlier discussion of acid strength in inorganic acids (see Section 15.3) and illustrates the usefulness of chemical concepts such as electronegativity and resonance in predicting reactivity. This section depends on the thermodynamic description in Section 14.3.

Table 15.2 lists a number of organic acids with pK_a values in aqueous solution between 0 (strong acid) and 14 (weak acid). Almost all of them are carboxylic acids with the characteristic —COOH functional group, which can donate a proton by breaking the O—H bond. Acid ionization constants can be defined for many other functional groups besides carboxylic acids, because many organic reactions involve the transfer of hydrogen ions or catalysis by acids or bases. Consequently these acid ionization constants provide important information about reactivity of the compounds.

Aqueous solutions can be used to describe acidity only in compounds with values of the pK_a between about 14 and 0. Values much greater than 14 mean that there is negligible ionization in aqueous solution, and values much less than 0 mean that ionization is essentially complete. Because our goal is a scale of *relative* acidities, we can use information from nonaqueous solvents as well as from water. In a sufficiently basic solvent, even a very weak acid will show some ionization; in a sufficiently acidic solvent, even a very strong acid will be only partially ionized. This allows an extension of the pK_a scale above 14 and below 0, provided we consistently think of it as only a relative scale. We thus generalize our earlier definition of K_a, which was limited to aqueous solvents, to describe acid ionization in a general solvent:

$$\text{HA} + \text{solvent} \rightleftharpoons \text{solvent-H}^+ + \text{A}^-$$

Our assumption is that the *difference* in pK_a values for two different acids in a given solvent

$$pK_a - pK'_a = -\log_{10}(K_a/K'_a)$$

depends only weakly on the particular solvent chosen, even though the actual pK_a values are very sensitive to the solvent. If this is the case, we can extend the pK_a scale beyond the range that comes from measurements of pH in aqueous solution. The result is given in Table 15.4.

A thermodynamic analysis shows that this difference in pK_a values is related to the difference in the standard Gibbs free energy changes for the two reactions:

$$\Delta G^\circ - \Delta G^{\circ\prime} = -RT(\ln K_a - \ln K'_a) = 2.3\ RT(pK_a - pK'_a) \qquad [15.8]$$

The factor 2.3 appears when we relate the natural logarithm to the base 10 logarithm. The difference in standard Gibbs free energy changes can be separated into one contribution arising from standard enthalpy changes and one from absolute entropy changes:

$$\Delta G^\circ - \Delta G^{\circ\prime} = \Delta H^\circ - \Delta H^{\circ\prime} - T(\Delta S^\circ - \Delta S^{\circ\prime})$$

If we change the structure of an organic acid, what will be the effect on the pK_a? In general, modest structural changes such as the replacement of a functional group have only small effects on the entropy change of ionization, and most of the influence comes through changes in the enthalpy change of ionization. The quantitative magnitude of this effect is calculated in the following example.

EXAMPLE 15.17

How large a change in energy (or enthalpy) of reaction is needed for an acid ionization to lower the pK_a by one unit at 25°C? Assume that the entropy of ionization is unchanged.

Solution

The entropy of ionization is unchanged, so $\Delta S° = \Delta S°'$, and $\Delta H° - \Delta H°' = \Delta G° - \Delta G°'$. If the change in pK_a is 1.00, then the change in Gibbs free energy must be

$$\Delta G° - \Delta G°' = -RT(\ln K_a - \ln K'_a) = 2.3\,RT(pK_a - pK'_a) = 2.3\,RT(-1)$$

$$= 2.3(8.315\text{ J mol}^{-1}\text{ K}^{-1})(298\text{ K})(-1) = -5700\text{ J mol}^{-1} = -5.7\text{ kJ mol}^{-1}$$

If we assume that this change in Gibbs free energy is entirely due to a change in enthalpy, then one unit of pK_a change corresponds to a lowering of the enthalpy of the products relative to the reactants by 5.7 kJ mol^{-1}.

The sign of the effect is clear from Example 15.17: If a change in structure of a molecule lowers its pK_a (making it a stronger acid), then the energy change for the acid ionization must be lowered. Another way to say this is that the effect of the structural change is to lower the energy of the conjugate base relative to that of the original acid, in other words, to increase the stability of the conjugate base.

An exploration of structure–function relations that lie behind the data in Table 15.4 must examine the effects of changes in molecular structure on the relative energetic stability of acid and conjugate base. We discuss three effects in turn: electronegativity, steric hindrance, and resonance.

Electronegativity

In Section 15.3 (see Fig. 15.6), we pointed out that in inorganic oxoacids with structures $-X-O-H$, the more electronegative the atom X, the more readily the O^--H^+ bond breaks and the stronger the acid. A parallel effect of electronegativity explains the relative acid strengths of hydrocarbons, amines, and alcohols. Table 15.4 shows that ethane, C_2H_6, has a pK_a of 50, whereas that for ethylamine, $C_2H_5NH_2$, is 35 and that for ethanol, C_2H_5OH, is 16. These large differences occur because as the electronegativity increases from carbon to nitrogen to oxygen, the $-X^-$ conjugate base becomes more and more stable and thus the corresponding acid becomes stronger.

A similar situation occurs when electronegative atoms are substituted somewhat farther from the site where ionization takes place. Compare the acid strengths of acetic acid, CH_3COOH, with chloroacetic acid, $ClCH_2COOH$. The electronegative chlorine atom stabilizes the net negative charge of the conjugate base more strongly than does the hydrogen atom in acetic acid, reducing the pK_a from 4.8 to 2.9. Another way to describe this result is as an "inductive" effect involving bond dipoles. The negative charge on the chlorine atom in the Cl—C bond (and the corresponding positive charge on the carbon atom) interact favorably with the negative charge on the $-COO^-$ group of the conjugate base through a dipole-charge interaction (see Section 10.2), stabilizing the base and making the acid stronger:

$$Cl^{\delta-}-C^{\delta+}H_2-COO^-$$

As the substituted electronegative atom moves farther from the site of ionization, its effect on acid strength decreases. Thus, 4-chlorobutanoic acid, $ClCH_2CH_2CH_2COOH$, is a weaker acid (pK_a = 4.5) than 2-chlorobutanoic acid, $CH_3CH_2CHClCOOH$ (pK_a = 2.9).

Because most common functional groups in organic chemistry are more electronegative than hydrogen or carbon atoms (with the exception of metal atoms), their substitution tends to make organic acids stronger; the same is true of positively charged substituents. On the other hand, a negatively charged species such as $-COO^-$ interacts unfavorably with the additional negative change on the base and tends to reduce acidity.

EXAMPLE 15.18

Consider the dicarboxylic acid malonic acid, $HOOC-CH_2-COOH$. It ionizes in two stages with pK_a values pK_{a1} and pK_{a2}. Predict the magnitudes of these two constants compared with the pK_a of acetic acid, CH_3COOH, which is 4.8.

Solution

Malonic acid shows a substitution of a $-COOH$ functional group for one $-H$ atom in acetic acid. Because this carboxylic acid functional group is more electronegative, it should make the compound more acidic, lowering its pK_a relative to acetic acid (measured value: pK_{a1} = 2.8). Once the first dissociation has taken place, however, the attached functional group in comparison with acetic acid is now $-COO^-$. Because this

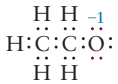
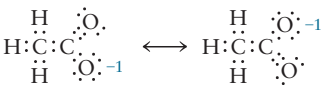
is negatively charged, it interacts unfavorably with the negative charge that results from the second acid ionization, raising the pK_a relative to that of acetic acid (measured value: $pK_{a2} = 5.7$).

Related Problem: 71



Steric Hindrance

As described in Section 11.2, ions in solution are stabilized through ion–dipole interactions with surrounding solvent molecules. This stabilization is reduced if the charged site is surrounded by bulky groups that prevent solvent molecules from approaching closely enough. This is an effect of **steric hindrance** on acidity. For example, compare the acidity of methanol, CH_3OH, with *tert*-butanol, $(CH_3)_3COH$. The latter compound is obtained by substituting $-CH_3$ groups for the three $-H$ atoms attached to the carbon atom in methanol. In the corresponding negatively charged conjugate bases CH_3O^- and $(CH_3)_3CO^-$, the former is more stable in solution because solvent molecules can approach the negatively charged site more closely. In the latter, the bulkier $—CH_3$ groups reduce the stability of the solvated base anion. The net effect is that methanol is a stronger acid in solution ($pK_a = 15$) than *tert*-butanol ($pK_a = 18$).

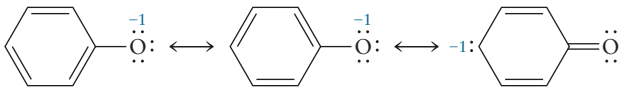


This observation depends on the presence of a liquid solvent around the acid and conjugate base. For the corresponding acid–base pair in the gas phase, *tert*-butanol is a stronger acid than methanol.

Resonance

A third and final contribution to relative acidity of organic compounds is resonance. Let's begin by noting that the acidity of carboxylic acids is considerably greater than that of alcohols. For example, the pK_a of acetic acid, CH_3COOH, is considerably lower than that of ethanol, CH_3CH_2OH (4.8 versus 16). Some of this may be due to the "inductive effect" of substituting an electronegative O atom for two H atoms. But, inductive effects do not typically cause such large changes (more than 11 units of pH). An alternative explanation is found in the concept of resonance stabilization, which was introduced in Section 3.9 and discussed in the context of organic molecules in Section 7.4. A single Lewis diagram can be drawn for the conjugate base of ethanol:

On the other hand, the conjugate base of acetic acid is represented by a resonance hybrid of two Lewis diagrams:



The possibility of more than one resonance form stabilizes the acetate ion and contributes to the greater acidity of acetic acid.

A second example of resonance stabilization affecting acidity arises in a comparison of phenols and alcohols. Phenol (also called carbolic acid) has a pK_a of 10, whereas the pK_a values for typical alcohols range from 16 to 18. The reason for this difference is the greater stability of the conjugate base (the phenoxide ion, $C_6H_5O^-$)

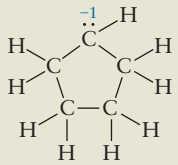
due to the spreading out of the negative charge over the aromatic ring. Several different resonance forms contribute to the stability of the phenoxide ion.

Phenol, although not a strong acid, does react readily with sodium hydroxide to form the salt sodium phenoxide:

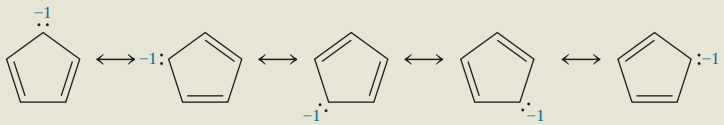
$$C_6H_5OH + NaOH \longrightarrow C_6H_5O^-Na^+ + H_2O$$

The corresponding reaction between NaOH and alcohols does not occur to a significant extent, although sodium ethoxide can be prepared by reaction of metallic sodium with anhydrous ethanol:



$$Na + C_2H_5OH \longrightarrow C_2H_5O^-Na^+ + \frac{1}{2}\ H_2$$

EXAMPLE 15.19



By using resonance Lewis diagrams, predict which will be the stronger acid: cyclopentane (C_5H_{10}) or cyclopentadiene (C_5H_6).

Solution

We can write only one Lewis diagram for the conjugate base of cyclopentane:

It is a very weak acid. In contrast, we can write five resonance diagrams for the conjugate base of cyclopentadiene:

This is very stable, so cyclopentadiene will be a stronger acid (its pK_a is 16).

A DEEPER LOOK

15.9 EXACT TREATMENT OF ACID–BASE EQUILIBRIA

Sections 15.4 and 15.5 outline methods for calculating equilibria involving weak acids, bases, and buffer solutions. There we assume that the amount of hydronium ion (or hydroxide ion) resulting from the ionization of water can be neglected in comparison with that produced by the ionization of dissolved acids or bases. In this

section, we replace that approximation by a treatment of acid–base equilibria that is exact, within the limits of the mass-action law. This approach leads to somewhat more complicated equations, but it serves several purposes. It has great practical importance in cases in which the previous approximations no longer hold, such as very weak acids or bases or very dilute solutions. It includes as special cases the various aspects of acid–base equilibrium considered earlier. Finally, it provides a foundation for treating amphoteric equilibrium later in this section.

Consider a general case in which the initial concentration of a weak acid HA is called c_a, and the initial concentration of its conjugate base (which for simplicity is assumed to come from the salt NaA) is c_b. In solution there will be five dissolved species: HA, A^-, Na^+, H_3O^+, and OH^-. It is necessary to write down and solve five independent equations that relate the equilibrium concentrations of these species to the initial concentrations c_a and c_b and to K_a, the acid ionization constant of HA. The first equation is simply

$$[Na^+] = c_b \tag{a}$$

reflecting the fact that the $Na^+(aq)$ from the dissolved salt is a spectator ion that does not take part in the acid–base equilibrium. Next there are two equilibrium relations:

$$[H_3O^+][OH^-] = K_w \tag{b}$$

$$\frac{[H_3O^+][A^-]}{[HA]} = K_a \tag{c}$$

The fourth relation is one of stoichiometry, or conservation of "A-material":

$$c_a + c_b = [HA] + [A^-] \tag{d}$$

The original A-material was introduced either as acid or as base, with a total concentration of $c_a + c_b$. When equilibrium is reached, some redistribution has doubtless occurred, but the *total* concentration, $[HA] + [A^-]$, must be the same. The fifth and final relation results from charge balance. The solution must be electrically neutral, so the total amount of positive charge must be equal to the total amount of negative charge:

$$[Na^+] + [H_3O^+] = [A^-] + [OH^-] \tag{e}$$

These five independent equations completely determine the five unknown concentrations. To solve them, begin by substituting (a) into (e) and solving for $[A^-]$:

$$[A^-] = c_b + [H_3O^+] - [OH^-] \tag{e′}$$

Next, insert (e′) into (d) and solve for [HA]:

$$[HA] = c_a + c_b - [A^-] = c_a - [H_3O^+] + [OH^-] \tag{d′}$$

Next, substitute both (d′) and (e′) into (c) to find

$$\frac{[H_3O^+](c_b + [H_3O^+] - [OH^-])}{(c_a - [H_3O^+] + [OH^-])} = K_a \tag{c′}$$

There are two ways to proceed with the general equation (c′). First, we can set up the exact solution for $[H_3O^+]$, a procedure that is useful for very weak acids or bases or for very dilute solutions. Or, we can reduce (c′) in various limits to cases already considered.

For the exact solution, eliminate $[OH^-]$ in (c′) by using (b). This gives

$$\frac{[H_3O^+]\left(c_b + [H_3O^+] - \dfrac{K_w}{[H_3O^+]}\right)}{\left(c_a - [H_3O^+] + \dfrac{K_w}{[H_3O^+]}\right)} = K_a$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The numerator and denominator are multiplied by $[H_3O^+]$ and the fraction is cleared by moving the denominator to the right side:

$$[H_3O^+](c_b[H_3O^+] + [H_3O^+]^2 - K_w) = K_a(c_a[H_3O^+] - [H_3O^+]^2 + K_w)$$

This can be rewritten as

$$[H_3O^+]^3 + (c_b + K_a)[H_3O^+]^2 - (K_w + c_aK_a)[H_3O^+] - K_aK_w = 0$$

This is a cubic equation for $[H_3O^+]$, which can be solved with a calculator. The concentrations of OH^-, A^-, and HA can then be found by successive substitutions into (b), (e′), and (d′).

Alternatively, the general equation (c′) can be examined in various limits. In an acidic buffer (as in Examples 15.10 and 15.11), if it can be assumed that $[H_3O^+] \gg [OH^-]$, then (c′) simplifies to

$$\frac{[H_3O^+](c_b + [H_3O^+])}{(c_a - [H_3O^+])} = K_a$$

which is exactly the equation used in those examples. If, in addition, $c_b = 0$, the weak-acid ionization limit of Examples 15.6 and 15.7 is reached. In a basic buffer, if it can be assumed that $[OH^-] \gg [H_3O^+]$, then (c′) simplifies to

$$\frac{(K_w/[OH^-])(c_b - [OH^-])}{(c_a + [OH^-])} = K_a$$

Here (b) was used to substitute for $[H_3O^+]$ where it multiplies the whole expression. This can be rewritten as

$$\frac{[OH^-](c_a + [OH^-])}{(c_b - [OH^-])} = \frac{K_w}{K_a} = K_b$$

which is exactly the equation used in Example 15.12. If no acid is present initially ($c_a = 0$), this expression reduces to the weak-base ionization limits of Examples 15.8 and 15.9. The general approach includes all of the previous calculations as special cases.

Unless conditions require the use of the exact solution, approximate equations are preferable because they are easier to apply and provide greater physical insight. If a calculation (ignoring water autoionization) of the ionization of a weak acid gives a concentration of H_3O^+ smaller than 10^{-6} M or if a calculation of base ionization gives a concentration of OH^- smaller than 10^{-6} M, then we have to use the more exact treatment. For buffer solutions, a pH near 7 does not necessarily mean that water ionization is important, unless the acid or base concentration becomes very small.

EXAMPLE 15.20

Calculate the pH of a 1.00×10^{-5} M solution of HCN*(aq)*. The K_a of HCN*(aq)* is 6.17×10^{-10}.

Solution

Suppose the autoionization of water is ignored and the method of Examples 15.6 and 15.7 is used. This gives $[H_3O^+] = 7.9 \times 10^{-8}$ M, which of course makes no sense, because it is *lower* than the concentration of hydronium ion in pure water. HCN is a very weak acid, but it is nonetheless an acid, not a base.

So, we have to use the exact cubic equation for $[H_3O^+]$, inserting into it the proper coefficients and taking $c_a = 1.00 \times 10^{-5}$ and $c_b = 0$. This gives

$$[H_3O^+]^3 + 6.17 \times 10^{-10}[H_3O^+]^2 - 1.617 \times 10^{-14}[H_3O^+] - 6.17 \times 10^{-24} = 0$$

Unfortunately, there is no method as simple as the quadratic formula to solve a cubic equation. The easiest way to solve this equation is to try a series of values for $[H_3O^+]$ on

the left side, varying them to obtain a result as close as possible to 0 (see Appendix C). It is safe to assume that the final answer will be slightly larger than 1×10^{-7}, so the initial guesses should be of that magnitude. Carrying out the procedure gives

$$[H_3O^+] = 1.27 \times 10^{-7} \text{ M} \qquad \text{pH} = 6.90$$

Related Problems: 77, 78

Amphoteric Equilibria

A second situation in which an exact analysis of acid–base equilibrium is useful occurs when an amphoteric species is dissolved in water. The hydrogen carbonate ion (HCO_3^-) is amphoteric because it can act as an acid in the equilibrium

$$HCO_3^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CO_3^{2-}(aq)$$

$$\frac{[H_3O^+][CO_3^{2-}]}{[HCO_3^-]} = K_{a2} = 4.8 \times 10^{-11}$$

or as a base in the equilibrium

$$H_2O(\ell) + HCO_3^-(aq) \rightleftharpoons H_2CO_3(aq) + OH^-(aq)$$

$$\frac{[OH^-][H_2CO_3]}{[HCO_3^-]} = K_{b2} = 2.3 \times 10^{-8}$$

If sodium hydrogen carbonate ($NaHCO_3$) is dissolved in water, there is a competition between the tendency of HCO_3^- to accept hydrogen ions and to donate them. Because $K_{b2} > K_{a2}$, there should be more production of OH^- than of H_3O^+, so the solution should be basic.

In an exact treatment of this equilibrium, there are six unknown concentrations—those of Na^+, H_2CO_3, HCO_3^-, CO_3^{2-}, OH^-, and H_3O^+. Two equilibrium equations were already presented, and a third relates $[OH^-]$ and $[H_3O^+]$ to K_w. If $[HCO_3^-]_0$ is the original concentration of $NaHCO_3$, then from stoichiometry

$$[HCO_3^-]_0 = [HCO_3^-] + [H_2CO_3] + [CO_3^{2-}]$$

because the total amount of carbonate material is conserved. Any reduction in $[HCO_3^-]$ must be compensated by a corresponding increase in either $[H_2CO_3]$ or $[CO_3^{2-}]$. Next we use the principle of conservation of charge. The positively charged species present are Na^+ and H_3O^+, and the negatively charged species are HCO_3^-, CO_3^{2-}, and OH^-. Because there is overall charge neutrality,

$$[Na^+] + [H_3O^+] = [HCO_3^-] + 2\,[CO_3^{2-}] + [OH^-]$$

where the coefficient 2 for $[CO_3^{2-}]$ arises because each carbonate ion is doubly charged. In addition, the Na^+ concentration is unchanged, so

$$[Na^+] = [HCO_3^-]_0$$

In principle, these six equations can be solved simultaneously to calculate the exact $[H_3O^+]$ for an arbitrary initial concentration of HCO_3^-. The result is complex and gives little physical insight. Instead, we give only a simpler, approximate solution, which is sufficient in the cases considered here. Subtracting the carbonate balance equation from the charge balance equation gives

$$[H_3O^+] = [CO_3^{2-}] - [H_2CO_3] + [OH^-]$$

The three equilibrium expressions are used to rewrite this as

$$[H_3O^+] = K_{a2}\,\frac{[HCO_3^-]}{[H_3O^+]} - \frac{[H_3O^+][HCO_3^-]}{K_{a1}} + \frac{K_w}{[H_3O^+]}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

where $[CO_3^{2-}]$ and $[H_2CO_3]$ have been eliminated in favor of $[HCO_3^-]$.

Multiplying by $K_{a1}[H_3O^+]$ gives

$$K_{a1}[H_3O^+]^2 + [HCO_3^-][H_3O^+]^2 = K_{a1}K_{a2}[HCO_3^-] + K_{a1}K_w$$

$$[H_3O^+]^2 = \frac{K_{a1}K_{a2}[HCO_3^-] + K_{a1}K_w}{K_{a1} + [HCO_3^-]}$$

This equation still contains two unknown quantities, $[H_3O^+]$ and $[HCO_3^-]$. Because both K_{a2} and K_{b2} are small, $[HCO_3^-]$ should be close to its original value, $[HCO_3^-]_0$. If $[HCO_3^-]$ is set equal to $[HCO_3^-]_0$, this becomes

$$[H_3O^+]^2 \approx \frac{K_{a1}K_{a2}[HCO_3^-]_0 + K_{a1}K_w}{K_{a1} + [HCO_3^-]_0}$$

which can be solved for $[H_3O^+]$. In many cases of interest, $[HCO_3^-]_0 \gg K_{a1}$, and $K_{a2}\,[HCO_3^-]_0 \gg K_w$. When this is so, the expression simplifies to

$$[H_3O^+]^2 \approx K_{a1}K_{a2}$$

$$\left[H_3O^+\right] \approx \sqrt{K_{a1}K_{a2}}$$

$$\text{pH} \approx \frac{1}{2}\,(\text{p}K_{a1} + \text{p}K_{a2})$$

so the pH of such a solution is the average of the pK_a values for the two ionizations.

EXAMPLE 15.21

What is the pH of a solution that is 0.100 M in $NaHCO_3$?

Solution

First, the two assumptions are checked:

$$[HCO_3^-]_0 = 0.100 \gg 4.3 \times 10^{-7} = K_{a1}$$

$$HCO_3^-]_0 K_{a2} = 4.8 \times 10^{-12} \gg 1.0 \times 10^{-14} = K_w$$

so both are satisfied. Therefore,

$$[H_3O^+] = \sqrt{K_{a1}K_{a2}} = 4.5 \times 10^{-9}\ \text{M}$$

$$\text{pH} = 8.34$$

and the solution is basic, as expected.

Titration of a Polyprotic Acid

A polyprotic acid has more than one equivalence point. The first equivalence point occurs when the volume V_{e1} of base added is sufficient to remove one hydrogen ion from each acid molecule, V_{e2} is the volume sufficient to remove two hydrogen ions from each, and so forth. A diprotic acid shows two equivalence points, and a triprotic acid, three. The equivalent volumes are related to each other by

$$V_{e1} = \frac{1}{2}\,V_{e2} = \frac{1}{3}\,V_{e3}$$

Figure 15.17 shows a titration curve for triprotic phosphoric acid. The three equivalence points are at 100.0 mL, 200.0 mL, and 300.0 mL. Calculating the pH as a function of the volume of added base presents no new complications beyond those already considered. The initial pH is given by a calculation analogous to that of

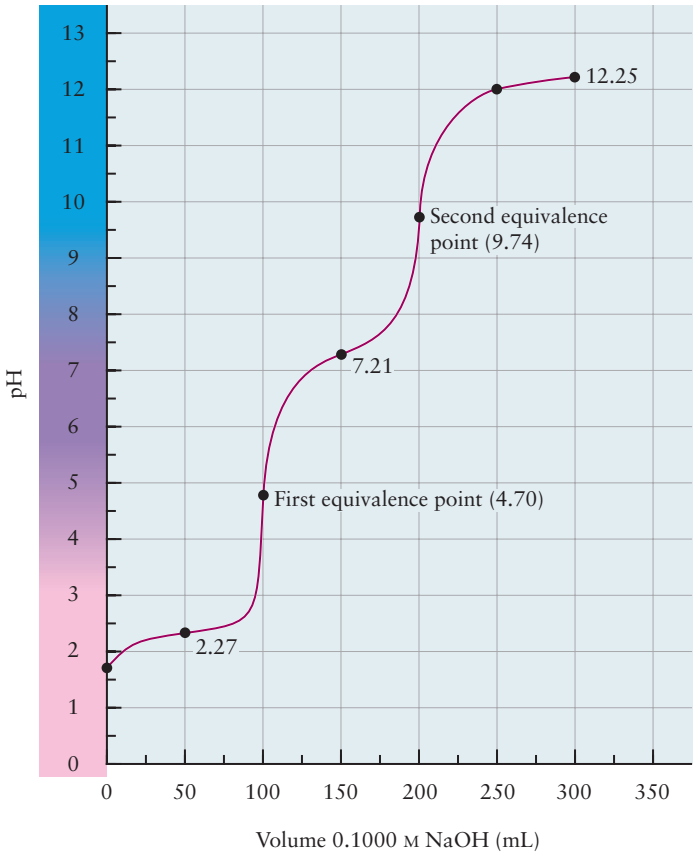

FIGURE 15.17 A titration curve for the titration of a polyprotic acid (phosphoric acid) by a strong base. The curve shown is for 100.0 mL of 0.1000 M H_3PO_4 titrated with 0.1000 M NaOH. No clear third equivalence point is seen at 300 mL because K_a for HPO_4^{2-} is not much greater than K_a for H_2O in aqueous solution.

Example 15.15, and the pH in the flat regions between equivalence points is obtained by a buffer calculation like that for a diprotic acid. For example, the pH after addition of 50.0 mL of base is that of an equimolar $H_3PO_4/H_2PO_4^-$ buffer (subsequent ionization of $H_2PO_4^-$ can be ignored). Finally, the pH at the first equivalence point is that for a solution of NaH_2PO_4 and uses the amphoteric equilibria equations presented earlier in this section (PO_4^{3-} can be ignored in this case). The pH at the second equivalence point is an amphoteric equilibrium in which HPO_4^{2-} is in equilibrium with $H_2PO_4^-$ and with PO_4^{3-}.

CHAPTER SUMMARY

According to the Brønsted–Lowry model, acid–base chemistry encompasses a broad range of reactions in which protons are donated by species called the acid and accepted by species called the base. These reactions play key roles in situations that include industrial manufacturing processes, ordinary household substances, and the life-sustaining reactions in living systems. In aqueous solutions, all acids and bases react with the water in which they are dissolved. An acid increases the concentration of the hydronium ion H_3O^+ above its value in pure water, which is controlled by the ion product constant of water. A base increases the concentration of the hydroxide ion OH^- above the value it takes in pure water, due to the ion product constant of water. The concentration of the hydronium ion is conveniently expressed by pH, and that of the hydroxide by pOH. These quantities are related as pH + pOH = 14 by the ion product constant of water. Some acids and bases dissociate completely in solution to produce concentrations of hydronium and hydroxide equivalent to the concentration of parent acid or base with which the solutions were prepared. These are called strong acids and bases, and reactions of their solutions are completely described by the laws of stoichiometry. Most acids and

bases dissociate only partially, so we must use the principles of chemical equilibrium to describe the concentration of hydronium and hydroxide in their solutions. These are the weak acids and bases, and description of their reactions requires methods of stoichiometry combined with methods of equilibrium. Acid–base neutralization reactions produce water and salts as their products. These reactions can be followed quantitatively and precisely by titration, as a means to determine the amount of acid or base in an unknown sample. The Brønsted–Lowry model does not require acids and bases to be neutral molecules. Positive and negative ions dissolved in water can react with the water as either Brønsted–Lowry acids or bases. When the salt of a weak acid is dissolved in water, hydrolysis of the anion produces the undissociated acid, and the solution is basic. Similarly, hydrolysis of the salt of a weak base produces an acidic solution. In both cases the pH is calculated by equilibrium methods. An especially interesting situation arises when a weak acid is dissolved along with one of its salts. The combination of weak acid equilibrium and hydrolysis—called a buffer solution—keeps the pH of the solution constant as small amounts of acid are added. This stabilization mechanism is extremely important in biochemical and biological situations, where success of various reactions depends critically on keeping pH constant. The extent of all these acid–base reactions can be correlated with the structures of their molecules. The extent of reaction is governed by the equilibrium constant, which in turn depends on the Gibbs standard free energy of formation of the reactants and products, which depends on their molecular structure.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 15.1 – Classifications of Acids and Bases

Define acids and bases in the Brønsted–Lowry and Lewis models and provide several examples of their reactions with a solvent (Problems 1–12).

- In the Brønsted–Lowry model acids are proton donors, and bases are proton acceptors. Acid–base reactions are proton transfer reactions.
- In the Lewis model acids are electron pair acceptors, and bases are electron pair donors. Acid–base reactions are electron pair transfer reactions that lead to the formation of new chemical bonds.

Section 15.2 – Properties of Acids and Bases in Aqueous Solutions: The Brønsted–Lowry Scheme

Define the pH function and convert between pH and $[H_3O^+]$ (Problems 13–16).

- The autoionization of water produces free hydronium and hydroxide ions whose concentrations in liquid water obey the ion product expression for water:
  - $[H_3O^+][OH^-] = K_w = 10^{-14}$ for pure water at 25°C
  - $[H_3O^+] = [OH^-] = 10^{-7}$ M
- Strong acids and bases dissociate essentially completely in aqueous solution and increase the concentrations of hydronium and hydroxide ions, respectively.
- The pH function $pH = -\log [H_3O^+]$ is a convenient way to express the concentration of hydronium ions over a very large range of values. The pH value tells us at a glance the nature of the solution: $pH < 7$ is an acidic solution; $pH > 7$ is a basic solution; $pH = 7$ is a neutral solution.

Section 15.3 – Acid and Base Strength

State the relationship between the ionization constant for an acid or base and the strength of that acid or base.

- For the reaction of an acid with water $HA(aq) + H_2O(\ell) \longrightarrow H_3O^+(aq) + A^-(aq)$
  - $([H_3O^+][A^-])/[HA] = K_a$
  - Strong acids have $K_a > 1$, with large $[H_3O^+]$ at equilibrium.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- For the reaction of a base with water $B(aq) + H_2O(\ell) \longrightarrow BH^+(aq) + OH^-(aq)$
  - $([BH^+][OH^-])/[B] = K_b$
  - Strong bases have $K_b < 1$, with large $[OH^-]$ at equilibrium.

State the relationship between the ionization constant for an acid and that for its conjugate base (Problems 21–22).

- For a conjugate acid–base pair $K_aK_b = K_w$. Stronger conjugate acids have weaker conjugate bases and vice versa.

Describe how the strengths of oxoacids relate to their molecular structure and bonding.

- The strength of oxoacids containing the structural unit X—O—H increases as electronegativity of X increases. As X withdraws electron density from the H atom to the O—X bond, it becomes easier to break the O—H bond and release H^+.

Explain how indicators allow the pH of a solution to be estimated (Problems 25–26).

- An indicator is a weak organic acid (HIn) that has a different color from its conjugate base (In^-). As the pH of the solution changes, the ratio of [HIn] to $[In^-]$ changes according to the acid ionization equilibrium expression $K_a = ([H_3O^+]\,[In^-])/[HIn]$ and the color of the solution changes accordingly.

Section 15.4 – Equilibria Involving Weak Acids and Bases

Formulate the equilibrium expression for the ionization of a weak acid or base, and use it to determine the pH and the fraction ionized (Problems 27–36).

- For a weak acid $HA(aq) + H_2O(\ell) \longrightarrow H_3O^+(aq) + A^-(aq)$ the equilibrium expression is
  - $K_a = ([H_3O^+][A^-])/[HA] = K_a$
  - let $x = [H_3O^+] = [A^-]$
  - then $x^2/([HA] - x) = K_a$
  - If K_a is very small and the initial concentration of HA ≥ 0.05 M, use the approximation $x^2/[HA] = K_a$.
  - Otherwise, use the quadratic equation.
- For a weak base $B(aq) + H_2O(\ell) \longrightarrow BH^+(aq) + OH^-(aq)$ the equilibrium expression is
  - $([BH^+][OH^-])/[B] = K_b$
  - Follow the same procedures as for the weak acid.
- Hydrolysis is the reaction of the salt of a weak base or the salt of a weak acid with water.
  - The cation of a weak base acts as an acid to form the conjugate base and produce an acidic solution.
  - The anion of a weak acid acts as a base to form the conjugate acid and produce a basic solution.
- For all conjugate acid–base pairs $K_b = K_w/K_a$.

Section 15.5 – Buffer Solutions

Explain the behavior of a buffer solution. Calculate its pH from the concentrations of its conjugate acid–base pair (Problems 43–46).

- A buffer solution contains either a weak acid and its salt, or a weak base and its salt, both in appreciable amounts. Adding a small amount of acid or base only slightly alters the ratio of the acid or base to its salt. Keeping this ratio nearly constant resists changes in pH when either acid or base is added.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The pH in a buffer solution given by these approximate equations is valid when the equilibrium concentrations of the acid and its conjugate base are close to their initial concentrations:
  - $[H_3O^+] = \dfrac{[HA]_0}{[A^-]_0} K_a$
  - $pH \approx pK_a - \log_{10} \dfrac{[HA]_0}{[A^-]_0}$
- To describe the response of a buffer to an added acid or base, follow the procedures demonstrated in Example 15.11.

Design a buffer system to produce and maintain a particular pH (Problems 47–50).

- The method is based on the equation for the pH of a buffer solution. Choose an acid with a pK_a as close as possible to the desired pH. Then adjust the ratio of the concentrations of the acid and its conjugate base to produce the desired pH. The method is illustrated in Example 15.13.

Section 15.6 – Acid–base Titration Curves

Calculate the pH at any stage in the titration of a strong acid or base by a strong base or acid (Problems 51–52).

- Titration curves for strong acids by strong bases and vice versa have four regions determined by the amount of titrant that has been added. In each of these regions the pH can be calculated by procedures of stoichiometry and definitions of solution concentration.
  - Before any titrant is added: The initial concentration of the starting acid or base determines the pH.
  - Before the equivalence point: Calculate the number of moles of acid or base remaining and divide by the total volume to calculate the concentration and determine the pH.
  - At the equivalence point: pH = 7.
  - After the equivalence point: Calculate the number of moles of excess acid or base and divide by the total volume to calculate the concentration and determine the pH.
- The choice of indicator is not critical in strong acid–strong base titrations since the slope of the transition at the equivalence point is very steep.

Calculate the pH at any stage in the titration of a weak acid or base by a strong base or acid (Problems 53–62).

- Titration curves for weak acids by strong bases and vice versa also have four regions identified by the amount of titrant that has been added. Calculating the pH in each of these requires consideration of equilibria in the solution, and each corresponds to a standard type of calculation illustrated in the chapter.
  - Before any titrant is added: This is simply the ionization of a weak acid or base, as described in Examples 15.6 and 15.7.
  - Before the equivalence point: This is a buffer solution, as described in Example 15.10.
  - At the equivalence point: This is a hydrolysis problem. All of the initial acid or base has been converted to a salt, which hydrolyzes back to the acid or base, so the pH $\neq$ 7. See Example 15.9.
  - After the equivalence point: The problem is very close to the titration of a strong acid or base. Calculate the number of moles of excess acid or base added and divide by the total volume to obtain the concentration and the pH.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The choice of indicator is critical in weak acid–strong base and weak base–strong acid titrations because the slope of the transition is not so steep and the pH of the equivalence point can be very different from 7. pK_a (indicator) ≈ pH at the equivalence point.)

Section 15.7 – Polyprotic Acids

Calculate the concentrations of all the species present in a solution of a weak polyprotic acid (Problems 63–68).

- If the initial acid concentration is not too small and the first ionization constant K_{a1} is about 100 times larger than the second ionization constant K_{a2}, the two equilibria can be treated sequentially. Set up the equilibrium expression for the first dissociation. Assume y moles of acid dissociate to produce y moles of the hydronium ion and y moles of the first conjugate base. Calculate y. Set up the equilibrium expression for the second dissociation. Assume that the equilibrium concentrations of hydronium ion and the first conjugate base take the value y determined from the first step, and calculate the equilibrium concentration of the conjugate base produced in the second ionization. The details are illustrated in Example 15.15.

Section 15.8 – Organic Acids and Bases: Structure and Reactivity

Use structure–function relations to predict effects of substitutions on relative strengths of organic acids (Problems 69–76).

- The strength of an organic acid increases with the stability of its conjugate base anion. Any structural change that increases the stability of the conjugate base increases the strength of the organic acid.
  - As the atom X to which the H is bonded in the acid (—X^-H) becomes more electronegative, the conjugate base —X^- can accommodate the negative charge and becomes more stable.
  - Electronegative atoms more distant from the ionization site can stabilize the anion through the inductive effect.
  - If several resonance structures are possible for the anion, its stability is increased.

Section 15.9 – A Deeper Look . . . Exact Treatment of Acid–Base Equilibria

Outline the procedure for the exact treatment of acid–base equilibrium and use it to find the pH of a very dilute solution of a weak acid or base (Problems 77–78).

- For a weak acid, the dissolved species are HA, A^-, H_3O^+, and OH^-. The amount of hydronium produced by dissociation of water cannot be neglected compared to the amount produced by the dissociated acid. The concentrations of these four dissolved species must be determined from four independent equations, which are then solved simultaneously.
  - Equilibrium expression for dissociation of the acid $\dfrac{[H_3O^+][A^-]}{[HA]} = K_a$
  - Ion product of water $[H_3O^+][OH^-] = K_w$
  - Conservation of the anion of the acid: $c_a = [HA] + [A^-]$
  - Charge balance for electrical neutrality of the solution $[H_3O^+] = [A^-] + [OH^-]$
- Detailed procedures for solving these equations simultaneously are illustrated in Example 15.20.

Calculate the pH at selected points in the titration of a polyprotic acid (Problems 79–80).

- A polyprotic acid has multiple equivalent points at which the equivalent volumes of titrant are related as $V_{el} = \dfrac{1}{2} V_{e2} = \dfrac{1}{3} V_{e3}$
  - The initial pH before titration begins is calculated by treating the first two equilibria sequentially as in Example 15.15.

The effect of acid rain on a stand of trees in the Great Smoky Mountains of the United States.

- Between equivalence points pH is calculated as for a buffer involving a diprotic acid.
- The pH at each equivalence point is calculated as for an amphoteric equilibrium.
- Detailed procedures are outlined in Figure 15.17.

CUMULATIVE EXERCISE

Acid Rain

Acid rain is a major environmental problem throughout the industrialized world. One major source is the burning of fossil fuels containing sulfur (coal, oil, and natural gas). The sulfur dioxide released into the air dissolves in water or, more seriously, may be oxidized further to sulfur trioxide. The SO_3 dissolves in water to form sulfuric acid:

$$SO_3(g) + H_2O(\ell) \longrightarrow H_2SO_4(aq)$$

The net effect is to increase the acidity of the rain, which damages trees, kills fish in lakes, dissolves stone, and corrodes metal.

(a) A sample of rainwater is tested for acidity by using two indicators. Addition of methyl orange to half of the sample gives a yellow color, and addition of methyl red to the other half gives a red color. Estimate the pH of the sample.

(b) The pH in acid rain can range down to 3 or even lower in heavily polluted areas. Calculate the concentrations of H_3O^+ and OH^- in a raindrop at pH 3.30 at 25°C.

(c) When SO_2 dissolves in water to form sulfurous acid, $H_2SO_3(aq)$, that acid can donate a hydrogen ion to water. Write a balanced chemical equation for this reaction, and identify the stronger Brønsted–Lowry acid and base in the equation.

(d) Ignore the further ionization of HSO_3^-, and calculate the pH of a solution whose initial concentration of H_2SO_3 is 4.0×10^{-4} M. (*Hint:* Use the quadratic equation in this case.)

(e) Now suppose that all the dissolved SO_2 from part (d) has been oxidized further to SO_3, so that 4.0×10^{-4} mol of H_2SO_4 is dissolved per liter. Calculate the pH in this case. (*Hint:* Because the first ionization of H_2SO_4 is that of a strong acid, the concentration of H_3O^+ can be written as 4.0×10^{-4} plus the unknown amount of dissociation from $HSO_4^-(aq)$.)

(f) Lakes have a natural buffering capacity, especially in regions where limestone gives rise to dissolved calcium carbonate. Write an equation for the effect of a small amount of acid rain containing sulfuric acid if it falls into a lake containing carbonate (CO_3^{2-}) ions. Discuss how the lake will resist further pH changes. What happens if a large excess of acid rain is deposited?

(g) A sample of 1.00 L of rainwater known to contain only sulfurous (and not sulfuric) acid is titrated with 0.0100 M NaOH. The equivalence point of the H_2SO_3/HSO_3^- titration is reached after 31.6 mL has been added. Calculate the original concentration of sulfurous acid in the sample, again ignoring any effect of SO_3^{2-} on the equilibria.

(h) Calculate the pH at the half-equivalence point, after 15.8 mL has been added. (*Hint:* Use the quadratic equation.)

Answers

(a) 4.4 to 4.8

(b) $[H_3O^+] = 5.0 \times 10^{-4}$ M; $[OH^-] = 2.0 \times 10^{-11}$ M

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(c) $H_2SO_3(aq) + H_2O(\ell) \rightleftharpoons HSO_3^-(aq) + H_3O^+(aq)$. The stronger acid is H_3O^+, and the stronger base is HSO_3^-.

(d) The pH is 3.41.

(e) The pH is 3.11.

(f) The H_3O^+ in the sulfuric acid solution reacts according to $H_3O^+(aq) + CO_3^{2-}(aq) \rightleftharpoons HCO_3^-(aq) + H_2O(\ell)$. The HSO_4^- in the sulfuric acid reacts according to $HSO_4^-(aq) + CO_3^{2-}(aq) \rightleftharpoons SO_4^{2-}(aq) + HCO_3^-(aq)$. This gives rise to a HCO_3^-/CO_3^{2-} buffer that can resist further changes in pH. An excess of acid rain overwhelms the buffer and leads to the formation of H_2CO_3.

(g) 3.16×10^{-4} M

(h) The pH is 3.81.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

Classifications of Acids and Bases

1. Which of the following can act as Brønsted–Lowry acids? Give the formula of the conjugate Brønsted–Lowry base for each of them.
(a) Cl^- (b) HSO_4^- (c) NH_4^+
(d) NH_3 (e) H_2O

2. Which of the following can act as Brønsted–Lowry bases? Give the formula of the conjugate Brønsted–Lowry acid for each of them.
(a) F^- (b) SO_4^{2-} (c) O^{2-}
(d) OH^- (e) H_2O

3. Lemon juice contains citric acid ($C_6H_8O_7$). What species serves as a base when lemon juice is mixed with baking soda (sodium hydrogen carbonate) during the preparation of some lemon cookies?

4. A treatment recommended in case of accidental swallowing of ammonia-containing cleanser is to drink large amounts of diluted vinegar. Write an equation for the chemical reaction on which this procedure depends.

5. An important step in many industrial processes is the slaking of lime, in which water is added to calcium oxide to make calcium hydroxide.
(a) Write the balanced equation for this process.
(b) Can this be considered a Lewis acid–base reaction? If so, what is the Lewis acid and what is the Lewis base?

6. Silica (SiO_2) is an impurity that must be removed from a metal oxide or sulfide ore when the ore is being reduced to elemental metal. To do this, lime (CaO) is added. It reacts with the silica to form a slag of calcium silicate ($CaSiO_3$), which can be separated and removed from the ore.
(a) Write the balanced equation for this process.
(b) Can this be considered a Lewis acid–base reaction? If so, what is the Lewis acid and what is the Lewis base?

7. Chemists working with fluorine and its compounds sometimes find it helpful to think in terms of acid–base reactions in which the fluoride ion (F^-) is donated and accepted.
(a) Would the acid in this system be the fluoride donor or fluoride acceptor?
(b) Identify the acid and base in each of these reactions:

$$ClF_3O_2 + BF_3 \longrightarrow ClF_2O_2 \cdot BF_4$$

$$TiF_4 + 2\ KF \longrightarrow K_2[TiF_6]$$

8. Researchers working with glasses often think of acid–base reactions in terms of oxide donors and oxide acceptors. The oxide ion is O^{2-}.
(a) In this system, is the base the oxide donor or the oxide acceptor?
(b) Identify the acid and base in each of these reactions:

$$2\ CaO + SiO_2 \longrightarrow Ca_2SiO_4$$

$$Ca_2SiO_4 + SiO_2 \longrightarrow 2\ CaSiO_3$$

$$Ca_2SiO_4 + CaO \longrightarrow Ca_3SiO_5$$

9. Identify each of the following oxides as an acid or base anhydride. Write the chemical formula and give the name of the acid or base formed upon reaction with water.
(a) MgO (b) Cl_2O
(c) SO_3 (d) Cs_2O

10. Write the chemical formula and give the name of the anhydride corresponding to each of the following acids or bases, and identify it as an acid or base anhydride.
(a) H_3AsO_4 (b) H_2MoO_4
(c) RbOH (d) H_2SO_3

11. Tin(II) oxide is amphoteric. Write balanced chemical equations for its reactions with an aqueous solution of hydrochloric acid and with an aqueous solution of sodium hydroxide. (**Note:** The hydroxide complex ion of tin(II) is $[Sn(OH)_3]^-$.)

12. Zinc oxide is amphoteric. Write balanced chemical equations for its reactions with an aqueous solution of hydrochloric acid and with an aqueous solution of sodium hydroxide. (**Note:** The hydroxide complex ion of zinc is $[Zn(OH)_4]^{2-}$.)

Properties of Acids and Bases in Aqueous Solutions: The Brønsted–Lowry Scheme

13. The concentration of H_3O^+ in a sample of wine is 2.0×10^{-4} M. Calculate the pH of the wine.

14. The concentration of OH^- in a solution of household bleach is 3.6×10^{-2} M. Calculate the pH of the bleach.

15. The pH of normal human urine is in the range of 5.5 to 6.5. Compute the range of the H_3O^+ concentration and the range of the OH^- concentration in normal urine.

16. The pH of normal human blood is in the range of 7.35 to 7.45. Compute the range of the concentration of H_3O^+ and the range of the OH^- concentration in normal blood.

17. The pK_w of seawater at 25°C is 13.776. This differs from the usual pK_w of 14.00 at this temperature because dissolved salts make seawater a nonideal solution. If the pH in seawater is 8.00, what are the concentrations of H_3O^+ and OH^- in seawater at 25°C?

18. At body temperature (98.6°F = 37.0°C), K_w has the value 2.4×10^{-14}. If the pH of blood is 7.4 under these conditions, what are the concentrations of H_3O^+ and OH^-?

19. When placed in water, potassium starts to react instantly and continues to react with great vigor. On the basis of this information, select the better of the following two equations to represent the reaction.

$$2\ K(s) + 2\ H_2O(\ell) \longrightarrow 2\ KOH(aq) + H_2(g)$$

$$2\ K(s) + 2\ H_3O^+(aq) \longrightarrow 2\ K^+(aq) + H_2(g) + 2H_2O(\ell)$$

State the reason for your choice.

20. Molecules of *t*-butyl chloride, $(CH_3)_3CCl$, react very slowly when mixed with water at low pH to give *t*-butyl alcohol, $(CH_3)_3COH$. When the pH is raised, the reaction takes place rapidly. Write an equation or equations to explain these facts.

Acid and Base Strength

21. Ephedrine ($C_{10}H_{15}ON$) is a base that is used in nasal sprays as a decongestant.
- (a) Write an equation for its equilibrium reaction with water.
- (b) The K_b for ephedrine is 1.4×10^{-4}. Calculate the K_a for its conjugate acid.
- (c) Is ephedrine a weaker or a stronger base than ammonia?

22. Niacin (C_5H_4NCOOH), one of the B vitamins, is an acid.
- (a) Write an equation for its equilibrium reaction with water.
- (b) The K_a for niacin is 1.5×10^{-5}. Calculate the K_b for its conjugate base.
- (c) Is the conjugate base of niacin a stronger or a weaker base than pyridine, C_5H_5N?

23. Use the data in Table 15.2 to determine the equilibrium constant for the reaction.

$$HClO_2(aq) + NO_2^-(aq) \rightleftharpoons HNO_2(aq) + ClO_2^-(aq)$$

Identify the stronger Brønsted–Lowry acid and the stronger Brønsted–Lowry base.

24. Use the data in Table 15.2 to determine the equilibrium constant for the reaction

$$HPO_4^{2-} + HCO_3^- \rightleftharpoons PO_4^{3-} + H_2CO_3$$

Identify the stronger Brønsted–Lowry acid and the stronger Brønsted–Lowry base.

25.
- (a) Which is the stronger acid—the acidic form of the indicator bromocresol green or the acidic form of methyl orange?
- (b) A solution is prepared in which bromocresol green is green and methyl orange is orange. Estimate the pH of this solution.

26.
- (a) Which is the stronger base—the basic form of the indicator cresol red or the basic form of thymolphthalein?
- (b) A solution is prepared in which cresol red is red and thymolphthalein is colorless. Estimate the pH of this solution.

Equilibria Involving Weak Acids and Bases

27. Aspirin is acetylsalicylic acid, $HC_9H_7O_4$, which has a K_a of 3.0×10^{-4}. Calculate the pH of a solution made by dissolving 0.65 g of acetylsalicylic acid in water and diluting to 50.0 mL.

28. Vitamin C is ascorbic acid ($HC_6H_7O_6$), for which K_a is 8.0×10^{-5}. Calculate the pH of a solution made by dissolving a 500-mg tablet of pure vitamin C in water and diluting to 100 mL.

29.
- (a) Calculate the pH of a 0.20 M solution of benzoic acid at 25°C.
- (b) How many moles of acetic acid must be dissolved per liter of water to obtain the same pH as that from part (a)?

30.
- (a) Calculate the pH of a 0.35 M solution of propionic acid at 25°C.
- (b) How many moles of formic acid must be dissolved per liter of water to obtain the same pH as that from part (a)?

31. Iodic acid (HIO_3) is fairly strong for a weak acid, having a K_a equal to 0.16 at 25°C. Compute the pH of a 0.100 M solution of HIO_3.

32. At 25°C, the K_a of pentafluorobenzoic acid (C_6F_5COOH) is 0.033. Suppose 0.100 mol of pentafluorobenzoic acid is dissolved in 1.00 L of water. What is the pH of this solution?

33. Papaverine hydrochloride ($papH^+Cl^-$) is a drug used as a muscle relaxant. It is a weak acid. At 25°C, a 0.205 M solution of $papH^+Cl^-$ has a pH of 3.31. Compute the K_a of the $papH^+$ ion.

34. The unstable weak acid 2-germaacetic acid (GeH_3COOH) is derived structurally from acetic acid (CH_3COOH) by having a germanium atom replace one of the carbon atoms. At 25°C, a 0.050 M solution of 2-germaacetic acid has a pH of 2.42. Compute the K_1 of 2-germaacetic acid and compare it with that of acetic acid.

35. Morphine is a weak base for which K_b is 8×10^{-7}. Calculate the pH of a solution made by dissolving 0.0400 mol of morphine in water and diluting to 600.0 mL.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

36. Methylamine is a weak base for which K_b is 4.4×10^{-4}. Calculate the pH of a solution made by dissolving 0.070 mol of methylamine in water and diluting to 800.0 mL.

37. The pH at 25°C of an aqueous solution of hydrofluoric acid, HF, is 2.13. Calculate the concentration of HF in this solution, in moles per liter.

38. The pH at 25°C of an aqueous solution of sodium cyanide (NaCN) is 11.50. Calculate the concentration of CN^- in this solution, in moles per liter.

39. You have 50.00 mL of a solution that is 0.100 M in acetic acid, and you neutralize it by adding 50.00 mL of a solution that is 0.100 M in sodium hydroxide. The pH of the resulting solution is not 7.00. Explain why. Is the pH of the solution greater than or less than 7?

40. A 75.00-mL portion of a solution that is 0.0460 M in $HClO_4$ is treated with 150.00 mL of 0.0230 M KOH(*aq*). Is the pH of the resulting mixture greater than, less than, or equal to 7.0? Explain.

41. Suppose a 0.100 M solution of each of the following substances is prepared. Rank the pH of the resulting solutions from lowest to highest: NH_4Br, NaOH, KI, $NaCH_3COO$, HCl.

42. Suppose a 0.100 M solution of each of the following substances is prepared. Rank the pH of the resulting solutions from lowest to highest: KF, NH_4I, HBr, NaCl, LiOH.

Buffer Solutions

43. "Tris" is short for tris(hydroxymethyl)aminomethane. This weak base is widely used in biochemical research for the preparation of buffers. It offers low toxicity and a pK_b (5.92 at 25°C) that is convenient for the control of pH in clinical applications. A buffer is prepared by mixing 0.050 mol of tris with 0.025 mol of HCl in a volume of 2.00 L. Compute the pH of the solution.

44. "Bis" is short for bis(hydroxymethyl)aminomethane. It is a weak base that is closely related to tris (see problem 43) and has similar properties and uses. Its pK_b is 8.8 at 25°C. A buffer is prepared by mixing 0.050 mol of bis with 0.025 mol of HCl in a volume of 2.00 L (the same proportions as in the preceding problem). Compute the pH of the solution.

45. (a) Calculate the pH in a solution prepared by dissolving 0.050 mol of acetic acid and 0.020 mol of sodium acetate in water and adjusting the volume to 500 mL.
(b) Suppose 0.010 mol of NaOH is added to the buffer from part (a). Calculate the pH of the solution that results.

46. Sulfanilic acid ($NH_2C_6H_4SO_3H$) is used in manufacturing dyes. It ionizes in water according to the equilibrium equation

$$NH_2C_6H_4SO_3H(aq) + H_2O(\ell) \rightleftharpoons NH_2C_6H_4SO_3^-(aq) + H_3O^+(aq) \qquad K_a = 5.9 \times 10^{-4}$$

A buffer is prepared by dissolving 0.20 mol of sulfanilic acid and 0.13 mol of sodium sulfanilate ($NaNH_2C_6H_4SO_3$) in water and diluting to 1.00 L.
(a) Compute the pH of the solution.
(b) Suppose 0.040 mol of HCl is added to the buffer. Calculate the pH of the solution that results.

47. A physician wishes to prepare a buffer solution at pH = 3.82 that efficiently resists changes in pH yet contains only small concentrations of the buffering agents. Determine which one of the following weak acids, together with its sodium salt, would probably be best to use: *m*-chlorobenzoic acid, $K_a = 1.04 \times 10^{-4}$; *p*-chlorocinnamic acid, $K_a = 3.89 \times 10^{-5}$; 2,5-dihydroxybenzoic acid, $K_a = 1.08 \times 10^{-3}$; or acetoacetic acid, $K_a = 2.62 \times 10^{-4}$. Explain.

48. Suppose you were designing a buffer system for imitation blood and wanted the buffer to maintain the blood at the realistic pH of 7.40. All other things being equal, which buffer system would be preferable: H_2CO_3/HCO_3^- or $H_2PO_4^-/HPO_4^{2-}$? Explain.

49. You have at your disposal an ample quantity of a solution of 0.0500 M NaOH and 500 mL of a solution of 0.100 M formic acid (HCOOH). How much of the NaOH solution should be added to the acid solution to produce a buffer of pH 4.00?

50. You have at your disposal an ample quantity of a solution of 0.100 M HCl and 400 mL of a solution of 0.0800 M NaCN. How much of the HCl solution should be added to the NaCN solution to produce a buffer of pH 9.60?

Acid–Base Titration Curves

51. Suppose 100.0 mL of a 0.3750 M solution of the strong base $Ba(OH)_2$ is titrated with a 0.4540 M solution of the strong acid $HClO_4$. The neutralization reaction is

$$Ba(OH)_2(aq) + 2\ HClO_4(aq) \longrightarrow Ba(ClO_4)_2(aq) + 2\ H_2O(\ell)$$

Compute the pH of the titration solution before any acid is added, when the titration is 1.00 mL short of the equivalence point, when the titration is at the equivalence point, and when the titration is 1.00 mL past the equivalence point. (**Note:** Each mole of $Ba(OH)_2$ gives *two* moles of OH^- in solution.)

52. A sample containing 26.38 mL of 0.1439 M HBr is titrated with a solution of NaOH having a molarity of 0.1219 M. Compute the pH of the titration solution before any base is added, when the titration is 1.00 mL short of the equivalence point, when the titration is at the equivalence point, and when the titration is 1.00 mL past the equivalence point.

53. A sample containing 50.00 mL of 0.1000 M hydrazoic acid (HN_3) is being titrated with 0.1000 M sodium hydroxide. Compute the pH before any base is added, after the addition of 25.00 mL of the base, after the addition of 50.00 mL of the base, and after the addition of 51.00 mL of the base.

54. A sample of 50.00 mL of 0.1000 M aqueous solution of chloroacetic acid, $CH_2ClCOOH$ ($K_1 = 1.4 \times 10^{-3}$), is titrated with a 0.1000 M NaOH solution. Calculate the pH at the following stages in the titration, and plot the titration curve: 0, 5.00, 25.00, 49.00, 49.90, 50.00, 50.10, and 55.00 mL NaOH.

55. The base ionization constant of ethylamine ($C_2H_5NH_2$) in aqueous solution is $K_b = 6.41 \times 10^{-4}$ at 25°C. Calculate the pH for the titration of 40.00 mL of a 0.1000 M solution of ethylamine with 0.1000 M HCl at the following volumes of added HCl: 0, 5.00, 20.00, 39.90, 40.00, 40.10, and 50.00 mL.

56. Ammonia is a weak base with a K_b of 1.8×10^{-5}. A 140.0-mL sample of a 0.175 M solution of aqueous ammonia is titrated with a 0.106 M solution of the strong acid HCl. The reaction is

$$NH_3(aq) + HCl(aq) \longrightarrow NH_4^+(aq) + Cl^-(aq)$$

Compute the pH of the titration solution before any acid is added, when the titration is at the half-equivalence point, when the titration is at the equivalence point, and when the titration is 1.00 mL past the equivalence point.

57. Sodium benzoate, the sodium salt of benzoic acid, is used as a food preservative. A sample containing solid sodium benzoate mixed with sodium chloride is dissolved in 50.0 mL of 0.500 M HCl, giving an acidic solution (benzoic acid mixed with HCl). This mixture is then titrated with 0.393 M NaOH. After the addition of 46.50 mL of the NaOH solution, the pH is found to be 8.2. At this point, the addition of one more drop (0.02 mL) of NaOH raises the pH to 9.3. Calculate the mass of sodium benzoate (NaC_6H_5COO) in the original sample. (*Hint:* At the equivalence point, the *total* number of moles of acid [here HCl] equals the *total* number of moles of base [here, both NaOH and NaC_6H_5COO].)

58. An antacid tablet (such as Tums or Rolaids) weighs 1.3259 g. The only acid-neutralizing ingredient in this brand of antacid is $CaCO_3$. When placed in 12.07 mL of 1.070 M HCl, the tablet fizzes merrily as $CO_2(g)$ is given off. After all of the CO_2 has left the solution, an indicator is added, followed by 11.74 mL of 0.5310 M NaOH. The indicator shows that at this point the solution is definitely basic. Addition of 5.12 mL of 1.070 M HCl makes the solution acidic again. Then 3.17 mL of the 0.5310 M NaOH brings the titration exactly to an endpoint, as signaled by the indicator. Compute the percentage by mass of $CaCO_3$ in the tablet.

59. What is the mass of diethylamine, $(C_2H_5)_2NH$, in 100.0 mL of an aqueous solution if it requires 15.90 mL of 0.0750 M HCl to titrate it to the equivalence point? What is the pH at the equivalence point if $K_b = 3.09 \times 10^{-4}$? What would be a suitable indicator for the titration?

60. A chemist who works in the process laboratory of the Athabasca Alkali Company makes frequent analyses of ammonia recovered from the Solvay process for making sodium carbonate. What is the pH at the equivalence point if she titrates the aqueous ammonia solution (approximately 0.10 M) with a strong acid of comparable concentration? Select an indicator that would be suitable for the titration.

61. If 50.00 mL of a 0.200 M solution of the weak base *N*-ethylmorpholine ($C_6H_{13}NO$) is mixed with 8.00 mL of 1.00 M HCl and then diluted to a final volume of 100.0 mL with water, the result is a buffer with a pH of 7.0. Compute the K_b of *N*-ethylmorpholine.

62. The sodium salt of cacodylic acid, a weak acid, has the formula $NaO_2As(CH_3)_2 \cdot 3H_2O$. Its molar mass is 214.02 g mol^{-1}. A solution is prepared by mixing 21.40 g of this substance with enough water to make 1.000 L of solution. Then 50.00 mL of the sodium cacodylate solution is mixed with 29.55 mL of 0.100 M HCl and enough water to bring the volume to a total of 100.00 mL. The pH of the solution is 6.00. Determine the K_a of cacodylic acid.

Polyprotic Acids

63. Arsenic acid (H_3AsO_4) is a weak triprotic acid. Given the three acid ionization constants from Table 15.2 and an initial concentration of arsenic acid (before ionization) of 0.1000 M, calculate the equilibrium concentrations of H_3AsO_4, $H_2AsO_4^-$, $HAsO_4^{2-}$, AsO_4^{3-}, and H_3O^+.

64. Phthalic acid ($H_2C_8H_4O_4$, abbreviated H_2Ph) is a diprotic acid. Its ionization in water at 25°C takes place in two steps:

$$H_2Ph(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HPh^-(aq) \qquad K_{a1} = 1.26 \times 10^{-3}$$

$$HPh^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + Ph^{2-}(aq) \qquad K_{a2} = 3.10 \times 10^{-6}$$

If 0.0100 mol of phthalic acid is dissolved per liter of water, calculate the equilibrium concentrations of H_2Ph, HPh^-, Ph^{2-}, and H_3O^+.

65. A solution as initially prepared contains 0.050 mol L^{-1} of phosphate ion (PO_4^{3-}) at 25°C. Given the three acid ionization constants from Table 15.2, calculate the equilibrium concentrations of PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, H_3PO_4, and OH^-.

66. Oxalic acid ionizes in two stages in aqueous solution:

$$H_2C_2O_4(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HC_2O_4^-(aq) \qquad K_{a1} = 5.9 \times 10^{-2}$$

$$HC_2O_4^-(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + C_2O_4^{2-}(aq) \qquad K_{a2} = 6.4 \times 10^{-5}$$

Calculate the equilibrium concentrations of $C_2O_4^{2-}$, $HC_2O_4^-$, $H_2C_2O_4$, and OH^- in a 0.10 M solution of sodium oxalate ($Na_2C_2O_4$).

67. The pH of a normal raindrop is 5.60. Compute the concentrations of $H_2CO_3(aq)$, $HCO_3^-(aq)$, and $CO_3^{2-}(aq)$ in this raindrop if the total concentration of dissolved carbonates is 1.0×10^{-5} mol L^{-1}.

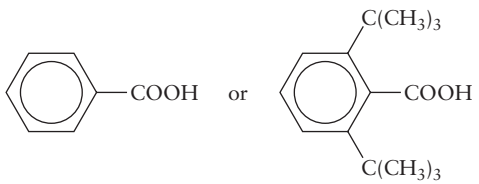
68. The pH of a drop of acid rain is 4.00. Compute the concentrations of $H_2CO_3(aq)$, $HCO_3^-(aq)$, and $CO_3^{2-}(aq)$ in the acid raindrop if the total concentration of dissolved carbonates is 3.6×10^{-5} mol L^{-1}.

Organic Acids and Bases: Structure and Reactivity

69. Use data from Table 15.4 to estimate the stabilization (in kJ per mol) associated with substituting a phenyl ($-C_6H_5$) group for one of the hydrogen atoms in methane. Assume that the effect on the pK_a enters entirely through the greater energetic stability of the conjugate base.

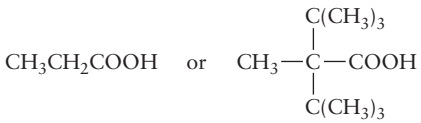
70. Use data from Table 15.4 to estimate the stabilization (in kJ per mol) associated with substituting a nitro ($-NO_2$) group for one of the hydrogen atoms in methane. Assume that the effect on the pK_a enters entirely through the greater energetic stability of the conjugate base.

71. Propionic acid, CH_3CH_2COOH, has a pK_a of 4.9. Compare this with the diprotic succinic acid, $HOOCCH_2CH_2COOH$. Will the pK_{a1} and pK_{a2} of succinic acid be larger than or smaller than 4.9?



Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

72. Predict the relative magnitudes of the pK_a's for a carboxylic acid, RCOOH, a ketone, $RCOCH_3$, and an amide, $RCONH_2$.



73. Which will be the stronger acid: benzene (C_6H_6) or cyclohexane (C_6H_{12})? Explain by using resonance Lewis structures.

74. Which will be the stronger acid: propene ($CH_2{=}CHCH_3$) or propane (C_3H_8)? Explain by using resonance Lewis structures.

75. For each of the following pairs of molecules, predict which is the stronger acid.
(a) CF_3COOH or CCl_3COOH.
(b) $CH_2FCH_2CH_2COOH$ or $CH_3CH_2CHFCOOH$
(c)

76. For each of the following pairs of molecules, predict which is the stronger acid.
(a)

(b) CI_3COOH or CCl_3COOH
(c) $CH_3CHClCH_2COOH$ or $CH_3CH_2CHClCOOH$

A Deeper Look . . . Exact Treatment of Acid–Base Equilibria

77. Thiamine hydrochloride (vitamin B_1 hydrochloride, $HC_{12}H_{17}ON_4SCl_2$) is a weak acid with $K_a = 3.4 \times 10^{-7}$. Suppose 3.0×10^{-5} g of thiamine hydrochloride is dissolved in 1.00 L of water. Calculate the pH of the resulting solution. (*Hint:* This is a sufficiently dilute solution that the autoionization of water cannot be neglected.)

78. A sample of vinegar contains 40.0 g of acetic acid (CH_3COOH) per liter of solution. Suppose 1.00 mL is removed and diluted to 1.00 L, and 1.00 mL of *that* solution is removed and diluted to 1.00 L. Calculate the pH of the resulting solution. (*Hint:* This is a sufficiently dilute solution that the autoionization of water cannot be neglected.)

79. At 25°C, 50.00 mL of a 0.1000 M solution of maleic acid, a diprotic acid whose ionization constants are $K_{a1} = 1.42 \times 10^{-2}$ and $K_{a2} = 8.57 \times 10^{-7}$, is titrated with a 0.1000 M NaOH solution. Calculate the pH at the following volumes of added base: 0, 5.00, 25.00, 50.00, 75.00, 99.90, 100.00, and 105.00 mL.

80. Quinine ($C_{20}H_{24}O_2N_2$) is a water-soluble base that ionizes in two stages, with $K_{b1} = 3.31 \times 10^{-6}$ and $K_{b2} = 1.35 \times 10^{-10}$, at 25°C. Calculate the pH during the titration of an aqueous solution of 1.622 g of quinine in 100.00 mL of water as a function of the volume of added 0.1000 M HCl solution at the following volumes: 0, 25.00, 50.00, 75.00, 99.90, 100.00, and 105.00 mL.

ADDITIONAL PROBLEMS

81. Although acetic acid is normally regarded as a weak acid, it is about 34% dissociated in a 10^{-4} M solution at 25°C. It is less than 1% dissociated in 1 M solution. Discuss this variation in degree of dissociation with dilution in terms of Le Châtelier's principle, and explain how it is consistent with the supposed constancy of equilibrium constants.

82. Suppose that a 0.10 M aqueous solution of a monoprotic acid HX has just 11 times the conductivity of a 0.0010 M aqueous solution of HX. What is the approximate dissociation constant of HX? (*Hint:* In thinking about this problem, consider what the ratio of the conductivities would be if HX were a strong acid and if HX were extremely weak, as limiting cases.)

83. The ionization constant of chloroacetic acid ($ClCH_2COOH$) in water is 1.528×10^{-3} at 0°C and 1.230×10^{-3} at 40°C. Calculate the enthalpy of ionization of the acid in water, assuming that ΔH and ΔS are constant over this range of temperature.

84. The autoionization constant of water (K_w) is 1.139×10^{-15} at 0°C and 9.614×10^{-14} at 60°C.
(a) Calculate the enthalpy of autoionization of water.

$$2\ H_2O(\ell) \rightleftharpoons H_3O^+(aq) + OH^-(aq)$$

(b) Calculate the entropy of autoionization of water.
(c) At what temperature will the pH of pure water be 7.00, from these data?

85. Calculate the concentrations of H_3O^+ and OH^- at 25°C in the following:
(a) Orange juice (pH 2.8)
(b) Tomato juice (pH 3.9)
(c) Milk (pH 4.1)
(d) Borax solution (pH 8.5)
(e) Household ammonia (pH 11.9)

86. Try to choose which of the following is the pH of a 6.44×10^{-10} M $Ca(OH)_2(aq)$ solution, without doing any written calculations.
(a) 4.81 (b) 5.11
(c) 7.00 (d) 8.89
(e) 9.19

87. $Cl_2(aq)$ reacts with $H_2O(\ell)$ as follows:

$$Cl_2(aq) + 2\ H_2O(\ell) \rightleftharpoons H_3O^+(aq) + Cl^-(aq) + HOCl(aq)$$

For an experiment to succeed, $Cl_2(aq)$ must be present, but the amount of $Cl^-(aq)$ in the solution must be minimized. For this purpose, should the pH of the solution be high, low, or neutral? Explain.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

88. Use the data in Table 15.2 to determine the equilibrium constant for the reaction

$$H_2PO_4^-(aq) + 2\ CO_3^{2-}(aq) \rightleftharpoons PO_4^{3-}(aq) + 2\ HCO_3^-(aq)$$

89. The first acid ionization constant of the oxoacid H_3PO_2 is 8×10^{-2}. What molecular structure do you predict for H_3PO_2? Will this acid be monoprotic, diprotic, or triprotic in aqueous solution?

90. Oxoacids can be formed that involve several central atoms of the same chemical element. An example is $H_3P_3O_9$, which can be written $P_3O_6(OH)_3$. (Sodium salts of these polyphosphoric acids are used as "builders" in detergents to improve their cleaning power.) In such a case, we would expect acid strength to correlate approximately with the *ratio* of the number of lone oxygen atoms to the number of central atoms (this ratio is 6:3 for $H_3P_3O_9$, for example). Rank the following in order of increasing acid strength: H_3PO_4, $H_3P_3O_9$, $H_4P_2O_6$, $H_4P_2O_7$, $H_5P_3O_{10}$. Assume that no hydrogen atoms are directly bonded to phosphorus in these compounds.

91. Urea (NH_2CONH_2) is a component of urine. It is a very weak base, having an estimated pK_b of 13.8 at room temperature.
   (a) Write the formula of the conjugate acid of urea.
   (b) Compute the equilibrium concentration of urea in a solution that contains no urea but starts out containing 0.15 mol L^{-1} of the conjugate acid of urea.

92. Exactly 1.0 L of solution of acetic acid gives the same color with methyl red as 1.0 L of a solution of hydrochloric acid. Which solution will neutralize the greater amount of 0.10 M NaOH*(aq)*? Explain.

* 93. The K_a for acetic acid drops from 1.76×10^{-5} at 25°C to 1.63×10^{-5} at 50°C. Between the same two temperatures, K_w increases from 1.00×10^{-14} to 5.47×10^{-14}. At 50°C the density of a 0.10 M solution of acetic acid is 98.81% of its density at 25°C. Will the pH of a 0.10 M solution of acetic acid in water increase, decrease, or remain the same when it is heated from 25°C to 50°C? Explain.

94. Calculate the pH of a solution that is prepared by dissolving 0.23 mol of hydrofluoric acid (HF) and 0.57 mol of hypochlorous acid (HClO) in water and diluting to 3.60 L. Also, calculate the equilibrium concentrations of HF, F^-, HClO, and ClO^-. (*Hint:* The pH will be determined by the stronger acid of this pair.)

95. For each of the following compounds, indicate whether a 0.100 M aqueous solution is acidic (pH < 7), basic (pH > 7), or neutral (pH = 7): HCl, NH_4Cl, KNO_3, Na_3PO_4, $NaCH_3COO$.

* 96. Calculate $[H_3O^+]$ in a solution that contains 0.100 mol of NH_4CN per liter.

$$NH_4^+(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + NH_3(aq) \qquad K_a = 5.6 \times 10^{-10}$$

$$HCN(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + CN^-(aq) \qquad K_a = 6.17 \times 10^{-10}$$

97. Discuss the justification for this statement: "Although one does not normally regard NH_4^+ as an acid, it is actually only slightly weaker as an acid than hydrocyanic acid, HCN, in aqueous solution."

* 98. Imagine that you want to do physiological experiments at a pH of 6.0 and the organism with which you are working is sensitive to most available materials other than a certain weak acid, H_2Z, and its sodium salts. K_{a1} and K_{a2} for H_2Z are 3×10^{-1} M and 5×10^{-7} M. You have available 1.0 M aqueous H_2Z and 1.0 M NaOH. How much of the NaOH solution should be added to 1.0 L of the acid solution to give a buffer at pH = 6.0?

99. A buffer solution is prepared by mixing 1.00 L of 0.050 M pentafluorobenzoic acid (C_6F_5COOH) and 1.00 L of 0.060 M sodium pentafluorobenzoate (NaC_6F_5COO). The K_a of this weak acid is 0.033. Determine the pH of the buffer solution.

100. A chemist needs to prepare a buffer solution with pH = 10.00 and has both Na_2CO_3 and $NaHCO_3$ in pure crystalline form. What mass of each should be dissolved in 1.00 L of solution if the combined mass of the two salts is to be 10.0 g?

101. Which of these procedures would *not* make a pH = 4.75 buffer?
   (a) Mix 50.0 mL of 0.10 M acetic acid and 50.0 mL of 0.10 M sodium acetate.
   (b) Mix 50.0 mL of 0.20 M acetic acid and 50.0 mL of 0.10 M NaOH.
   (c) Start with 50.0 mL of 0.20 M acetic acid and add a solution of strong base until the pH equals 4.75.
   (d) Start with 50.0 mL of 0.20 M HCl and add a solution of strong base until the pH equals 4.75.
   (e) Start with 100.0 mL of 0.20 M sodium acetate and add 50.0 mL of 0.20 M HCl.

102. It takes 4.71 mL of 0.0410 M NaOH to titrate a 50.00-mL sample of flat (no CO_2) GG's Cola to a pH of 4.9. At this point the addition of one more drop (0.02 mL) of NaOH raises the pH to 6.1. The only acid in GG's Cola is phosphoric acid. Compute the concentration of phosphoric acid in this cola. Assume that the 4.71 mL of base removes only the first hydrogen from the H_3PO_4; that is, assume that the reaction is

$$H_3PO_4(aq) + OH^-(aq) \longrightarrow H_2O(\ell) + H_2PO_4^-(aq)$$

* 103. Sodium carbonate exists in various crystalline forms with different amounts of water of crystallization, including Na_2CO_3, $Na_2CO_3 \cdot 10H_2O$, and others. The water of crystallization can be driven off by heating; the amount of water removed depends on the temperature and duration of heating.

A sample of $Na_2CO_3 \cdot 10H_2O$ had been heated inadvertently, and it was not known how much water had been removed. A 0.200-g sample of the solid that remained after the heating was dissolved in water, 30.0 mL of 0.100 M NaOH was added, and the CO_2 formed was removed. The solution was acidic; 6.4 mL of 0.200 M NaOH was needed to neutralize the excess acid. What fraction of the water had been driven from the $Na_2CO_3 \cdot 10H_2O$?

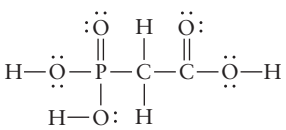
104. An aqueous solution of sodium carbonate, Na_2CO_3, is titrated with strong acid to a point at which two H^+ ions have reacted with each carbonate ion. (a) If 20.0 mL of the carbonate solution reacts with just 40.0 mL of 0.50 M acid, what is the molarity of the carbonate solution? (b) If the solution contains 5.0 percent by mass sodium carbonate, what is the density of the solution? (c) Suppose that you wanted to prepare a liter of an identical solution by starting with crystalline sodium carbonate decahydrate, $Na_2CO_3 \cdot 10H_2O$, rather than with solid Na_2CO_3 itself. How much of this substance would you need?

105. Three flasks, labeled *A*, *B*, and *C*, contained aqueous solutions of the same pH. It was known that one of the solutions was 1.0×10^{-3} M in nitric acid, one was 6×10^{-3} M in formic acid, and one was 4×10^{-2} M in the salt formed by the weak organic base aniline with hydrochloric acid ($C_6H_5NH_3Cl$). (Formic acid is monoprotic.) (a) Describe a procedure for identifying the solutions. (b) Compare qualitatively (on the basis of the preceding information) the strengths of nitric and formic acids with each other and with the acid strength of the anilinium ion, $C_6H_5NH_3^+$. (c) Show how the information given may be used to derive values for K_a for formic acid and K_b for aniline. Derive these values.

106. Novocain, the commonly used local anaesthetic, is a weak base with $K_b = 7 \times 10^{-6}$ M. (a) If you had a 0.0200 M solution of Novocain in water, what would be the approximate concentration of OH^- and the pH? (b) Suppose that you wanted to determine the concentration of Novocain in a solution that is about 0.020 M by titration with 0.020 M HCl. Calculate the expected pH at the equivalence point.

107. A 0.1000 M solution of a weak acid, HA, requires 50.00 mL of 0.1000 M NaOH to titrate it to its equivalence point. The pH of the solution is 4.50 when only 40.00 mL of the base has been added.
(a) Calculate the ionization constant K_a of the acid.
(b) Calculate the pH of the solution at the equivalence point.



108. The chief chemist of Victory Vinegar Works, Ltd., interviews two chemists for employment. He states, "Quality control requires that our high-grade vinegar contain 5.00 ± 0.01% acetic acid by mass. How would you analyze our product to ensure that it meets this specification?"

Anne Dalton says, "I would titrate a 50.00-mL sample of the vinegar with 1.000 M NaOH, using phenolphthalein to detect the equivalence point to within ±0.02 mL of base."

Charlie Cannizzarro says, "I would use a pH meter to determine the pH to ±0.01 pH units and interface it with a computer to print out the mass percentage of acetic acid."

Which candidate did the chief chemist hire? Why?

109. Phosphonocarboxylic acid

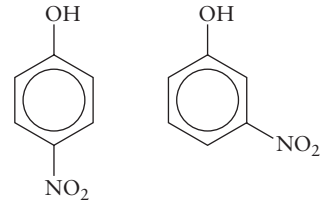
effectively inhibits the replication of the herpes virus. Structurally, it is a combination of phosphoric acid and acetic acid. It can donate three protons. The equilibrium constant values are $K_{a1} = 1.0 \times 10^{-2}$, $K_{a2} = 7.8 \times 10^{-6}$, and $K_{a3} = 2.0 \times 10^{-9}$. Enough phosphonocarboxylic acid is added to blood (pH 7.40) to make its total concentration 1.0×10^{-5} M. The pH of the blood does not change. Determine the concentrations of all four forms of the acid in this mixture.

110. Egg whites contain dissolved carbon dioxide and water, which react together to give carbonic acid (H_2CO_3). In the few days after an egg is laid, it loses carbon dioxide through its shell. Does the pH of the egg white increase or decrease during this period?

111. If you breathe too rapidly (hyperventilate), the concentration of dissolved CO_2 in your blood drops. What effect does this have on the pH of the blood?

112. A reference book states that a saturated aqueous solution of potassium hydrogen tartrate is a buffer with a pH of 3.56. Write two chemical equations that show the buffer action of this solution. (Tartaric acid is a diprotic acid with the formula $H_2C_4H_4O_6$. Potassium hydrogen tartrate is $KHC_4H_4O_6$.)

*113. Glycine, the simplest amino acid, has both an acid group and a basic group in its structure ($H_2N{-}CH_2{-}COOH$). In aqueous solution it exists predominantly as a self-neutralized species called a zwitterion ($H_3\overset{+}{N}{-}CH_2{-}COO^-$). The zwitterion therefore behaves both as an acid and as a base, according to the equilibria at 25°C:



$$H_3\overset{+}{N}{-}CH_2{-}COO^-(aq) + H_2O(\ell) \rightleftharpoons H_2N{-}CH_2{-}COO^-(aq) + H_3O^+(aq) \qquad K_a = 1.7 \times 10^{-10}$$

$$H_3\overset{+}{N}{-}CH_2{-}COO^-(aq) + H_2O(\ell) \rightleftharpoons H_3\overset{+}{N}{-}CH_2{-}COOH(aq) + OH^-(aq) \qquad K_b = 2.2 \times 10^{-12}$$

Calculate the pH of a 0.10 M aqueous solution of glycine at 25°C. (*Hint:* You may need to take account of the autoionization of water.)

114. Use the effect of steric hindrance to predict whether a tertiary amine should be a stronger base than ammonia in aqueous solution. (*Hint:* Assume that the effect of solvation is greater for ions than for neutral species.)

*115. Consider the two following nitrophenol structures:

p-nitrophenol *m*-nitrophenol

Predict which will be the stronger acid. (*Hint:* Consider possible resonance structures analogous to those given in the text for phenol.)

CUMULATIVE PROBLEMS

116. Use the data from Table 15.1, together with Le Châtelier's principle, to decide whether the autoionization of water is exothermic or endothermic.

117. Baking soda (sodium hydrogen carbonate, $NaHCO_3$) is used in baking because it reacts with acids in foods to form carbonic acid (H_2CO_3), which in turn decomposes to water and carbon dioxide. In a batter the carbon dioxide appears as gas bubbles that cause the bread or cake to rise.
   (a) A rule of thumb in cooking is that $\frac{1}{2}$ teaspoon baking soda is neutralized by 1 cup of sour milk. The acid component of sour milk is lactic acid ($HC_3H_5O_3$). Write an equation for the neutralization reaction.
   (b) If the density of baking soda is 2.16 g cm^{-3}, calculate the concentration of lactic acid in the sour milk, in moles per liter. Take 1 cup = 236.6 mL = 48 teaspoons.
   (c) Calculate the volume of carbon dioxide that is produced at 1 atm pressure and 350°F (177°C) from the reaction of $\frac{1}{2}$ teaspoon of baking soda.

118. Boric acid, $B(OH)_3$, is an acid that acts differently from the usual Brønsted–Lowry acids. It reacts with water according to

$$B(OH)_3(aq) + 2\ H_2O(\ell) \rightleftharpoons B(OH)_4^-(aq) + H_3O^+(aq) \qquad K_a = 5.8 \times 10^{-10}$$

   (a) Draw Lewis structures for $B(OH)_3$ and $B(OH)_4^-$. Can these be described as Lewis acids or Lewis bases?
   (b) Calculate the pH of a 0.20 M solution of $B(OH)_3(aq)$.

119. At 40°C and 1.00 atm pressure, a gaseous monoprotic acid has a density of 1.05 g L^{-1}. After 1.85 g of this gas is dissolved in water and diluted to 450 mL, the pH is measured to be 5.01. Determine the K_a of this acid and use Table 15.2 to identify it.

120. At 25°C, the Henry's law constant for carbon dioxide dissolved in water is 1.8×10^3 atm. Calculate the pH of water saturated with $CO_2(g)$ at 25°C in Denver, where the barometric pressure is 0.833 atm.

Sodium acetate crystals ($NaC_2H_3O_2$) form quickly in a supersaturated solution when a small speck of solute is added.

Dissolution and precipitation are chemical reactions by which solids pass into and out of solution. A brief introduction and several examples appear in Section 11.2. These reactions involve equilibria between dissolved species and species in the solid state, and so are described by the general principles of chemical equilibrium in Chapter 14. These reactions rank alongside acid–base reactions in practical importance. The dissolution and reprecipitation of solids permit chemists to isolate single products from reaction mixtures and to purify impure solid samples. Understanding the mechanisms of these reactions helps engineers prevent formation of deposits in water processing and distribution systems and helps doctors

reduce the incidence of painful kidney stones. Dissolution and precipitation control the formation of mineral deposits and profoundly affect the ecologies of rivers, lakes, and oceans.

The theme of this chapter is to understand how to manipulate solubility equilibria in order to control the maximum concentration of particular ionic solids in the solution. In the first section we present the general aspects of the equilibria that govern the extent of dissolution and precipitation reactions. In the remaining sections we develop the quantitative descriptions for these equilibria, including the effects of adding more solutes, adding acids or bases, and adding ligands that can bind to dissolved metal ions to form complex ions.

16.1 THE NATURE OF SOLUBILITY EQUILIBRIA

General Features of Solubility Equilibria

Solubility equilibria resemble the equilibria between volatile liquids (or solids) and their vapors in a closed container. In both cases, particles from a condensed phase tend to escape and spread through a larger, but limited, volume. In both cases, equilibrium is a dynamic compromise in which the rate of escape of particles from the condensed phase is equal to their rate of return. In a vaporization–condensation equilibrium, we assumed that the vapor above the condensed phase was an ideal gas. The analogous starting assumption for a dissolution–precipitation reaction is that the solution above the undissolved solid is an ideal solution. A solution in which sufficient solute has been dissolved to establish a dissolution–precipitation equilibrium between the solid substance and its dissolved form is called a **saturated solution.**

Le Châtelier's principle applies to these equilibria, as it does to all equilibria. One way to exert a stress on a solubility equilibrium is to change the amount of solvent. Adding solvent reduces the concentration of dissolved substance; more solid then tends to dissolve to restore the concentration of the dissolved substance to its equilibrium value. If an excess of solvent is added so that all of the solid dissolves, then obviously the solubility equilibrium ceases to exist and the solution is **unsaturated.** In a vaporization–condensation equilibrium, this corresponds to the complete evaporation of the condensed phase. Removing solvent from an already saturated solution forces additional solid to precipitate in order to maintain a constant concentration. A volatile solvent is often removed by simply letting a solution stand uncovered until the solvent evaporates. When sufficient solvent has evaporated, the solid forms as crystals on the bottom and sides of the container (Fig. 16.1).

Cengage Learning/Leon Lewandowski

FIGURE 16.1 The beaker contains an aqueous solution of K_2PtCl_4, a substance used as a starting material in the synthesis of anticancer drugs. It is loosely covered to keep out dust and allowed to stand. As the water evaporates, the solution becomes saturated and deposits solid K_2PtCl_4 in the form of long, needle-like red crystals.

Controlled precipitation by manipulating solubility is a widely used technique for purifying reaction products in synthetic chemistry. Side reactions can generate significant amounts of impurities; other impurities may enter with the starting materials, and catalysts (introduced to increase the reaction rates) must be removed from the final products. Running a reaction may take only hours, but the *workup* (separation of crude product) and subsequent purification may require weeks. **Recrystallization,** one of the most powerful methods for purifying solids, relies on differences between the solubilities of the desired substance and its contaminants. An impure product is dissolved and reprecipitated, repeatedly if necessary, with careful control of the factors that influence solubility. Manipulating solubility requires an understanding of the equilibria that exist between an undissolved substance and its solution.

In recrystallization a solution begins to deposit a compound when it is brought to the point of saturation with respect to that compound. In dissolution the solvent attacks the solid and **solvates** it at the level of individual particles. In precipitation

the reverse occurs: Solute-to-solute attractions are reestablished as the solute leaves the solution. Often, solute-to-solvent attractions persist right through the process of precipitation, and solvent incorporates itself into the solid. When lithium sulfate (Li_2SO_4) precipitates from water, it brings with it into the solid one molecule of water per formula unit:

$$2\ Li^+(aq) + SO_4^{2-}(aq) + H_2O(\ell) \longrightarrow Li_2SO_4 \cdot H_2O(s)$$

Such loosely bound solvent is known as solvent of crystallization (Fig. 2.2). Dissolving and then reprecipitating a compound may thus furnish material that has a different chemical formula and a different mass. Consequently, recrystallization processes for purification of reaction products must be planned carefully.

Dissolution–precipitation reactions frequently come to equilibrium slowly. Days or even weeks of shaking a solid in contact with a solvent may be required before the solution becomes saturated. Moreover, solutions sometimes become **supersaturated,** a state in which the concentration of dissolved solid exceeds its equilibrium value and the solid remains in solution rather than form a precipitate. This state is analogous to superheating a pure liquid above its boiling point or supercooling it below its freezing point. A supersaturated solution may persist for months or years and require extraordinary measures to be brought to equilibrium by precipitating the solid, although thermodynamics shows that the possibility for equilibrium is there all along. Precipitation from a supersaturated solution is a spontaneous process, but its rate may be slow. The generally sluggish approach to equilibrium in dissolution–precipitation reactions is quite the opposite of the rapid rates at which acid–base reactions reach equilibrium.

The Solubility of Ionic Solids

The **solubility** of a substance in a solvent is defined as the greatest amount (expressed either in grams or in moles) that will dissolve in equilibrium in a specified volume of solvent at a particular temperature. Although solvents other than water are used in many applications, aqueous solutions are the most important and are the exclusive concern here. Salts show a wide range of solubilities in water (Fig. 16.2). Silver perchlorate ($AgClO_4$) dissolves to the remarkable extent of about 5570 g (or almost 27 mol) per liter of water at 25°C, but at the same temperature only about 0.0018 g (or 1.3×10^{-5} mol) of silver chloride (AgCl) dissolves per liter of water. Many salts with even lower solubilities are known. Solubilities often de-

Cengage Learning/Leon Lewandowski

FIGURE 16.2 Vastly different quantities of different compounds will dissolve in 1 L of water at 20°C. Clockwise from the front are borax, potassium permanganate, lead(II) chloride, sodium phosphate decahydrate, calcium oxide, and potassium dichromate.

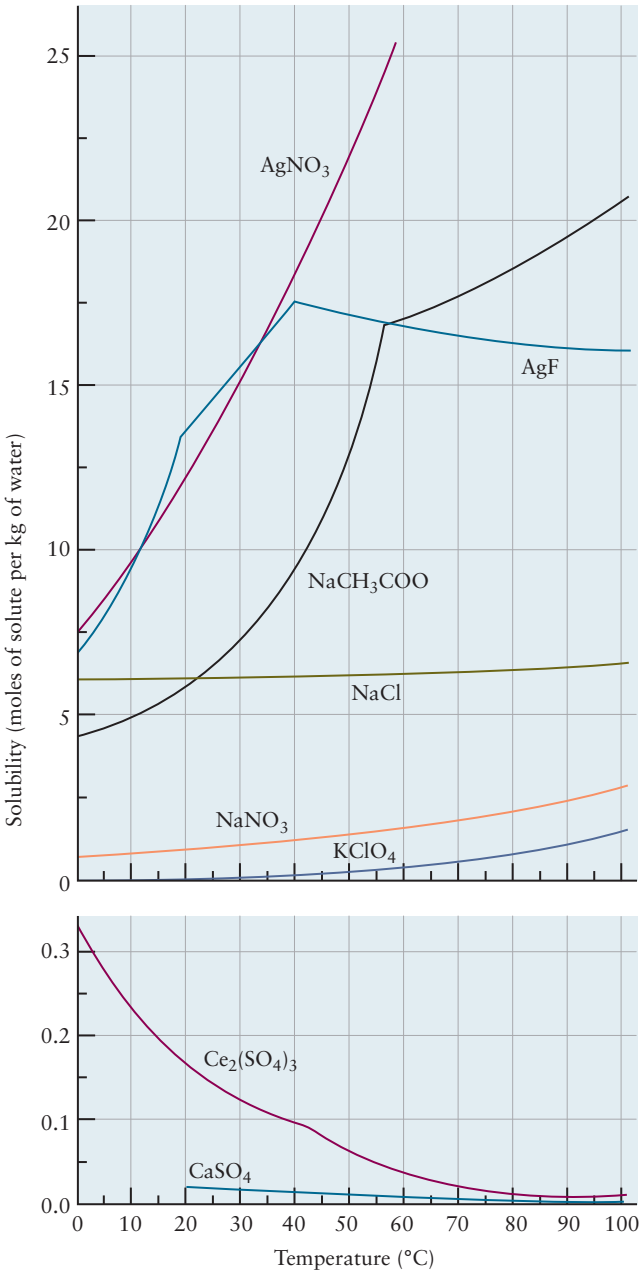

FIGURE 16.3 Most solubilities increase with increasing temperature, but some decrease. Note that the changes are not always smooth because different solid hydrates form over different temperature ranges.

pend strongly on temperature (Fig. 16.3). Most dissolution reactions for ionic solids are endothermic (heat is absorbed), so by Le Châtelier's principle the solubility increases with increasing temperature. Those dissolution reactions that are exothermic (such as for $CaSO_4$) show the opposite behavior.

Although all ionic compounds dissolve to some extent in water, those having solubilities (at 25°C) of less than 0.1 g L^{-1} are called *insoluble*. Those having solubilities of more than 10 g L^{-1} are *soluble,* and the intermediate cases (0.1 to 10 g L^{-1}) are said to be *slightly soluble*. Fortunately, it is not necessary to memorize long lists of solubility data. Table 16.1 lists some generalizations concerning groups of salts and gives enough factual data to support good predictions about precipitation or dissolution in thousands of situations of practical importance. Knowing the solubilities of ionic substances, even in these qualitative terms, provides a way to predict the courses of numerous reactions. For example, when a solution of KI is added to one of $Pb(NO_3)_2$, K^+ and NO_3^- ions are brought into contact, as are Pb^{2+} and I^- ions. From the table, KNO_3 is a soluble salt but PbI_2 is insoluble; therefore, a precipitate of PbI_2 will appear (Fig. 16.4).

© Cengage Learning/Charles D. Winters

FIGURE 16.4 A yellow precipitate of lead iodide forms when a drop of KI solution is added to a solution of $Pb(NO_3)_2$.

TABLE 16.1

Solubilities of Ionic Compounds in Water

Anion	Soluble†	Slightly Soluble	Insoluble
NO_3^- (nitrate)	All	—	—
CH_3COO^- (acetate)	Most	—	$Be(CH_3COO)_2$
ClO_3^- (chlorate)	All	—	—
ClO_4^- (perchlorate)	Most	$KClO_4$	—
F^- (fluoride)	Group I, AgF, BeF_2	SrF_2, BaF_2, PbF_2	MgF_2, CaF_2
Cl^- (chloride)	Most	$PbCl_2$	AgCl, Hg_2Cl_2
Br^- (bromide)	Most	$PbBr_2$, $HgBr_2$	AgBr, Hg_2Br_2
I^- (iodide)	Most	—	AgI, Hg_2I_2, PbI_2, HgI_2
SO_4^{2-}(sulfate)	Most	$CaSO_4$, Ag_2SO_4, Hg_2SO_4	$SrSO_4$, $BaSO_4$, $PbSO_4$
S^{2-} (sulfide)	Groups I and II, $(NH_4)_2S$	—	Most
CO_3^{2-}(carbonate)	Group I, $(NH_4)_2CO_3$	—	Most
SO_3^{2-}(sulfite)	Group I, $(NH_4)_2SO_3$	—	Most
PO_4^{3-}(phosphate)	Group I, $(NH_4)_3PO_4$	—	Most
OH^- (hydroxide)	Group I, $Ba(OH)_2$	$Sr(OH)_2$, $Ca(OH)_2$	Most

†Soluble compounds are defined as those that dissolve to the extent of 10 or more grams per liter; slightly soluble compounds, 0.1 to 10 grams per liter; and insoluble compounds, less than 0.1 gram per liter at room temperature.

16.2 IONIC EQUILIBRIA BETWEEN SOLIDS AND SOLUTIONS

When an ionic solid such as CsCl dissolves in water, it breaks up into ions that move apart from each other and become solvated by water molecules (*aquated*, or *hydrated;* Fig. 16.5). The aquated ions are shown in the chemical equation for the solubility equilibrium. Thus,

$$CsCl(s) \rightleftharpoons Cs^+(aq) + Cl^-(aq)$$

shows that the dissolved particles are ions. For a highly soluble salt (such as CsCl), the concentrations of the ions in a saturated aqueous solution are so large that the solution is nonideal. There is much association among the ions in solution, resulting in temporary pairs of oppositely charged ions and in larger clusters as well. In such cases the simple type of equilibrium expression developed in Sections 14.2 and 14.3 does not apply; therefore, we restrict our attention to sparingly soluble and "insoluble" salts, for which the concentrations in a saturated solution are 0.1 mol L^{-1} or less—low enough that the interactions among the solvated ions are relatively small.

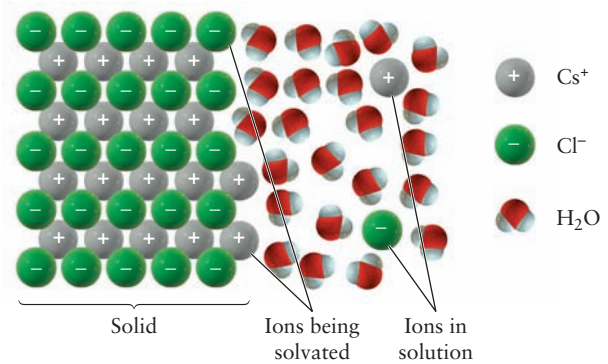

FIGURE 16.5 The dissolution of the ionic solid CsCl in water. Note the different solvation patterns of positive and negative ions. Water molecules arrange themselves so that the atoms with partial negative charges (oxygen) point toward the positively charged Cs^+ ions. The water molecules form hydrogen bonds to the Cl^- anions, so the O—H—Cl atoms lie nearly in a straight line.

The sparingly soluble salt silver chloride, for example, establishes the following equilibrium when placed in water:

$$AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq)$$

The equilibrium law for this reaction (written by following the rules for heterogeneous equilibria from Sections 14.2 and 14.3) is

$$[Ag^+][Cl^-] = K_{sp}$$

where the subscript "sp," standing for **"solubility product,"** distinguishes the K as referring to the dissolution of a slightly soluble ionic solid in water. At 25°C, K_{sp} has the numerical value 1.6×10^{-10} for silver chloride. In the AgCl solubility product expression, the concentrations of the two ions produced are raised to the first power because their coefficients are 1 in the chemical equation. Solid AgCl does not appear in the equilibrium expression; the amount of pure solid AgCl does not affect the equilibrium as long as *some* is present. If no solid is present, the system is not in a state of equilibrium, and the product of the two ion concentrations does not obey the solubility equilibrium expression.

Solubility and K_{sp}

The molar solubility of a salt in water is not the same as its solubility product constant, but a simple relation often exists between them. For example, let's define S

TABLE 16.2

Solubility Product Constants K_{sp} at 25°C

Iodates	
$AgIO_3$	$[Ag^+][IO_3^-] = 3.1 \times 10^{-8}$
$CuIO_3$	$[Cu^+][IO_3^-] = 1.4 \times 10^{-7}$
$Pb(IO_3)_2$	$[Pb^{2+}][IO_3^-]^2 = 2.6 \times 10^{-13}$
Carbonates

as the molar solubility of AgCl(*s*) in water at 25°C. Then, from stoichiometry, $[Ag^+] = [Cl^-] = S$ is the molarity of either ion at equilibrium. Hence,

$$[Ag^+][Cl^-] = S^2 = K_{sp} = 1.6 \times 10^{-10}$$

Taking the square roots of both sides of the equation gives

$$S = 1.26 \times 10^{-5} \text{ M}$$

which rounds off to 1.3×10^{-5} M. This is the molar solubility of AgCl in water. It is converted to a gram solubility by multiplying by the molar mass of AgCl:

$$(1.26 \times 10^{-5} \text{ mol L}^{-1})(143.3 \text{ g mol}^{-1}) = 1.8 \times 10^{-3} \text{ g L}^{-1}$$

Therefore, 1.8×10^{-3} g of AgCl dissolves per liter of water at 25°C.

Solubility product constants (like solubilities) can be sensitive to temperature. At 100°C the K_{sp} for silver chloride is 2.2×10^{-8}; hot water dissolves about 12 times as much silver chloride as does water at 25°C. Refer to Table 16.2 for the solubility product constants at 25°C of a number of important sparingly soluble salts.

EXAMPLE 16.1

The K_{sp} of calcium fluoride is 3.9×10^{-11}. Calculate the concentrations of calcium and fluoride ions in a saturated solution of CaF_2 at 25°C, and determine the solubility of CaF_2 in grams per liter.

Solution

The solubility equilibrium is

$$CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2\ F^-(aq)$$

and the expression for the solubility product is

$$[Ca^{2+}][F^-]^2 = K_{sp}$$

The concentration of fluoride ion is squared because it has a coefficient of 2 in the chemical equation.

If S mol of CaF_2 dissolves in 1 L, the equilibrium concentration of Ca^{2+} will be $[Ca^{2+}] = S$. The concentration of F^- will be $[F^-] = 2S$, because each mole of CaF_2 produces *two* moles of fluoride ions. Therefore,

$$[Ca^{2+}][F^-]^2 = S \times (2S)^2 = 4S^3 = K_{sp} = 3.9 \times 10^{-11}$$

Solving for S^3 gives

$$S^3 = \tfrac{1}{4}(3.9 \times 10^{-11})$$

Taking the cube roots of both sides of this equation gives

$$S = 2.1 \times 10^{-4}$$

The equilibrium concentrations are therefore

$$[Ca^{2+}] = S = 2.1 \times 10^{-4} \text{ M}$$

$$[F^-] = 2S = 4.3 \times 10^{-4} \text{ M}$$

Because the molar mass of CaF_2 is 78.1 g mol^{-1}, the gram solubility is

$$\text{gram solubility} = (2.1 \times 10^{-4} \text{ mol L}^{-1})(78.1 \text{ g mol}^{-1}) = 0.017 \text{ g L}^{-1}$$

It is possible to reverse the procedure just outlined, of course, and determine the value of K_{sp} from measured solubilities, as the following example illustrates.

EXAMPLE 16.2

Silver chromate (Ag_2CrO_4) is a red solid that dissolves in water to the extent of 0.029 g L^{-1} at 25°C. Estimate its K_{sp} and compare your estimate with the value in Table 16.2.

Solution

The molar solubility is calculated from the gram solubility and the molar mass of silver chromate (331.73 g mol^{-1}):

$$\text{molar solubility} = \frac{0.029 \text{ g L}^{-1}}{331.73 \text{ g mol}^{-1}} = 8.74 \times 10^{-5} \text{ mol L}^{-1}$$

An extra significant digit is carried in this intermediate result to avoid round-off errors. Because each mole of Ag_2CrO_4 that dissolves gives *two* moles of silver ion, the concentration of $Ag^+(aq)$ is

$$[Ag^+] = 2 \times 8.74 \times 10^{-5} \text{ M} = 1.75 \times 10^{-4} \text{ M}$$

and that of CrO_4^{2-} is simply 8.74×10^{-5} M. The solubility product constant is then

$$K_{sp} = [Ag^+]^2[CrO_4^{2-}] = (1.75 \times 10^{-4})^2 \times (8.74 \times 10^{-5})$$
$$= 2.7 \times 10^{-12}$$

This estimate is about 42% greater than the tabulated value, 1.9×10^{-12}.

Related Problems: 13, 14, 15, 16

Computing K_{sp} from a solubility and solubility from K_{sp} is valid if the solution is ideal and if there are no side reactions that reduce the concentrations of the ions after they enter solution. If such reactions are present, they cause higher solubilities than are predicted from the K_{sp} expression. For example, the solubility computed for $PbSO_4(s)$ at 25°C from its K_{sp} is 0.032 g L^{-1}, whereas that measured experimentally is 0.0425 g L^{-1}. The difference is caused by the presence of species other than $Pb^{2+}(aq)$ in solution, such as $PbOH^+(aq)$. Further discussion of these side reactions is deferred to Section 16.5.

16.3 PRECIPITATION AND THE SOLUBILITY PRODUCT

So far, we have considered only cases in which a single slightly soluble salt attains equilibrium with its component ions in water. The relative concentrations of the cations and anions in such solutions echo their relative numbers of moles in the original salt. Thus, when AgCl is dissolved, equal numbers of moles of $Ag^+(aq)$ and $Cl^-(aq)$ ions result, and when Ag_2SO_4 is dissolved, twice as many moles of $Ag^+(aq)$ ions as $SO_4^{2-}(aq)$ are produced. A solubility product relationship such as

$$[Ag^+][Cl^-] = K_{sp}$$

is more general than this, however, and continues in force even if the relative number of moles of the two ions in solution differ from those in the pure solid compound. Such a situation often results when two solutions are mixed to give a precipitate or when another salt is present that contains an ion common to the salt under consideration.

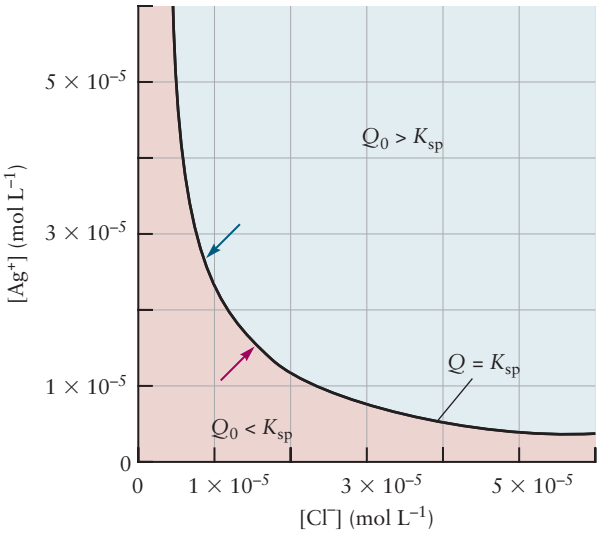

FIGURE 16.6 Some solid silver chloride is in contact with a solution containing $Ag^+(aq)$ and $Cl^-(aq)$ ions. If a solubility equilibrium exists, then the product Q of the concentrations of the ions $[Ag^+] \times [Cl^-]$ is a constant, K_{sp} (curved line). When Q exceeds K_{sp}, solid silver chloride tends to precipitate until equilibrium is attained. When Q is less than K_{sp}, additional solid tends to dissolve. If no solid is present, Q remains less than K_{sp}. The red and blue arrows represent the path toward equilibrium for a 1:1 salt like AgCl; the system moves along a path with slope = 1.

Precipitation from Solution

Suppose a solution is prepared by mixing one soluble salt, such as $AgNO_3$, with a solution of a second, such as NaCl. Will a precipitate of very slightly soluble silver chloride form? The answer is found by examining the reaction quotient Q that was defined in Section 14.6. The initial reaction quotient Q_0, when the mixing of the solutions is complete but before any reaction occurs, is

$$Q_0 = [Ag^+]_0[Cl^-]_0$$

If $Q_0 < K_{sp}$, no solid silver chloride can appear. On the other hand, if $Q_0 > K_{sp}$, solid silver chloride precipitates until the reaction quotient Q reaches K_{sp} (Fig. 16.6).

EXAMPLE 16.3

An emulsion of silver chloride for photographic film is prepared by adding a soluble chloride salt to a solution of silver nitrate. Suppose 500 mL of a solution of $CaCl_2$ with a chloride ion concentration of 8.0×10^{-6} M is added to 300 mL of a 0.0040 M solution of $AgNO_3$. Will a precipitate of $AgCl(s)$ form when equilibrium is reached?

Solution

The "initial concentrations" to be used in calculating Q_0 are those *before* reaction but *after* dilution through mixing the two solutions. The initial concentration of $Ag^+(aq)$ after dilution from 300 mL to 800 mL of solution is

$$[Ag^+]_0 = 0.00400 \text{ M} \times \left(\frac{300 \text{ mL}}{800 \text{ mL}}\right) = 0.0015 \text{ M}$$

and that of $Cl^-(aq)$ is

$$[Cl^-]_0 = 8.0 \times 10^{-6} \text{ M} \times \left(\frac{500 \text{ mL}}{800 \text{ mL}}\right) = 5.0 \times 10^{-6} \text{ M}$$

The initial reaction quotient is

$$Q_0 = [Ag^+]_0[Cl^-]_0 = (0.0015)(5.0 \times 10^{-6}) = 7.5 \times 10^{-9}$$

Because $Q_0 > K_{sp}$, a precipitate of silver chloride appears at equilibrium, although there may be too little to detect visually. Another possible precipitate, calcium nitrate, is far too soluble to form in this experiment (see Table 16.1).

The equilibrium concentrations of ions after the mixing of two solutions to give a precipitate are most easily calculated by supposing that the reaction first goes to completion (consuming one type of ion) and that subsequent dissolution of the solid restores some of that ionic species to solution—just the approach used in Example 15.11 for the addition of a strong acid to a buffer solution.

EXAMPLE 16.4

Calculate the equilibrium concentrations of silver and chloride ions resulting from the precipitation reaction of Example 16.3.

Solution

In this case the silver ion is clearly in excess; therefore, the chloride ion is the limiting reactant. If all of it were used up to make solid AgCl, the concentration of the remaining silver ion would be

$$[Ag^+] = 0.0015 - 5.0 \times 10^{-6} = 0.0015 \text{ M}$$

Set up the equilibrium calculation as

	$AgCl(s) \rightleftharpoons$	$Ag^+(aq)$ +	$Cl^-(aq)$
Initial concentration (M)		0.0015	0
Change in concentration (M)		$+y$	$+y$
Equilibrium concentration (M)		$0.0015 + y$	y

so that the equilibrium expression is

$$(0.0015 + y)y = K_{sp} = 1.6 \times 10^{-10}$$

This quadratic equation can be solved using the quadratic formula function on your calculator but *only* if it carries ten significant figures. It can be solved more easily by making the approximation that y is much smaller than 0.0015; the equation therefore simplifies to

$$0.0015y \approx 1.6 \times 10^{-10}$$

$$y \approx 1.1 \times 10^{-7} \text{ M} = [Cl^-]$$

The assumption about the size of y was justified. The concentration of silver ion is

$$[Ag^+] = 0.0015 \text{ M}$$

Related Problems: 21, 22, 23, 24

The Common-Ion Effect

Suppose a small amount of NaCl(*s*) is added to a saturated solution of AgCl. What happens? Sodium chloride is quite soluble in water and dissolves to form $Na^+(aq)$ and $Cl^-(aq)$ ions, raising the concentration of chloride ion. The quantity $Q_0 = [Ag^+][Cl^-]$ then exceeds the K_{sp} of silver chloride, and silver chloride precipitates until the concentrations of $Ag^+(aq)$ and $Cl^-(aq)$ are sufficiently reduced that the solubility product expression once again is satisfied.

The same equilibrium may be approached from the other direction. The amount of AgCl(*s*) that can dissolve in a solution of sodium chloride is less than the amount that could dissolve in the same volume of pure water. Because $[Ag^+][Cl^-] = K_{sp}$, a graph of the equilibrium concentration of silver ion against chloride concentration has the form of a hyperbola (Fig. 16.7). The presence of excess $Cl^-(aq)$ reduces the concentration of $Ag^+(aq)$ permitted, and the solubil-

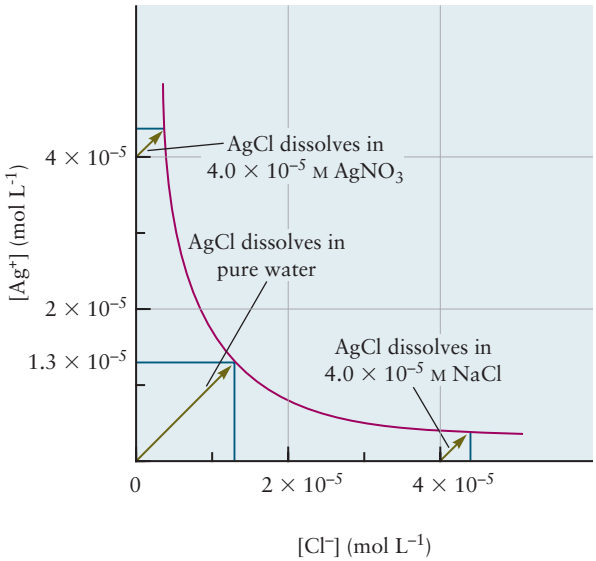

FIGURE 16.7 The presence of a dissolved common ion reduces the solubility of a salt in solution. As the AgCl dissolves, the concentrations of the ions follow the paths shown by the green arrows until they reach the red equilibrium curve. The molar solubilities are proportional to the lengths of the blue lines: 1.3×10^{-5} mol L^{-1} for AgCl in pure water, but only 0.37×10^{-5} mol L^{-1} in either 4.0×10^{-5} M $AgNO_3$ or 4.0×10^{-5} M NaCl.

ity of AgCl(*s*) is reduced. In the same way, the prior presence of $Ag^+(aq)$ in the solvent (for example, when an attempt is made to dissolve AgCl in water that already contains $AgNO_3$) reduces the amount of $Cl^-(aq)$ permitted at equilibrium and also reduces the solubility of AgCl. This is referred to as the **common-ion effect:** If the solution and the solid salt to be dissolved in it have an ion in common, then the solubility of the salt is depressed.

Let's examine the quantitative consequences of the common-ion effect. Suppose an excess of AgCl(*s*) is added to 1.00 L of a 0.100 M NaCl solution and the solubility is again determined. If *S* mol of AgCl dissolves per liter, the concentration of $Ag^+(aq)$ will be *S* mol L^{-1} and that of $Cl^-(aq)$ will be

$$[Cl^-] = 0.100 + S$$

because the chloride ion comes from two sources: the 0.100 M NaCl and the dissolution of AgCl. The expression for the solubility product is written as

$$[Ag^+][Cl^-] = S(0.100 + S) = K_{sp} = 1.6 \times 10^{-10}$$

The solubility of AgCl(*s*) in this solution must be smaller than it is in pure water, which is much smaller than 0.100. That is,

$$S < 1.3 \times 10^{-5} \ll 0.100$$

Thus, (0.100 + *S*) can be approximated by 0.100 (as in Example 16.4), giving

$$(0.100)S \approx 1.6 \times 10^{-10}$$

$$S \approx 1.6 \times 10^{-9}$$

This is indeed much smaller than 0.100, so the approximation was a very good one. Therefore, at equilibrium,

$$[Ag^+] = S = 1.6 \times 10^{-9} \text{ M}$$

$$[Cl^-] = 0.100 \text{ M}$$

The gram solubility of AgCl in this example is

$$(1.6 \times 10^{-9} \text{ mol L}^{-1})(143.3 \text{ g mol}^{-1}) = 2.3 \times 10^{-7} \text{ g L}^{-1}$$

The solubility of AgCl in 0.100 M NaCl is lower than that in pure water by a factor of about 8000.

EXAMPLE 16.5

What is the gram solubility of $CaF_2(s)$ in a 0.100 M solution of NaF?

Solution

Again, the molar solubility is denoted by S. The only source of the $Ca^{2+}(aq)$ in the solution at equilibrium is the dissolution of CaF_2, whereas the $F^-(aq)$ has two sources, the CaF_2 and the NaF. Hence,

	$CaF_2(s) \rightleftharpoons Ca^{2+}(aq)$	+	$2\ F^-(aq)$
Initial concentration (M)	0		0.100
Change in concentration (M)	$+S$		$+2S$
Equilibrium concentration (M)	S		$0.100 + 2S$

If $0.100 + 2S$ is approximated as 0.100, then

$$[Ca^{2+}][F^-]^2 = K_{sp}$$

$$S(0.100)^2 = 3.9 \times 10^{-11}$$

$$S = 3.9 \times 10^{-9}$$

Clearly,

$$2S = 7.8 \times 10^{-9} \ll 0.100$$

so the assumption was justified. The gram solubility of CaF_2 is

$$(3.9 \times 10^{-9}\ \text{mol L}^{-1})(78.1\ \text{g mol}^{-1}) = 3.0 \times 10^{-7}\ \text{g L}^{-1}$$

and the solubility in this case is reduced by a factor of 50,000.

Related Problems: 25, 26, 27, 28

16.4 THE EFFECTS OF pH ON SOLUBILITY

Some solids are only weakly soluble in water but dissolve readily in acidic solutions. Copper and nickel sulfides from ores, for example, can be brought into solution with strong acids, a fact that aids greatly in the separation and recovery of these valuable metals in their elemental forms. The effect of pH on solubility is shown dramatically in the damage done to buildings and monuments by acid precipitation (Fig. 16.8). Both marble and limestone are made up of small crystals of calcite ($CaCO_3$), which dissolves to only a limited extent in "natural" rain (with a pH of about 5.6) but dissolves much more extensively as the rainwater becomes more acidic. The reaction

$$CaCO_3(s) + H_3O^+(aq) \longrightarrow Ca^{2+}(aq) + HCO_3^-(aq) + H_2O(\ell)$$

causes this increase. This section examines the role of pH in solubility.

Solubility of Hydroxides

One direct effect of pH on solubility occurs with the metal hydroxides. The concentration of OH^- appears explicitly in the expression for the solubility product of such compounds. Thus, for the dissolution of $Zn(OH)_2(s)$,

$$Zn(OH)_2(s) \rightleftharpoons Zn^{2+}(aq) + 2\ OH^-(aq)$$

the solubility product expression is

$$[Zn^{2+}][OH^-]^2 = K_{sp} = 4.5 \times 10^{-17}$$

FIGURE 16.8 The calcium carbonate in marble and limestone is very slightly soluble in neutral water. Its solubility is much greater in acidic water. Objects carved of these materials dissolve relatively rapidly in areas where rain, snow, or fog is acidified from air pollution. Shown here is the damage to a marble statue of George Washington between 1935 (left) and 1994 (right).

As the solution is made more acidic, the concentration of hydroxide ion decreases, causing an increase in the concentration of $Zn^{2+}(aq)$ ion. Zinc hydroxide is thus more soluble in acidic solution than in pure water.

EXAMPLE 16.6

Compare the solubility of $Zn(OH)_2$ in pure water with that in a solution buffered at pH 6.00.

Solution

In pure water the usual solubility product calculation applies:

$$[Zn^{2+}] = S \qquad [OH^-] = 2S$$

$$S(2S)^2 = 4S^3 = K_{sp} = 4.5 \times 10^{-17}$$

$$S = 2.2 \times 10^{-6}\ \text{M} = [Zn^{2+}]$$

so the solubility is 2.2×10^{-6} mol L^{-1}, or 2.2×10^{-4} g L^{-1}. Using

$$[OH^-] = 2S = 4.5 \times 10^{-6}\ \text{M}$$

the resulting solution is found to have pH 8.65.

In the second case it is assumed that the solution is buffered sufficiently that the pH remains 6.00 after dissolution of the zinc hydroxide. Then

$$[OH^-] = 1.0 \times 10^{-8}\ \text{M}$$

$$[Zn^{2+}] = \frac{K_{sp}}{[OH^-]^2} = \frac{4.5 \times 10^{-17}}{(1.0 \times 10^{-8})^2} = 0.45\ \text{M}$$

so that 0.45 mol L^{-1}, or 45 g L^{-1}, should dissolve in this case. When ionic concentrations are this high, the simple form of the solubility expression will likely break down, but the qualitative conclusion is still valid: $Zn(OH)_2$ is far more soluble at pH 6.00 than in pure water.

Solubility of Salts of Bases

Metal hydroxides can be described as salts of a strong base, the hydroxide ion. The solubility of salts in which the anion is a different weak or strong base is also affected by pH. For example, consider a solution of a slightly soluble fluoride, such as calcium fluoride. The solubility equilibrium is

$$CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2\ F^-(aq) \qquad K_{sp} = 3.9 \times 10^{-11}$$

As the solution is made more acidic, some of the fluoride ion reacts with hydronium ion through

$$H_3O^+(aq) + F^-(aq) \rightleftharpoons HF(aq) + H_2O(\ell)$$

Because this is just the reverse of the acid ionization of HF, its equilibrium constant is the reciprocal of K_a for HF, or $1/(3.5 \times 10^{-4}) = 2.9 \times 10^3$. As acid is added, the concentration of fluoride ion is reduced, so the calcium ion concentration must increase to maintain the solubility product equilibrium for CaF_2. As a result, the solubility of fluoride salts increases in acidic solution. The same applies to other ionic substances in which the anion is a weak or a strong base. By contrast, the solubility of a salt such as AgCl is only very slightly affected by a decrease in pH. The reason is that HCl is a strong acid, so Cl^- is ineffective as a base. The reaction

$$Cl^-(aq) + H_3O^+(aq) \longrightarrow HCl(aq) + H_2O(\ell)$$

occurs to a negligible extent in acidic solution.

16.5 COMPLEX IONS AND SOLUBILITY

Many transition-metal ions form **coordination complexes** in solution or in the solid state; these consist of a metal ion surrounded by a group of anions or neutral molecules called **ligands.** (See Section 8.2.) The interaction involves the sharing by the metal ion of a lone pair on each ligand molecule, giving a partially covalent bond with that ligand. Such complexes often have strikingly deep colors. When exposed to gaseous ammonia, greenish white crystals of copper sulfate ($CuSO_4$) give a deep blue crystalline solid with the chemical formula $[Cu(NH_3)_4]SO_4$ (Fig. 16.9). The anions in the solid are still sulfate ions (SO_4^{2-}) but the cations are now **complex ions,** or coordination complexes of the central Cu^{2+} ion with four ammonia molecules, called ammine ligands and represented by the molecular formula $Cu(NH_3)_4^{2+}$. The ammonia molecules called ammine ligands and represented by the molecular formula coordinate to the copper ion through their lone-pair electrons (Fig. 16.10), acting as Lewis bases toward the metal ion, the Lewis acid. When the solid is dissolved in water, the deep blue color remains. This is evidence that the complex persists in water, because when ordinary $CuSO_4$ (without ammonia ligands) is dissolved in water, a much paler blue color results (see Fig. 16.9b).

Here we explore the effects of the formation of complex ions on equilibria in aqueous solutions. The microscopic structure and bonding in these complexes is presented in Chapter 8.

Complex-Ion Equilibria

When silver ions are dissolved in an aqueous ammonia solution, doubly coordinated silver–ammonia complexes, shown in Figure 16.11, form in two stepwise reactions:

$$Ag^+(aq) + NH_3(aq) \rightleftharpoons Ag(NH_3)^+(aq)$$

$$\frac{[Ag(NH_3)^+]}{[Ag^+][NH_3]} = K_1 = 2.1 \times 10^3$$

$Co(NH_3)_6^{2+}$	2.5×10^4	1.0×10^2	32	8.5	4.4	1.1	0.18
$Cu(NH_3)_4^{2+}$	1.1×10^{12}	1.0×10^4	2×10^3	5×10^2	90		
$Ni(NH_3)_6^{2+}$	8×10^{-7}	5×10^2	1.3×10^2	40	12	3.3	0.8
$Zn(NH_3)_4^{2+}$	5×10^8	1.5×10^2	1.8×10^2	2×10^2	90		
Chlorides							
$AgCl_2^-$	1.8×10^5	1.7×10^3	1.0×10^2				
$FeCl_4^-$	0.14	28	4.5	0.1	1.1×10^2		
$HgCl_4^{2-}$	1.2×10^{15}	5.5×10^6	3×10^6	7	10		
$PbCl_4^{2-}$	25	40	1.5	0.8	0.5		
$SnCl_4^{2-}$	30	32	5.4	0.6	0.3		
Hydroxides							
$Co(OH)_3^-$	3×10^{10}	4×10^4	1	8×10^5			
$Cu(OH)_4^{2-}$	3×10^{18}	1×10^7	5×10^6	2×10^3	30		
$Ni(OH)_3^-$	2×10^{11}	9×10^4	4×10^3	6×10^2			
$Pb(OH)_3^-$	4×10^{14}	7×10^7	1.1×10^3	5×10^3			
$Zn(OH)_4^{2-}$	5×10^{14}	2.5×10^4	8×10^6	70	33		

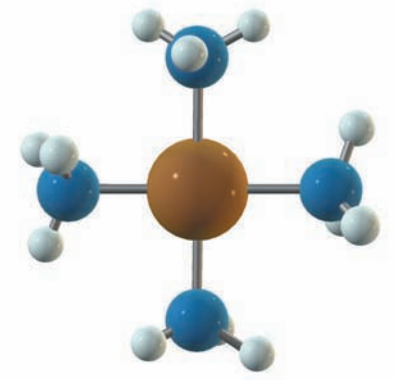

FIGURE 16.10 The structure of $Cu(NH_3)_4^{2+}$.

FIGURE 16.11 The structure of $Ag(NH_3)_2^+$.

$$Ag(NH_3)^+(aq) + NH_3(aq) \rightleftharpoons Ag(NH_3)_2^+(aq)$$

$$\frac{[Ag(NH_3)_2^+]}{[Ag(NH_3)^+][NH_3]} = K_2 = 8 \times 10^3$$

If these two chemical equations are added (and their corresponding equilibrium laws are multiplied), the result is

$$Ag^+(aq) + 2\ NH_3(aq) \rightleftharpoons Ag(NH_3)_2^+(aq)$$

$$\frac{[Ag(NH_3)_2^+]}{[Ag^+][NH_3]^2} = K_f = K_1K_2 = 1.7 \times 10^7$$

where K_f is the **formation constant** of the full complex ion $Ag(NH_3)_2^+$. Table 16.3 lists formation constants for a representative selection of complex ions. The larger the formation constant K_f, the more stable the corresponding complex ion (for ions with the same number of ligands).

Because K_1 and K_2 of the $Ag(NH_3)_2^+$ complex ion are both large, a silver salt dissolved in water that contains a high concentration of ammonia will be primarily in the form of the complex ion $[Ag(NH_3)_2]^+$ at equilibrium.

EXAMPLE 16.7

Suppose 0.100 mol of $AgNO_3$ is dissolved in 1.00 L of a 1.00 M in solution of NH_3. Calculate the concentrations of the Ag^+ and $Ag(NH_3)^+$ ions present at equilibrium.

Solution

Suppose that most of the Ag^+ is present as $Ag(NH_3)_2^+$ (this will be checked later). Then

$$[Ag(NH_3)_2^+]_0 = 0.100\ M$$

$$[NH_3]_0 = 1.00\ M - \left(2 \times 0.100\right)\ M = 0.80\ M$$

after each silver ion has become complexed with two ammonia molecules. The two stages of the dissociation of the $Ag(NH_3)_2^+$ ion are the reverse reaction of the complexation, so their equilibrium constants are the reciprocals of K_2 and K_1, respectively:

$$Ag(NH_3)_2^+(aq) \rightleftharpoons Ag(NH_3)^+(aq) + NH_3(aq)$$

$$\frac{[Ag(NH_3)^+][NH_3]}{[Ag(NH_3)_2^+]} = \frac{1}{K_2} = \frac{1}{8.2 \times 10^3}$$

$$Ag(NH_3)^+(aq) \rightleftharpoons Ag^+(aq) + NH_3(aq)$$

$$\frac{[Ag^+][NH_3]}{[Ag(NH_3)^+]} = \frac{1}{K_1} = \frac{1}{2.1 \times 10^3}$$

If y mol L^{-1} of $Ag(NH_3)_2^+$ dissociates at equilibrium according to the first equation,

$$Ag(NH_3)_2^+(aq) \rightleftharpoons Ag(NH_3)^+(aq) + NH_3(aq)$$

Initial concentration (M)	0.100	0	0.80
Change in concentration (M)	$-y$	$+y$	$+y$
Equilibrium concentration (M)	$0.100 - y$	y	$0.80 + y$

then the first equilibrium expression becomes

$$\frac{y(0.80 + y)}{0.10 - y} = \frac{1}{K_2} = \frac{1}{8.2 \times 10^3}$$

$$y = 1.5 \times 10^{-5} \text{ M} = [Ag(NH_3)^+]$$

We can then calculate the concentration of free Ag^+ ions from the equilibrium law for the second step of the dissociation of the complex ion:

$$\frac{[Ag^+][NH_3]}{[Ag(NH_3)^+]} = \frac{1}{K_1}$$

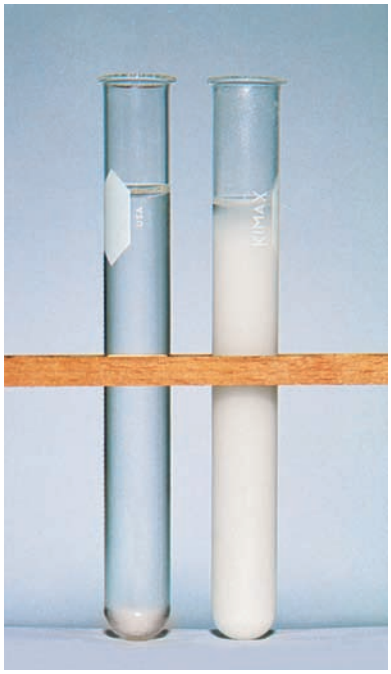
$$\frac{[Ag^+](0.80)}{1.5 \times 10^{-5}} = \frac{1}{2.1 \times 10^3}$$

$$[Ag^+] = 9 \times 10^{-9} \text{ M}$$

It is clear that the original assumption was correct, and most of the silver present is tied up in the $Ag(NH_3)_2^+$ complex.

Related Problems: 35, 36

There is a close similarity between the working of Example 16.7 and an acid–base calculation. The first step (the assumption that the reaction goes to completion and is followed by a small amount of back dissociation) is analogous to the procedure for dealing with the addition of a small amount of a strong acid to a solution of a weak base. The subsequent calculation of the successive dissociation steps resembles the calculation of polyprotic acid equilibria in Example 15.15. The only difference is that in complex-ion equilibria it is conventional to work with formation constants, which are the inverse of the dissociation constants used in acid–base equilibria.



The formation of coordination complexes can have a large effect on the solubility of a compound in water. Silver bromide is only very weakly soluble in water,

$$AgBr(s) \rightleftharpoons Ag^+(aq) + Br^-(aq) \qquad K_{sp} = 7.7 \times 10^{-13}$$

but addition of thiosulfate ion $(S_2O_3^{2-})$ to the solution allows the complex ion $Ag(S_2O_3)_2^{3-}$ to form:

$$AgBr(s) + 2\ S_2O_3^{2-}(aq) \rightleftharpoons Ag(S_2O_3)_2^{3-}(aq) + Br^-(aq)$$

FIGURE 16.12 An illustration of the effect of complex ion formation on solubility. Each test tube contains 2.0 g AgBr, but the one on the left also contains dissolved thiosulfate ion, which forms a complex ion with Ag^+. Almost none of the white solid AgBr has dissolved in pure water, but almost all of it has dissolved in the solution containing thiosulfate.

This greatly increases the solubility of the silver bromide (Fig. 16.12). The formation of this complex ion is an important step in the development of photographic images; thiosulfate ion is a component of the fixer that brings silver bromide into solution from the unexposed portion of the film.

EXAMPLE 16.8

Calculate the solubility of AgBr in a 1.00 M aqueous solution of ammonia.

Solution

We tentatively assume that almost all the silver that dissolves is complexed as $Ag(NH_3)_2^+$ (this will be checked later). The overall reaction is then

$$AgBr(s) + 2\ NH_3(aq) \rightleftharpoons Ag(NH_3)_2^+(aq) + Br^-(aq)$$

Note that this is the sum of the two reactions

$$AgBr(s) \rightleftharpoons Ag^+(aq) + Br^-(aq) \qquad K_{sp} = 7.7 \times 10^{-13}$$

$$Ag^+(aq) + 2\ NH_3(aq) \rightleftharpoons Ag(NH_3)_2^+(aq) \qquad K_f = 1.7 \times 10^7$$

so its equilibrium constant is the product $K_{sp}K_f = 1.3 \times 10^{-5}$.

If S mol L^{-1} of AgBr dissolves, then

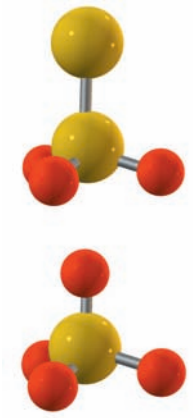
$$S = [Br^-] \approx [Ag(NH_3)_2^+]$$

$$[NH_3] = 1.00 - 2S$$

because 2 mol of NH_3 is used up for each mole of complex formed. The equilibrium expression is

$$\frac{S^2}{(1.00 - 2S)^2} = K_{sp}K_f = 1.3 \times 10^{-5}$$

$$S = 3.6 \times 10^{-3}\ \text{M} = [Ag(NH_3)_2^+] = [Br^-]$$



To check the original assumption, calculate the concentration of free silver ion:

$$[Ag^+] = \frac{K_{sp}}{[Br^-]} = \frac{K_{sp}}{S} = 2.1 \times 10^{-10} \ll [Ag(NH_3)_2^+]$$

verifying that almost all the silver is complexed. The solubility is therefore 3.6×10^{-3} mol L^{-1}, significantly greater than the solubility in pure water:

$$\text{solubility in pure water} = \sqrt{K_{sp}} = 8.8 \times 10^{-7}\ \text{mol L}^{-1}$$

Related Problems: 39, 40

The thiosulfate ion (*top*) is related to the sulfate ion, SO_4^{2-} (*bottom*), by the replacement of one oxygen atom with one sulfur atom. It is prepared, however, by the reaction of elemental sulfur with the sulfite ion (SO_3^{2-}).

Another interesting effect of complex ions on solubilities is illustrated by the addition of iodide ion to a solution containing mercury(II) ion. After a moderate amount of iodide ion has been added, an orange precipitate forms (Fig. 16.13) through the reaction

$$Hg^{2+}(aq) + 2\ I^-(aq) \rightleftharpoons HgI_2(s)$$

With further addition of iodide ion, however, the orange solid redissolves because complex ions form:

$$HgI_2(s) + I^-(aq) \rightleftharpoons HgI_3^-(aq)$$

$$HgI_3^-(aq) + I^-(aq) \rightleftharpoons HgI_4^{2-}(aq)$$

Cengage Learning/Leon Lewandowski

FIGURE 16.13 The "orange tornado" is a striking demonstration of the effects of complex ions on solubility. A solution is prepared with an excess of $I^-(aq)$ over $Hg^{2+}(aq)$ so that the Hg^{2+} is complexed as HgI_3^- and HgI_4^{2-}. A magnetic stirrer is used to create a vortex in the solution. Addition of a solution containing Hg^{2+} down the center of the vortex then causes the orange solid HgI_2 to form in a layer at the edges of the vortex, giving the tornado effect.

In the same way, silver chloride will dissolve in a concentrated solution of sodium chloride by forming soluble $AgCl_2^-$ complex ions. Complex ion formation affects solubility in the opposite direction from the common-ion effect of Section 16.3.

Acidity and Amphoterism of Complex Ions

When dissolved in water, many metal ions increase the acidity of the solution. The iron(III) ion is an example: Each dissolved Fe^{3+} ion is strongly solvated by six water molecules, leading to a complex ion $Fe(H_2O)_6^{3+}$. This complex ion can act as a Brønsted–Lowry acid, donating hydrogen ions to the solvent, water:

$$\underset{\text{Acid}_1}{Fe(H_2O)_6^{3+}(aq)} + \underset{\text{Base}_2}{H_2O(\ell)} \rightleftharpoons \underset{\text{Acid}_2}{H_3O^+(aq)} + \underset{\text{Base}_1}{Fe(H_2O)_5OH^{2+}(aq)}$$

$$\frac{[H_3O^+][Fe(H_2O)_5OH^{2+}]}{[Fe(H_2O)_6^{3+}]} = K_a = 7.7 \times 10^{-3}$$

Metal ion hydrolysis fits into the general scheme of the Brønsted–Lowry acid–base reaction.

EXAMPLE 16.9

Calculate the pH of a solution that is 0.100 M in $Fe(NO_3)_3$.

Solution

The iron(III) is present as $Fe(H_2O)_6^{3+}$, which reacts as a weak acid:

$$Fe(H_2O)_6^{3+}(aq) + H_2O(\ell) \rightleftharpoons Fe(H_2O)_5OH^{2+}(aq) + H_3O^+(aq)$$

with K_a equal to 7.7×10^{-3}. If y mol L^{-1} of $[Fe(H_2O)_6]^{3+}$ reacts, then (neglecting the ionization of water itself)

$$[H_3O^+] = [Fe(H_2O)_5OH^{2+}] = y$$

$$[Fe(H_2O)_6^{3+}] = 0.100 - y$$

The equilibrium expression has the form

$$\frac{y^2}{0.100 - y} = 7.7 \times 10^{-3}$$

$$y = 2.4 \times 10^{-2} \text{ M} = [H_3O^+]$$

so the pH is 1.62. Solutions of iron(III) salts are strongly acidic.

Related Problems: 43, 44

TABLE 16.4

pH of 0.1 M Aqueous Metal Nitrate Solutions at 25°C

Metal Nitrate	pH
$Fe(NO_3)_3$	1.6
$Pb(NO_3)_2$	3.6
$Cu(NO_3)_2$	4.0
$Zn(NO_3)_2$	5.3
$Ca(NO_3)_2$	6.7
$NaNO_3$	7.0

Another acceptable way to write the reaction that makes iron(III) solutions acidic is

$$Fe^{3+}(aq) + 2\ H_2O(\ell) \rightleftharpoons H_3O^+(aq) + FeOH^{2+}(aq)$$

in which the specific mention of the six waters of hydration is now omitted. The $FeOH^{2+}$ complex ions are brown, but Fe^{3+} ions are almost colorless. This reaction occurs to a sufficient extent to make a solution of $Fe(NO_3)_3$ in water pale brown. When strong acid is added, the equilibrium is driven back to the left and the color fades. Table 16.4 gives values of the pH for 0.1 M solutions of several metal ions. Those that form strong complexes with hydroxide ion have low pH (Fig. 16.14), whereas those that do not form such complexes give neutral solutions (pH 7).

FIGURE 16.14 The acidity of metal ions is illustrated by the vigorous reaction of anhydrous $AlCl_3$ with water to generate hydrated aluminum oxides, HCl(*aq*), and heat. The HCl turns the indicator, bromcresol red, to its red acid form.

Different cations behave differently as water ligands are replaced by hydroxide ions in an increasingly basic solution. A particularly interesting example is Zn^{2+}. It forms a series of hydroxo complex ions:

$$Zn^{2+}(aq) + OH^-(aq) \rightleftharpoons ZnOH^+(aq)$$

$$ZnOH^+(aq) + OH^-(aq) \rightleftharpoons Zn(OH)_2(s)$$

$$Zn(OH)_2(s) + OH^-(aq) \rightleftharpoons Zn(OH)_3^-(aq)$$

$$Zn(OH)_3^-(aq) + OH^-(aq) \rightleftharpoons Zn(OH)_4^{2-}(aq)$$

In the Brønsted–Lowry theory, a polyprotic acid, $Zn(H_2O)_4^{2+}(aq)$, donates hydrogen ions in succession to make all the product ions. The second product, $Zn(OH)_2$, is amphoteric; it can react as either acid or base. It is only slightly soluble in pure water (its K_{sp} is only 1.9×10^{-17}). If enough acid is added to solid $Zn(OH)_2$, the OH^- ligands are removed, forming the soluble Zn^{2+} ion; if enough base is added, OH^- ligands attach to form the soluble $Zn(OH)_4^{2+}$ (zincate) ion. Thus, $Zn(OH)_2$ is soluble in strongly acidic *or* strongly basic solutions but is only slightly soluble at intermediate pH values (Fig. 16.15). This amphoterism can be used to separate Zn^{2+} from other cations that do not share the property. For example, Mg^{2+} adds a maximum of two OH^- ions to form $Mg(OH)_2$, a sparingly soluble hydroxide. Further addition of OH^- does not lead to the formation of new complex ions. If a mixture of Mg^{2+} and Zn^{2+} ions is made sufficiently basic, the Mg^{2+} precipitates as $Mg(OH)_2$ but the zinc remains in solution as $Zn(OH)_4^{2-}$, allowing the two to be separated. In the same way, aluminum is separated from iron industrially by dissolving solid $Al(OH)_3$ in strong base as $Al(OH)_4^-(aq)$ while $Fe(OH)_3$ remains as a precipitate.

A DEEPER LOOK

16.6 SELECTIVE PRECIPITATION OF IONS

Cengage Learning/Leon Lewandowski

FIGURE 16.15 Zinc hydroxide is insoluble in water (*center*) but dissolves readily in acid (*left*) and base (*right*). The indicator used is bromocresol red, which turns from red to yellow in acidic solution.

One way to analyze a mixture of ions in solution is to separate the mixture into its components by exploiting the differences in the solubilities of compounds containing the ions. To separate silver ions from lead ions, for example, a search is made for compounds of these elements that (1) have a common anion and (2) have widely different solubilities. The chlorides AgCl and $PbCl_2$ are two such compounds, for which the solubility equilibria are

$$AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq) \qquad K_{sp} = 1.6 \times 10^{-10}$$

$$PbCl_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\ Cl^-(aq) \qquad K_{sp} = 2.4 \times 10^{-4}$$

Lead chloride is far more soluble in water than is silver chloride. Consider a solution that is 0.10 M in both Ag^+ and Pb^{2+}. Is it possible to add enough Cl^- to precipitate almost all the Ag^+ ions but leave all the Pb^{2+} ions in solution? If so, a quantitative separation of the two species can be achieved.

For Pb^{2+} to remain in solution, its reaction quotient must remain smaller than K_{sp}: $Q = [Pb^{2+}][Cl^-]^2 < K_{sp}$. Inserting K_{sp} and the concentration of Pb^{2+} gives

$$[Cl^-]^2 < \frac{K_{sp}}{[Pb^{2+}]} = \frac{2.4 \times 10^{-4}}{0.10} = 2.4 \times 10^{-3}$$

The square root of this is

$$[Cl^-] < 4.9 \times 10^{-2}\ \text{M}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Thus, as long as the chloride ion concentration remains smaller than 0.049 M, no $PbCl_2$ should precipitate. To reduce the *silver* ion concentration in solution as far as possible (that is, to precipitate out as much silver chloride as possible), the chloride ion concentration should be kept as high as possible without exceeding 0.049 M. If exactly this concentration of $Cl^-(aq)$ is chosen, then at equilibrium,

$$[Ag^+] = \frac{K_{sp}}{[Cl^-]} = \frac{1.6 \times 10^{-10}}{0.049} = 3.3 \times 10^{-9}$$

At that concentration of Cl^-, the concentration of Ag^+ has been reduced to 3.3×10^{-9} from the original concentration of 0.10 M. In other words, only about three Ag^+ ions in 10^8 remain in solution, but all the Pb^{2+} ions are left in solution. A nearly perfect separation of the two ionic species has been achieved.

This calculation gave the optimal theoretical separation factor for the two ions. In practice it is necessary to keep the chloride concentration lower. If $[Cl^-]$ is ten times smaller, or 0.0049 M, about three Ag^+ ions in 10^7 remain in solution with the Pb^{2+}. This is ten times more Ag^+ than if $[Cl^-] = 0.049$ M, but the separation of Ag^+ from Pb^{2+} is still very good.

Figure 16.16 shows graphically how ions can be separated based on solubility. The relation between the concentration of Pb^{2+} and Cl^- ions in contact with solid $PbCl_2$

$$[Pb^{2+}] = \frac{K_{sp}}{[Cl^-]^2}$$

can be rewritten in a useful form by taking the common logarithms of both sides:

$$\log_{10}[Pb^{2+}] = -2 \log_{10}[Cl^-] + \log_{10}K_{sp}$$

That is, a graph of $\log_{10}[Pb^{2+}]$ against $\log_{10}[Cl^-]$ is a straight line with slope -2. The corresponding graph for the AgCl solubility equilibrium has slope -1.

$$\log_{10}[Ag^+] = -\log_{10}[Cl^-] + \log_{10}K_{sp}$$

If the concentration of Cl^- and the initial concentrations of the metal ions correspond to a point that lies between the two lines in Figure 16.16, then AgCl precipitates but $PbCl_2$ does not.

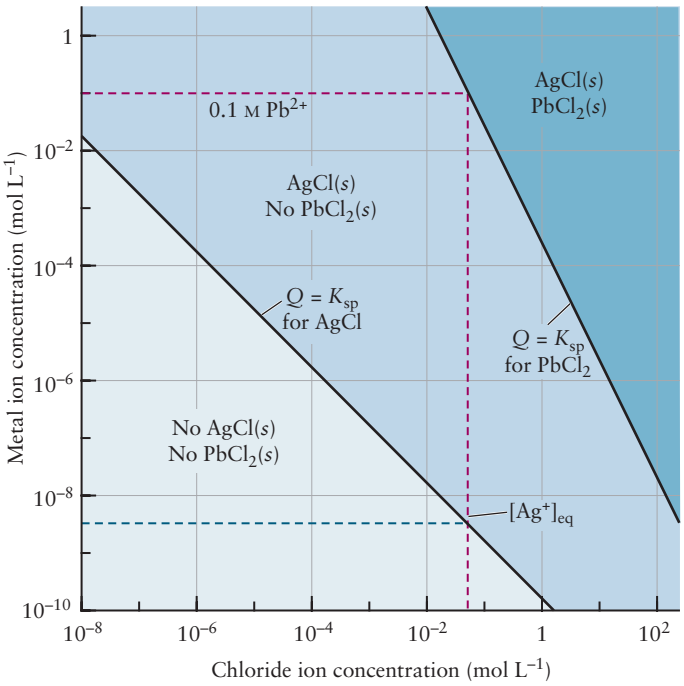

FIGURE 16.16 To separate a mixture of Ag^+ and Pb^{2+} ions, a chloride ion concentration is selected that gives a Pb^{2+} concentration below the equilibrium curve for $PbCl_2$ (so all Pb^{2+} remains in solution) but well above the equilibrium curve for Ag^+. As a result, nearly all the Ag^+ precipitates as AgCl. If $[Pb^{2+}]_0 = [Ag^+]_0 = 0.1$ M, then the maximum $[Cl^-]$ is found by tracing the horizontal red line and then dropping down the vertical red line to find $[Cl^-] = 0.049$ M. The concentration of Ag^+ still in solution is found by tracing the horizontal blue line from the intersection of the $[Cl^-]$ line of the AgCl equilibrium curve back to the vertical axis where $[Ag^+] = 3.3 \times 10^{-9}$ M.

Metal Sulfides

Controlling the solubility of metal sulfides has important applications. According to Table 16.2, most metal sulfides are very slightly soluble in water; only a very small amount of a compound such as ZnS(*s*) will dissolve in water. Although it is tempting to write the resulting equilibrium as

$$ZnS(s) \rightleftharpoons Zn^{2+}(aq) + S^{2-}(aq) \qquad K_{sp} = ?$$

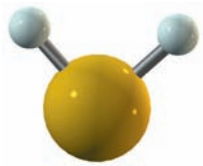
in analogy with the equilibria for other weakly soluble salts, this is misleading, because S^{2-}, like O^{2-}, is a very strong base (stronger than OH^-) and reacts almost quantitatively with water.

$$S^{2-}(aq) + H_2O(\ell) \longrightarrow HS^-(aq) + OH^-(aq)$$

The value of K_b for this reaction is on the order of 10^5; this means essentially no S^{2-} is present in aqueous solution. The net dissolution reaction is found by adding the two preceding equations,

$$ZnS(s) + H_2O(\ell) \rightleftharpoons Zn^{2+}(aq) + OH^-(aq) + HS^-(aq)$$

for which the equilibrium constant is



$$[Zn^{2+}][OH^-][HS^-] = K \approx 2 \times 10^{-25}$$

Table 16.5 gives values of the equilibrium constants for comparable reactions of other metal sulfides. As the pH decreases, the concentration of OH^- decreases. At the same time, the concentration of HS^- also decreases as the equilibrium

$$HS^-(aq) + H_3O^+(aq) \rightleftharpoons H_2S(aq) + H_2O(\ell)$$

shifts to the right upon addition of H_3O^+. If both $[OH^-]$ and $[HS^-]$ decrease, then $[Zn^{2+}]$ must increase in order to maintain a constant value for the product of the three concentrations. As a result, the solubility of ZnS(*s*) increases as the pH of the solution decreases. Other metal sulfides behave the same way, becoming more soluble in acidic solution.

A quantitative calculation of metal sulfide solubility requires treating several simultaneous equilibria, as the following example illustrates.

Hydrogen sulfide, H_2S, is a poisonous, foul-smelling gas. When dissolved in water, it gives a weak acid, hydrosulfuric acid.

TABLE 16.5

Equilibrium Constants for Metal Sulfide Dissolution at 25°C

Metal Sulfide	K†
CuS	5×10^{-37}
PbS	3×10^{-28}
CdS	7×10^{-28}
SnS	9×10^{-27}
ZnS	2×10^{-25}
FeS	5×10^{-19}
MnS	3×10^{-14}

†K is the equilibrium constant for the reaction $MS(s) + H_2O(\ell) \rightleftharpoons M^{2+}(aq) + OH^-(aq) + HS^-(aq)$.

EXAMPLE 16.10

In a solution that is saturated with H_2S (see ball and stick model in the margin), $[H_2S]$ is fixed at 0.1 M. Calculate the molar solubility of FeS(*s*) in such a solution if it is buffered at pH 3.0.

Solution

If the pH is 3.0, then

$$[OH^-] = 1 \times 10^{-11} \text{ M}$$

In addition, the acid ionization of H_2S must be considered:

$$H_2S(aq) + H_2O(\ell) \rightleftharpoons H_3O^+(aq) + HS^-(aq)$$

Substitution of $[H_2S] = 0.1$ M for a saturated solution and $[H_3O^+] = 1 \times 10^{-3}$ M (at pH 3.0) into the equilibrium expression for this reaction gives

$$\frac{[H_3O^+][HS^-]}{[H_2S]} = \frac{[1 \times 10^{-3}][HS^-]}{0.1} = K_a = 9.1 \times 10^{-8}$$

$$[HS^-] = 9 \times 10^{-6} \text{ M}$$

where K_a came from Table 15.2. For the reaction

$$FeS(s) + H_2O(\ell) \rightleftharpoons Fe^{2+}(aq) + HS^-(aq) + OH^-(aq)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the equilibrium constant from Table 16.3 is

$$[Fe^{2+}][HS^-][OH^-] = 5 \times 10^{-19}$$

Substituting the values of $[HS^-]$ and $[OH^-]$ and solving for $[Fe^{2+}]$ give

$$[Fe^{2+}](9 \times 10^{-6})(1 \times 10^{-11}) = 5 \times 10^{-19}$$

$$[Fe^{2+}] = 6 \times 10^{-3}\ \text{M}$$

Hence, 6×10^{-3} mol of FeS dissolves per liter under these conditions.

Related Problems: 55, 56

By adjusting the pH through appropriate choice of buffers, as in Example 16.10, conditions can be selected so that metal ions of one element remain entirely in solution, whereas those of a second element in the mixture precipitate almost entirely as solid metal sulfide (Fig. 16.17). Such a procedure is important for separating metal ions in qualitative analysis.

Cengage Learning/Leon Lewandowski

FIGURE 16.17 These sulfides are insoluble at pH 1, so they can be separated out of a mixture containing other, more soluble sulfides. From left to right, they are PbS, Bi_2S_3, CuS, CdS, Sb_2S_3, SnS_2, As_2S_3, and HgS. The precipitates occupy the lower part of the test tubes; in the 2nd and 6th from the left the precipitate appears as a dispersion of fine particles. The colored bands observed at each meniscus are refracted images of the colored solids at the bottom of each tube.

CHAPTER SUMMARY

Dissolution–precipitation reactions involve equilibrium between a substance in its solid form and molecules or ions of that same substance dissolved in solution. This equilibrium is described by the mass action law, so knowledge of the equilibrium constant permits manipulation of the concentrations in solution through the principles described in Chapter 14. Numerous separation and purification procedures are based on such manipulations. The significance of these dissolution–precipitation equilibria in practical applications is comparable to that of acid–base reactions. Solutions of slightly soluble solids are said to be saturated when the dissolved concentration is at equilibrium with the solid. In accordance with Le Châtelier's principle, if the solution goes to a state of supersaturation, it will return to equilibrium by precipitating solid out of solution. Similarly, according to Le Châtelier, solubility can be controlled by increasing temperature (for endothermic reactions) or decreasing temperature (for exothermic reactions). Solubility is greatly influenced by the presence of other species to the solution, through the way they shift the equilibrium concentration of the dissolved solid species. This general principle explains the common ion effect and the influence of pH on solubility.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 16.1 – The Nature of Solubility Equilibria

Discuss the dynamical processes that lead to solubility equilibria (Problems 1–4).

- When a solid substance is in contact with a solution in which this same substance is dissolved, molecules of the substance pass back and forth between the solid and dissolved states, just as molecules move between a liquid and its vapor. When the rate of passage from the solid into the solution is equal to the rate of the reverse passage from solution into the solid, a state of dissolution–precipitation equilibrium exists. At equilibrium, the solution is saturated and cannot accommodate more solute. The solubility S of a substance is the greatest amount that will dissolve in a specified volume of solvent at a specified temperature, and is expressed in g L^{-1} or mol L^{-1}. The solubility depends on temperature. In accordance with Le Châtelier's principle, solubility will increase with temperature if the dissolution reaction is endothermic, and decrease as temperature increases if the reaction is exothermic. A nonequilibrium supersaturated state can exist temporarily, in which the concentration of dissolved species exceeds the equilibrium concentration. The solution can return to equilibrium by precipitation of the excess dissolved species.

Section 16.2 – Ionic Equilibria between Solids and Solutions

Relate the solubilities of sparingly soluble salts in water to their solubility product constants (Problems 5–16).

- Slightly soluble ionic solids dissociate in solution to establish equilibrium with the dissolved cations and ions. The equilibrium expression is written in accordance with the stoichiometry of the compound. The solid does not appear in the equilibrium expression because it is in its standard state which has activity $a = 1$.
  - $AB(s) \rightleftharpoons A^+(aq) + B^-(aq)$
  - $K_{sp} = [A^+][B^-] = S^2$ if S is the molar solubility
  - $AB_2(s) \rightleftharpoons A^+(aq) + 2B^-(aq)$
  - $K_{sp} = [A^+][B^-]^2 = 4S^3$, and so on, for different stoichiometric ratios.

Section 16.3 – Precipitation and the Solubility Product

Use the reaction quotient to predict whether a precipitate will form when two solutions are mixed, and then calculate the equilibrium concentrations that result (Problems 17–24).

- At any point in the reaction $Q = [A^+][B^-]$. When $Q > K_{sp}$, a precipitate will form. Assume the reaction goes to completion and consumes all of one ion (the limiting reagent). Subsequent dissolution restores some of that ion to establish equilibrium between the precipitate and the solution. See Examples 16.3 and 16.4.

Calculate the solubility of a sparingly soluble salt in a solution that contains a given concentration of a common ion (Problems 25–30).

- The common ion effect describes the equilibrium of a solid with a solution that already contains some ions of the same type as one of those in the solid. No matter what the source of the ions, the total concentration of each in the solution must obey the equilibrium expression. The concentration of the "common ion" at equilibrium is the sum of its concentration initially present and the additional amount produced in the dissolution of the solid. Substitute this total concentration in the equilibrium expression and calculate the solubility at equilibrium. See Example 16.5.

Section 16.4 – The Effects of pH on Solubility

Determine the dependence on pH of the solubility of a salt of a weak base (Problems 31–34).

- Solubility of metal hydroxides increases at lower pH because the acid present ties up hydroxide ions in solution and so shifts the dissolution equilibrium to the right. Solubility of salts in which the anion is a weak base increases at lower pH because the hydronium ion in solution consumes the anion and so shifts the dissolution equilibrium to the right.

Section 16.5—Complex Ions and Solubility

Calculate the concentrations of molecular and ionic species in equilibrium with complex ions (Problems 35–38).

- The equilibrium expression relates the concentration of the complex ion and the concentration of the species that participate in its formation to the formation constant K_f for the ion. Set up the equilibrium expression by writing the total concentration of each species as the sum of its concentration initially present and the additional amount produced in formation of the complex ion, and solve for the resulting equilibrium concentration. See Example 16.7.

Determine the effect of complex ion formation on the solubility of sparingly soluble salts containing a common cation (Problems 39–40).

- Suppose a sparingly soluble salt such as AgCl is already in equilibrium with a solution. Adding a new reactant that forms a soluble complex with Ag^+ ions will consume the free Ag^+ ions in the solution. By Le Châtelier's principle this will drive the dissolution equilibrium to the right and increase the solubility of AgCl above its value in pure water. The resulting equilibrium is the sum of the dissolution–precipitation reaction and the complex formation reaction, and the resulting equilibrium constant is the product $K_{sp}K_{f.}$ See Example 16.8.

Calculate the pH of aqueous solutions containing metal cations (Problems 41–46).

- Many metal cations are highly solvated in aqueous solutions to form complex ions that function as Brønsted–Lowry acids by donating protons to the solution. If the acid dissociation constant K_a is known for the complex ion, the equilibrium concentration of H_3O^+ and the pH are readily calculated. See Example 16.9.

Section 16.6—A Deeper Look . . . Selective Precipitation of Ions

Specify the optimal conditions for separating two elements based on the differing solubilities of their ionic compounds (Problems 49–56.)

- Identify compounds of the two elements that have a common anion and widely different solubilities. Add enough of the common anion to precipitate all of the less soluble compound and leave the more soluble compound in solution. The maximum amount that can be added is determined by keeping the reaction quotient Q for the more soluble compound below its K_{sp} value. The quantitative degree of separation depends on the relative magnitudes of the K_{sp} values. This method is illustrated in Figure 16.16.

CUMULATIVE EXERCISE

Carbonate Minerals in Fresh Water and Seawater

The carbonates are among the most abundant and important minerals in the earth's crust. When these minerals come into contact with fresh water or seawater, solubility equilibria are established that greatly affect the chemistry of the natural waters. Calcium carbonate ($CaCO_3$), the most important natural carbonate, makes up

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

limestone and other forms of rock such as marble. Other carbonate minerals include dolomite, $CaMg(CO_3)_2$, and magnesite, $MgCO_3$. These compounds are sufficiently soluble that their solutions are nonideal, so calculations based on solubility product expressions are only approximate.

(a) The rare mineral nesquehonite contains $MgCO_3$ together with water of hydration. A sample containing 21.7 g of nesquehonite is acidified and heated, and the volume of $CO_2(g)$ produced is measured to be 3.51 L at 0°C and $P = 1$ atm. Assuming all the carbonate has reacted to form CO_2, give the chemical formula for nesquehonite.

(b) Write a chemical equation and a solubility product expression for the dissolution of dolomite in water.

(c) In a sufficiently basic solution, the carbonate ion does not react significantly with water to form hydrogen carbonate ion. Calculate the solubility (in grams per liter) of limestone (calcium carbonate) in a 0.10 M solution of sodium hydroxide. Use the K_{sp} from Table 16.2.

(d) In a strongly basic 0.10 M solution of Na_2CO_3, the concentration of CO_3^{2-} is 0.10 M. What is the gram solubility of limestone in this solution? Compare your answer with that for part (c).

(e) In a mountain lake having a pH of 8.1, the total concentration of carbonate species, $[CO_3^{2-}] + [HCO_3^-]$, is measured to be 9.6×10^{-4} M, whereas the concentration of Ca^{2+} is 3.8×10^{-4} M. Calculate the concentration of CO_3^{2-} in this lake, using $K_a = 4.8 \times 10^{-11}$ for the acid ionization of HCO_3^- to CO_3^{2-}. Is the lake unsaturated, saturated, or supersaturated with respect to $CaCO_3$?

(f) Will acid rainfall into the lake increase or decrease the solubility of limestone rocks in the lake's bed?

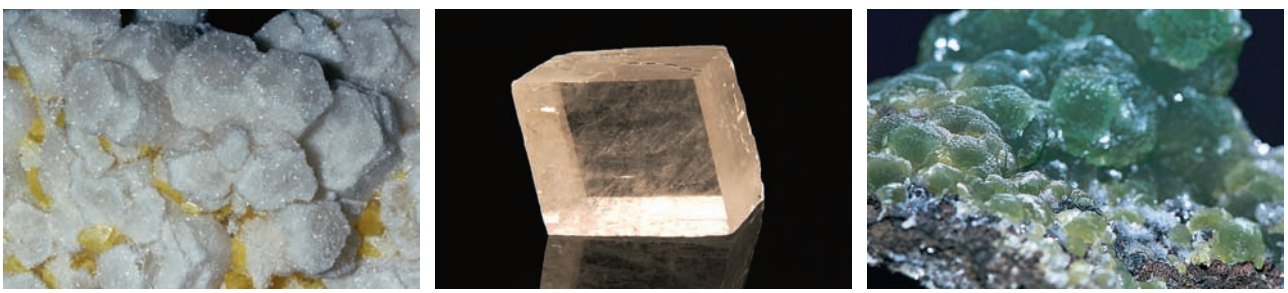
(g) Seawater contains a high concentration of Cl^- ions, which form weak complexes with calcium, such as the ion pair $CaCl^+$. Does the presence of such complexes increase or decrease the equilibrium solubility of $CaCO_3$ in seawater?

Answers

(a) $MgCO_3 \cdot 3H_2O$

(b) $CaMg(CO_3)_2(s) \rightleftharpoons Ca^{2+}(aq) + Mg^{2+}(aq) + 2\ CO_3^{2-}(aq)$

$$[Ca^{2+}][Mg^{2+}][CO_3^{2-}]^2 = K_{sp}$$



(c) 9.3×10^{-3} g L^{-1}

(d) 8.7×10^{-6} g L^{-1}, smaller than in part (c) because of the common-ion effect

(e) 5.8×10^{-6} M. $Q = 2.2 \times 10^{-9} < K_{sp} = 8.7 \times 10^{-9}$, so the lake is slightly less than saturated

(f) Increase

(g) Increase

Carbonate minerals. Calcite (*left*) and aragonite (*middle*) are both $CaCO_3$, and smithsonite (*right*) is $ZnCO_3$.

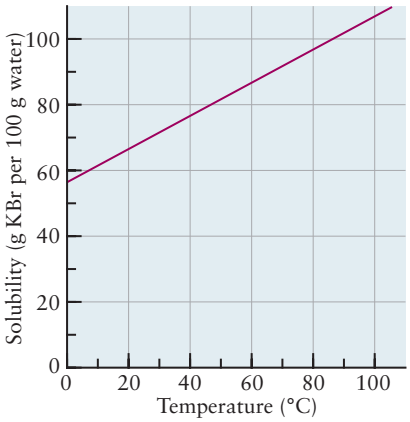
PROBLEMS



Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

The Nature of Solubility Equilibria

1. Gypsum has the formula $CaSO_4 \cdot 2H_2O$. Plaster of Paris has the chemical formula $CaSO_4 \cdot \frac{1}{2} H_2O$. In making wall plaster, water is added to plaster of Paris and the mixture then hardens into solid gypsum. How much water (in liters, at a density of 1.00 kg L^{-1}) should be added to 25.0 kg of plaster of Paris to turn it into gypsum, assuming no loss from evaporation?

2. A 1.00-g sample of magnesium sulfate is dissolved in water, and the water is then evaporated away until the residue is bone dry. If the temperature of the water is kept between 48°C and 69°C, the solid that remains weighs 1.898 g. If the experiment is repeated with the temperature held between 69°C and 100°C, however, the solid has a mass of 1.150 g. Determine how many waters of crystallization per $MgSO_4$ there are in each of these two solids.

3. The following graph shows the solubility of KBr in water in units of grams of KBr per 100 g of H_2O. If 80 g of KBr is added to 100 g of water at 10°C and the mixture is heated slowly, at what temperature will the last KBr dissolve?

4. Figure 16.3 shows the solubility of $AgNO_3$ in water in units of moles of $AgNO_3$ per kilogram of H_2O. If 255 g of $AgNO_3$ is added to 100 g of water at 95°C and cooled slowly, at what temperature will the solution become saturated?

Ionic Equilibria between Solids and Solutions

5. Iron(III) sulfate, $Fe_2(SO_4)_3$, is a yellow compound that is used as a coagulant in water treatment. Write a balanced chemical equation and a solubility product expression for its dissolution in water.

6. Lead antimonate, $Pb_3(SbO_4)_2$, is used as an orange pigment in oil-based paints and in glazes. Write a balanced chemical equation and a solubility product expression for its dissolution in water.

7. Thallium(I) iodate ($TlIO_3$) is only slightly soluble in water. Its K_{sp} at 25°C is 3.07×10^{-6}. Estimate the solubility of thallium(I) iodate in water in units of grams per 100.0 mL of water.

8. Thallium thiocyanate (TlSCN) is only slightly soluble in water. Its K_{sp} at 25°C is 1.82×10^{-4}. Estimate the solubility of thallium thiocyanate in units of grams per 100.0 mL of water.

9. Potassium perchlorate, $KClO_4$, has a K_{sp} at 25°C of 1.07×10^{-2}. Compute its solubility in grams per liter of solution.

10. Ammonium hexachloroplatinate(IV), $(NH_4)_2(PtCl_6)$, is one of the few sparingly soluble ammonium salts. Its K_{sp} at 20°C is 5.6×10^{-6}. Compute its solubility in grams per liter of solution.

11. The solubility product constant of mercury(I) iodide is 1.2×10^{-28} at 25°C. Estimate the concentration of Hg_2^{2+} and I^- in equilibrium with solid Hg_2I_2.

12. The solubility product constant of Hg_2Cl_2 is 2×10^{-18} at 25°C. Estimate the concentration of Hg_2^{2+} and Cl^- in equilibrium with solid Hg_2Cl_2 at 25°C.

13. The solubility of silver chromate (Ag_2CrO_4) in 500 mL of water at 25°C is 0.0129 g. Calculate its solubility product constant.

14. At 25°C, 400 mL of water can dissolve 0.00896 g of lead iodate, $Pb(IO_3)_2$. Calculate K_{sp} for lead iodate.

15. At 100°C, water dissolves 1.8×10^{-2} g of AgCl per liter. Compute the K_{sp} of AgCl at this temperature.

16. A mass of 0.017 g of silver dichromate ($Ag_2Cr_2O_7$) will dissolve in 300 mL of water at 25°C. Calculate the solubility product constant K_{sp} of silver dichromate.

Precipitation and the Solubility Product

17. A solution of barium chromate ($BaCrO_4$) is prepared by dissolving 6.3×10^{-3} g of this yellow solid in 1.00 L of hot water. Will solid barium chromate precipitate upon cooling to 25°C, according to the solubility product expression? Explain.

18. A solution is prepared by dissolving 0.090 g of PbI_2 in 1.00 L of hot water and cooling the solution to 25°C. Will solid precipitate result from this process, according to the solubility product expression? Explain.

19. A solution is prepared by mixing 250.0 mL of 2.0×10^{-3} M $Ce(NO_3)_3$ and 150.0 mL of 10×10^{-2} M KIO_3 at 25°C. Determine whether $Ce(IO_3)_3(s)$ ($K_{sp} = 1.9 \times 10^{-10}$) tends to precipitate from this mixture.

20. Suppose 100.0 mL of a 0.0010 M $CaCl_2$ solution is added to 50.0 mL of a 6.0×10^{-5} M NaF solution at 25°C. Determine whether $CaF_2(s)$ ($K_{sp} = 3.9 \times 10^{-11}$) tends to precipitate from this mixture.

21. Suppose 50.0 mL of a 0.0500 M solution of $Pb(NO_3)_2$ is mixed with 40.0 mL of a 0.200 M solution of $NaIO_3$ at 25°C. Calculate the $[Pb^{2+}]$ and $[IO_3^-]$ when the mixture comes to equilibrium. At this temperature, K_{sp} for $Pb(IO_3)_2$ is 2.6×10^{-13}.

22. Silver iodide (AgI) is used in place of silver chloride for the fastest photographic film because it is more sensitive to light and can therefore form an image in a very short exposure time. A silver iodide emulsion is prepared by adding 6.60 L of 0.10 M NaI solution to 1.50 L of 0.080 M $AgNO_3$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

solution at 25°C. Calculate the concentration of silver ion remaining in solution when the mixture comes to equilibrium and its chemical amount relative to the amount present initially.

23. When 50.0 mL of 0.100 M $AgNO_3$ and 30.0 mL of 0.0600 M Na_2CrO_4 are mixed, a precipitate of silver chromate (Ag_2CrO_4) is formed. The solubility product K_{sp} of silver chromate in water at 25°C is 1.9×10^{-12}. Calculate the $[Ag^+]$ and $[CrO_4^{2-}]$ remaining in solution at equilibrium.

24. When 40.0 mL of 0.0800 M $Sr(NO_3)_2$ and 80.0 mL of 0.0500 M KF are mixed, a precipitate of strontium fluoride (SrF_2) is formed. The solubility product K_{sp} of strontium fluoride in water at 25°C is 2.8×10^{-9}. Calculate the $[Sr^{2+}]$ and $[F^-]$ remaining in solution at equilibrium.

25. Calculate the solubility (in mol L^{-1}) of $CaF_2(s)$ at 25°C in a 0.040 M aqueous solution of NaF.

26. Calculate the mass of AgCl that can dissolve in 100 mL of 0.150 M NaCl solution.

27. The solubility product of nickel(II) hydroxide, $Ni(OH)_2$, at 25°C is $K_{sp} = 1.6 \times 10^{-16}$.

(a) Calculate the molar solubility of $Ni(OH)_2$ in pure water at 25°C.

(b) Calculate the molar solubility of $Ni(OH)_2$ in 0.100 M NaOH.

28. Silver arsenate (Ag_3AsO_4) is a slightly soluble salt having a solubility product of $K_{sp} = 1.0 \times 10^{-22}$ at 25°C for the equilibrium

$$Ag_3AsO_4(s) \rightleftharpoons 3\ Ag^+(aq) + AsO_4^{3-}(aq)$$

(a) Calculate the molar solubility of silver arsenate in pure water at 25°C.

(b) Calculate the molar solubility of silver arsenate in 0.10 M $AgNO_3$.

29. A saturated solution of $Mg(OH)_2$ at 25°C is prepared by equilibrating solid $Mg(OH)_2$ with water. Concentrated NaOH is then added until the solubility of $Mg(OH)_2$ is 0.0010 times that in H_2O alone. (Ignore the change in volume resulting from the addition of NaOH.) The solubility product K_{sp} of $Mg(OH)_2$ is 1.2×10^{-11} at 25°C. Calculate the concentration of hydroxide ion in the solution after the addition of the NaOH.

30. A saturated solution of BaF_2 at 25°C is prepared by equilibrating solid BaF_2 with water. Powdered NaF is then dissolved in the solution until the solubility of BaF_2 is 1.0% of that in H_2O alone. The solubility product K_{sp} of BaF_2 is 1.7×10^{-6} at 25°C. Calculate the concentration of fluoride ion in the solution after addition of the powdered NaF.

The Effects of pH on Solubility

31. Compare the molar solubility of AgOH in pure water with that in a solution buffered at pH 7.00. Note the difference between the two: When AgOH is dissolved in pure water, the pH does not remain at 7.

32. Compare the molar solubility of $Mg(OH)_2$ in pure water with that in a solution buffered at pH 9.00.

33. For each of the following ionic compounds, state whether the solubility will increase, decrease, or remain unchanged as a solution at pH 7 is made acidic.

(a) PbI_2 (b) AgOH (c) $Ca_3(PO_4)_2$

34. For each of the following ionic compounds, state whether the solubility will increase, decrease, or remain unchanged as a solution at pH 7 is made acidic.

(a) $SrCO_3$ (b) Hg_2Br_2 (c) MnS

Complex Ions and Solubility

35. Suppose 0.10 mol of $Cu(NO_3)_2$ and 1.50 mol of NH_3 are dissolved in water and diluted to a total volume of 1.00 L. Calculate the concentrations of $Cu(NH_3)_4^{2+}$ and of Cu^{2+} at equilibrium.

36. The formation constant of the $TlCl_4^-$ complex ion is 1×10^{18}. Suppose 0.15 mol of $Tl(NO_3)_3$ is dissolved in 1.00 L of a 0.50 M solution of NaCl. Calculate the concentration at equilibrium of $TlCl_4^-$ and of Tl^{3+}.

37. The organic compound "18-crown-6" binds alkali metals in aqueous solution by wrapping around and enfolding the ion. It presents a niche that nicely accommodates the K^+ ion but is too small for the Rb^+ ion and too large for the Na^+ ion. The values of the equilibrium constants show this:

$$Na^+(aq) + 18\text{-crown-}6(aq) \rightleftharpoons Na\text{-crown}^+(aq) \qquad K = 6.6$$

$$K^+(aq) + 18\text{-crown-}6(aq) \rightleftharpoons K\text{-crown}^+(aq) \qquad K = 111.6$$

$$Rb^+(aq) + 18\text{-crown-}6(aq) \rightleftharpoons Rb\text{-crown}^+(aq) \qquad K = 36$$

An aqueous solution is initially 0.0080 M in 18-crown-6(aq) and also 0.0080 M in $K^+(aq)$. Compute the equilibrium concentration of free K^+. ("Free" means not tied up with the 18-crown-6.) Compute the concentration of free Na^+ if the solution contains 0.0080 M $Na^+(aq)$ instead of $K^+(aq)$.

38. The organic compound 18-crown-6 (see preceding problem) also binds strongly with the alkali metal ions in methanol.

$$K^+ + 18\text{-crown-}6 \rightleftharpoons [\text{complex}]^+$$

In methanol solution the equilibrium constant is 1.41×10^6. A similar reaction with Cs^+ has an equilibrium constant of only 2.75×10^4. A solution is made (in methanol) containing 0.020 mol L^{-1} each of K^+ and Cs^+. It also contains 0.30 mol L^{-1} of 18-crown-6. Compute the equilibrium concentrations of both the uncomplexed K^+ and the uncomplexed Cs^+.

39. Will silver chloride dissolve to a significantly greater extent in a 1.00 M NaCl solution than in pure water due to the possible formation of $AgCl_2^-$ ions? Use data from Tables 16.2 and 16.3 to provide a quantitative answer to this question. What will happen in a 0.100 M NaCl solution?

40. Calculate how many grams of silver chloride will dissolve in 1.0 L of a 1.0 M NH_3 solution through formation of the complex ion $Ag(NH_3)_2^+$.

41. The pH of a 0.2 M solution of $CuSO_4$ is 4.0. Write chemical equations to explain why a solution of this salt is neither basic [from the reaction of $SO_4^{2-}(aq)$ with water] nor neutral, but acidic.

42. Will a 0.05 M solution of $FeCl_3$ be acidic, basic, or neutral? Explain your answer by writing chemical equations to describe any reactions taking place.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

43. The acid ionization constant for $Co(H_2O)_6^{2+}(aq)$ is 3×10^{-10}. Calculate the pH of a 0.10 M solution of $Co(NO_3)_2$.

44. The acid ionization constant for $Fe(H_2O)_6^{2+}(aq)$ is 3×10^{-6}. Calculate the pH of a 0.10 M solution of $Fe(NO_3)_2$, and compare it with the pH of the corresponding iron(III) nitrate solution from Example 16.9.

45. A 0.15 M aqueous solution of the chloride salt of the complex ion $Pt(NH_3)_4^{2+}$ is found to be weakly acidic with a pH of 4.92. This is initially puzzling because the Cl^- ion in water is not acidic and NH_3 in water is *basic*, not acidic. Finally, it is suggested that the $Pt(NH_3)_4^{2+}$ ion as a group donates hydrogen ions. Compute the K_a of this acid, assuming that just one hydrogen ion is donated.

46. The pH of a 0.10 M solution of $Ni(NO_3)_2$ is 5.0. Calculate the acid ionization constant of $Ni(H_2O)_6^{2+}(aq)$.

47. K_{sp} for $Pb(OH)_2$ is 4.2×10^{-15}, and K_f for $Pb(OH)_3^-$ is 4×10^{14}. Suppose a solution whose initial concentration of $Pb^{2+}(aq)$ is 1.00 M is brought to pH 13.0 by addition of solid NaOH. Will solid $Pb(OH)_2$ precipitate, or will the lead be dissolved as $Pb(OH)_3^-(aq)$? What will be $[Pb^{2+}]$ and $[Pb(OH)_3^-]$ at equilibrium? Repeat the calculation for an initial Pb^{2+} concentration of 0.050 M. (*Hint:* One way to solve this problem is to *assume* that $Pb(OH)_2(s)$ is present and calculate $[Pb^{2+}]$ and $[Pb(OH)_3^-]$ that would be in equilibrium with the solid. If the sum of these is less than the original $[Pb^{2+}]$, the remainder can be assumed to have precipitated. If not, there is a contradiction and we must assume that *no* $Pb(OH)_2(s)$ is present. In this case we can calculate $[Pb^{2+}]$ and $[Pb(OH)_3^-]$ directly from K_f.)

48. K_{sp} from $Zn(OH)_2$ is 4.5×10^{-17}, and K_f for $Zn(OH)_4^{2-}$ is 5×10^{14}. Suppose a solution whose initial concentration of $Zn^{2+}(aq)$ is 0.010 M is brought to pH 14.0 by addition of solid NaOH. Will solid $Zn(OH)_2$ precipitate, or will the zinc be dissolved as $Zn(OH)_4^{2-}(aq)$? What will be $[Zn^{2+}]$ and $[Zn(OH)_4^{2-}]$ at equilibrium? Repeat the calculation at pH 13 for an initial Zn^{2+} concentration of 0.10 M. See the hint in problem 47.

A Deeper Look . . . Selective Precipitation of Ions

49. An aqueous solution at 25°C is 0.10 M in both Mg^{2+} and Pb^{2+} ions. We wish to separate the two kinds of metal ions by taking advantage of the different solubilities of their oxalates, MgC_2O_4 and PbC_2O_4.

(a) What is the highest possible oxalate ion concentration that allows only one solid oxalate salt to be present at equilibrium? Which ion is present in the solid—Mg^{2+} or Pb^{2+}?

(b) What fraction of the less soluble ion still remains in solution under the conditions of part (a)?

50. An aqueous solution at 25°C is 0.10 M in Ba^{2+} and 0.50 M in Ca^{2+} ions. We wish to separate the two by taking advantage of the different solubilities of their fluorides, BaF_2 and CaF_2.

(a) What is the highest possible fluoride ion concentration that allows only one solid fluoride salt to be present at equilibrium? Which ion is present in the solid—Ba^{2+} or Ca^{2+}?

(b) What fraction of the less soluble ion still remains in solution under the conditions of part (a)?

51. The cations in an aqueous solution that contains 0.100 M $Hg_2(NO_3)_2$ and 0.0500 M $Pb(NO_3)_2$ are to be separated by taking advantage of the difference in the solubilities of their iodides. $K_{sp}(PbI_2) = 1.4 \times 10^{-8}$ and $K_{sp}(Hg_2I_2) = 1.2 \times 10^{-28}$. What should be the concentration of iodide ion for the best separation? In the "best" separation, one of the cations should remain entirely in solution and the other should precipitate as fully as possible.

52. The cations in an aqueous solution that contains 0.150 M $Ba(NO_3)_2$ and 0.0800 M $Ca(NO_3)_2$ are to be separated by taking advantage of the difference in the solubilities of their sulfates. $K_{sp}(BaSO_4) = 1.1 \times 10^{-10}$ and $K_{sp}(CaSO_4) = 2.4 \times 10^{-5}$. What should be the concentration of sulfate ion for the best separation?

53. Calculate the $[Zn^{2+}]$ in a solution that is in equilibrium with $ZnS(s)$ and in which $[H_3O^+] = 1.0 \times 10^{-5}$ M and $[H_2S] = 0.10$ M.

54. Calculate the $[Cd^{2+}]$ in a solution that is in equilibrium with $CdS(s)$ and in which $[H_3O^+] = 1.0 \times 10^{-3}$ M and $[H_2S] = 0.10$ M.

55. What is the highest pH at which 0.10 M Fe^{2+} will remain entirely in a solution that is saturated with H_2S at a concentration of $[H_2S] = 0.10$ M? At this pH, what would be the concentration of Pb^{2+} in equilibrium with solid PbS in this solution?

56. What is the highest pH at which 0.050 M Mn^{2+} will remain entirely in a solution that is saturated with H_2S at a concentration of $[H_2S] = 0.10$ M? At this pH, what would be the concentration of Cd^{2+} in equilibrium with solid CdS in this solution?

ADDITIONAL PROBLEMS

57. Write a chemical equation for the dissolution of mercury(I) chloride in water, and give its solubility product expression.

* **58.** Magnesium ammonium phosphate has the formula $MgNH_4PO_4 \cdot 6H_2O$. It is only slightly soluble in water (its K_{sp} is 2.3×10^{-13}). Write a chemical equation and the corresponding equilibrium law for the dissolution of this compound in water.

59. Soluble barium compounds are poisonous, but barium sulfate is routinely ingested as a suspended solid in a "barium cocktail" to improve the contrast in X-ray images. Calculate the concentration of dissolved barium per liter of water in equilibrium with solid barium sulfate.

60. A saturated aqueous solution of silver perchlorate ($AgClO_4$) contains 84.8% by mass $AgClO_4$, but a saturated solution

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

of $AgClO_4$ in 60% aqueous perchloric acid contains only 5.63% by mass $AgClO_4$. Explain this large difference using chemical equations.

61. Suppose 140 mL of 0.0010 M $Sr(NO_3)_2$ is mixed with enough 0.0050 M NaF to make 1.00 L of solution. Will $SrF_2(s)$ ($K_{sp} = 2.8 \times 10^{-9}$) precipitate at equilibrium? Explain.

62. The concentration of calcium ion in a town's supply of drinking water is 0.0020 M. (This water is referred to as hard water because it contains such a large concentration of Ca^{2+}.) Suppose the water is to be fluoridated by the addition of NaF for the purpose of reducing tooth decay. What is the maximum concentration of fluoride ion that can be achieved in the water before precipitation of CaF_2 begins? Will the water supply attain the level of fluoride ion recommended by the U.S. Public Health Service, about 5×10^{-5} M (1 mg fluorine per liter)?

63. Suppose that 150 mL of 0.200 M K_2CO_3 and 100 mL of 0.400 M $Ca(NO_3)_2$ are mixed together. Assume that the volumes are additive, that $CaCO_3$ is completely insoluble, and that all other substances that might be formed are soluble. Calculate the mass of $CaCO_3$ precipitated, and calculate the concentrations in the final solution of the four ions that were present initially.

64. The solubility of $CaCO_3$ in water is about 7 mg L^{-1}. Show how one can calculate the solubility product of $BaCO_3$ from this information and from the fact that when sodium carbonate solution is added slowly to a solution containing equimolar concentrations of Ca^{2+} and Ba^{2+}, no $CaCO_3$ is formed until about 90% of the Ba^{2+} has been precipitated as $BaCO_3$.

65. It is sometimes asserted that carbonates are soluble in strong acids because a gas is formed that escapes (CO_2). Suppose that CO_2 were extremely soluble in water (as, for example, ammonia is) and therefore it did not leave the site of the reaction, but that otherwise, its chemistry was unchanged. Would calcium carbonate be soluble in strong acids? Explain.

66. The solubility products of $Fe(OH)_3$ and $Ni(OH)_2$ are about 10^{-36} and 6×10^{-18}, respectively. Find the approximate pH range suitable for the separation of Fe^{3+} and Ni^{2+} by precipitation of $Fe(OH)_3$ from a solution initially 0.01 M in each ion, as follows: (a) Calculate the lowest pH at which all but 0.1% of the Fe^{3+} will be precipitated as $Fe(OH)_3$; (b) calculate the highest pH possible without precipitation of $Ni(OH)_2$.

67. The two solids CuBr(*s*) and AgBr(*s*) are only very slightly soluble in water: $K_{sp}(CuBr) = 4.2 \times 10^{-8}$ and $K_{sp}(AgBr) = 7.7 \times 10^{-13}$. Some CuBr(*s*) and AgBr(*s*) are both mixed into a quantity of water that is then stirred until it is saturated with respect to both solutes. Next, a small amount of KBr is added and dissolves completely. Compute the ratio of $[Cu^+]$ to $[Ag^+]$ after the system reestablishes equilibrium.

* 68. The two salts $BaCl_2$ and Ag_2SO_4 are both far more soluble in water than either $BaSO_4$ ($K_{sp} = 1.1 \times 10^{-10}$) or AgCl ($K_{sp} = 1.6 \times 10^{-10}$) at 25°C. Suppose 50.0 mL of 0.040 M $BaCl_2(aq)$ is added to 50.0 mL of 0.020 M $Ag_2SO_4(aq)$. Calculate the concentrations of $SO_4^{2-}(aq)$, $Cl^-(aq)$, $Ba^{2+}(aq)$, and $Ag^+(aq)$ that remain in solution at equilibrium.

69. The Mohr method is a technique for determining the amount of chloride ion in an unknown sample. It is based on the difference in solubility between silver chloride (AgCl; $K_{sp} = 1.6 \times 10^{-10}$) and silver chromate ($Ag_2CrO_4$; $K_{sp} = 1.9 \times 10^{-12}$). In using this method, one adds a small amount of chromate ion to a solution with unknown chloride concentration. By measuring the volume of $AgNO_3$ added before the appearance of the red silver chromate, one can determine the amount of Cl^- originally present. Suppose we have a solution that is 0.100 M in Cl^- and 0.00250 M in CrO_4^{2-}. If we add 0.100 M $AgNO_3$ solution drop by drop, will AgCl or Ag_2CrO_4 precipitate first? When $Ag_2CrO_4(s)$ first appears, what fraction of the Cl^- originally present remains in solution?

70. Oxide ion, like sulfide ion, is a strong base. Write an equation for the dissolution of CaO in water and give its equilibrium constant expression. Write the corresponding equation for the dissolution of CaO in an aqueous solution of a strong acid, and relate its equilibrium constant to the previous one.

71. Water that has been saturated with magnesia (MgO) at 25°C has a pH of 10.16. Write a balanced chemical equation for the equilibrium between MgO(*s*) and the ions it furnishes in aqueous solution, and calculate the equilibrium constant at 25°C. What is the solubility, in moles per liter, of MgO in water?

72. To 1.00 L of a 0.100 M $AgNO_3$ solution is added an excess of sodium chloride. Then 1.00 L of 0.500 M $NH_3(aq)$ is added. Finally, sufficient nitric acid is added until the pH of the resulting solution is 1.0. Write balanced equations for the reactions that take place (if any) at each of three steps in this process.

73. Only about 0.16 mg of AgBr(*s*) will dissolve in 1.0 L of water (this volume of solid is smaller than the head of a pin). In a solution of ammonia that contains 0.10 mol ammonia per liter of water, there are about 555 water molecules for every molecule of ammonia. However, more than 400 times as much AgBr (68 mg) will dissolve in this solution as in plain water. Explain how such a tiny change in the composition of the solution can have such a large effect on the solubility of AgBr.

* 74. (a) Calculate the solubility of calcium oxalate (CaC_2O_4) in 1.0 M oxalic acid ($H_2C_2O_4$) at 25°C, using the two acid ionization constants for oxalic acid from Table 15.2 and the solubility product $K_{sp} = 2.6 \times 10^{-9}$ for CaC_2O_4.
(b) Calculate the solubility of calcium oxalate in pure water at 25°C.
(c) Account for the difference between the results of (a) and (b).

* 75. When 6 M HCl is added to solid CdS, some of the solid dissolves to give the complex ion $CdCl_4^{2-}(aq)$.
(a) Write a balanced equation for the reaction that occurs.
(b) Use data from Tables 15.2 and 16.5 and the formation constant of $CdCl_4^{2-}$ ($K_f = 8 \times 10^2$) to calculate the equilibrium constant for the reaction of part (a).
(c) What is the molar solubility of CdS per liter of 6 M HCl?

* 76. Using data from Table 16.3, calculate the concentrations of $Hg^{2+}(aq)$, $HgCl^{+}(aq)$, and $HgCl_2(aq)$ that result when 1.00 L of a 0.100 M $Hg(NO_3)_2$ solution is mixed with an equal volume of a 0.100 M $HgCl_2$ solution. (*Hint:* Use the analogy with amphoteric equilibria discussed in Section 10.8.)

* 77. Calculate the concentration of $Cu^{2+}(aq)$ in a solution that contains 0.020 mol of $CuCl_2$ and 0.100 mol of NaCN in 1.0 L.

$$Cu^{2+}(aq) + 4\ CN^{-}(aq) \rightleftharpoons Cu(CN)_4^{2-}(aq) \qquad K = 2.0 \times 10^{30}$$

(*Hint:* Do not overlook the reaction of CN^- with water to give HCN.)

78. An aqueous solution of $K_2[Pt(OH)_6]$ has a pH greater than 7. Explain this fact by writing an equation showing the $Pt(OH)_6^{2-}$ ion acting as a Brønsted–Lowry base and accepting a hydrogen ion from water.

79. In Example 16.9 we included only the first acid dissociation K_{a1} of a 0.100 M aqueous solution of $Fe(H_2O)_6^{3+}$. Subsequent dissociation can also occur, with $K_{a2} = 2.0 \times 10^{-5}$, to give $Fe(H_2O)_4(OH)_2^{+}$.
   (a) Calculate the concentration of $Fe(H_2O)_4(OH)_2^{+}$ at equilibrium. Does the pH change significantly when this second dissociation is taken into account?
   (b) We can describe the same reaction as the dissociation of a complex ion $Fe(OH)_2^{+}$ to Fe^{3+} and two OH^- ions. Calculate K_f, the formation constant for $Fe(OH)_2^{+}$.

CUMULATIVE PROBLEMS

80. The volume of a certain saturated solution is greater than the sum of the volumes of the water and salt from which it is made. Predict the effect of increased pressure on the solubility of this salt.

81. Codeine has the molecular formula $C_{18}H_{21}NO_3$. It is soluble in water to the extent of 1.00 g per 120 mL of water at room temperature and 1.00 g per 60 mL of water at 80°C. Compute the molal solubility (in mol kg^{-1}) at both temperatures, taking the density of water to be fixed at 1.00 g cm^{-3}. Is the dissolution of codeine in water endothermic or exothermic?

82. Suppose 1.44 L of a saturated solution of strontium carbonate ($SrCO_3$) in boiling water at 100°C is prepared. The solution is then strongly acidified and shaken to drive off all the gaseous CO_2 that forms. The volume of this gas (at a temperature of 100°C and a partial pressure of 0.972 atm) is measured to be 0.20 L (200 mL).
   (a) Calculate the molar solubility of $SrCO_3$ in water at 100°C.
   (b) Estimate the solubility product constant K_{sp} of $SrCO_3$ at this temperature.
   (c) Explain why the actual K_{sp} at this temperature may be lower than you predicted in part (b).

83. A buffer is prepared by adding 50.0 mL of 0.15 M $HNO_3(aq)$ to 100.0 mL of 0.12 M NaHCOO(*aq*) (sodium formate). Calculate the solubility of $CaF_2(s)$ in this solution.

One mole of electrons.

Electrochemistry is the branch of chemistry concerned with the interconversion of chemical and electrical energy through oxidation–reduction reactions. Electrons are transferred between two half-reactions through external electrical circuits, in contrast to solution-phase redox reactions discussed in Section 11.4. Energy produced by spontaneous chemical reactions may be converted to electrical energy; conversely, electrical energy can be used to drive chemical reactions that are not normally spontaneous. Electrochemistry is historically a vital field, primarily for its important industrial applications. Bulk commodity chemicals, such as chlorine, and most metals are produced using large-scale electrochemical processes. In addition, considerable efforts have been directed toward preventing the corrosion of metals (electrochemically triggered oxidation), for example, alloy-based structural materials of pervasive importance in vehicles, ships, airplanes, buildings, and bridges. Another important practical application has been the development of batteries, which produce electrical energy from spontaneous redox reactions in electrochemical cells.

The field of electrochemistry is much broader than is represented by its industrial applications alone, and it has been transformed into a molecular science over the past forty years or so. Considerable insight into the molecular nature of electrochemical reactions has been provided by new techniques that couple electrochemical approaches with spectroscopic techniques and computational methods. The oxidation and reduction of single molecules have been detected and studied using the scanning electrochemical microscope, an analog of the scanning tunneling microscope described in Chapter 1, for example. Electrochemical methods are now widely used in medical diagnostics, where they routinely measure very low concentrations of molecules of clinical significance; current detection limits are the attomole (10^{-18}) level, which is about a million molecules. Finally, the current national interest in alternative energy provides enormous opportunities for research and development in electrochemistry. Solar energy conversion, fuel cells, and energy storage are technologies that rely on electrochemical transformations that occur at the molecular level. Electrochemistry has already made and will undoubtedly make new and important contributions to these technologies in an effort to address the energy problem. New experimental and theoretical understanding of electrochemical processes at the molecular level, along with the opportunities to apply these methods to technological problems of global importance, make it a particularly exciting time to learn about the field.

We begin our discussion of electrochemistry by reviewing redox reactions in aqueous solution, introducing the components of electrochemical cells, and distinguishing galvanic cells from electrolytic cells. We recommend that you review the discussion in Section 11.4 and are familiar with procedures for balancing redox reactions before continuing on to the next section, in which we discuss electrochemical processes from both thermodynamic and molecular points of view, as well as a variety of applications.

17.1 ELECTROCHEMICAL CELLS

Electrochemical reactions interconvert chemical and electrical energy through coupled redox reactions in which, generally, the oxidation and reduction half-reactions are separated in space in **electrochemical cells.** The half-reactions occur on or near the surfaces of **electrodes,** and the electrons produced or consumed are transferred between the electrodes by a wire. The half-reactions are also connected to one another by an ionic conductor, which allows ions to move between the electrodes so that they remain electrically neutral overall. The Gibbs free energy made available in spontaneous redox reactions in **galvanic cells** can be converted into electrical energy, which can be used to do work. Conversely, electrical work done *on* the system by an external power supply in **electrolytic cells** provides a source of free energy to drive redox reactions that are not normally spontaneous. Perhaps the most powerful characteristic of electrochemistry is its ability to control reversible chemical reactions by supplying or extracting electrical energy; this ability enables both very large-scale industrial chemical technologies (making chlorine from salt water or extracting metals from their ores) as well as very sensitive schemes for chemical analysis (sub-picogram sensitivity for clinical applications).

Galvanic Cells

Let's begin by considering the following redox reaction

$$Cu(s) + 2\ Ag^+(aq) \longrightarrow Cu^{2+}(aq) + 2\ Ag(s)$$

which was first discussed in Section 11.4 and illustrated in Figure 11.7. It is clear from the figure that copper metal has been oxidized to form copper ions (which are responsible for the blue color), and silver ions have been reduced to silver metal,

FIGURE 17.1 A metallic copper anode reacts to give a blue solution containing copper(II) ions as silver ions plate out on a silver cathode in a galvanic cell.

which appears in the form of the tree-like structures seen near the bottom of the test tube. The reaction may be written as the sum of two half-reactions:

$$Cu(s) \longrightarrow Cu^{2+}(aq) + 2e^-$$

$$2\ Ag^+(aq) + 2e^- \longrightarrow 2\ Ag(s)$$

which makes it clear that copper metal has been oxidized (it has lost electrons) and silver ions have been reduced (they have gained electrons). Let's now run the same reaction in a galvanic cell, like the one shown in the photograph in Figure 17.1 and also illustrated schematically in Figure 17.2.

The beaker on the left in both cases contains a strip of copper metal immersed in an aqueous solution of $Cu(NO_3)_2$, while the beaker on the right contains a strip of silver metal immersed in an aqueous solution of $AgNO_3$. A wire connects the two metal electrodes, allowing electrons to flow between them, and the ionic conductor connecting the cells in this case is called a **salt bridge** (an ionic solution such as $NaNO_3$ stabilized in a gel or prevented from leaving the bridge by porous plugs on each end). Copper has still been oxidized (as evidenced by the blue color of the $Cu^{2+}(aq)$ ions in Figure 17.1), and silver ions have still been reduced (as could be determined by weighing the silver electrode). The difference, however, is that the energy of the electrons being transferred through the wire in the galvanic cell is available to do work (run an electric motor, for example). The **ammeter** shown in the figure measures the magnitude and the direction of the electrical current that flows between the electrodes (in this case from copper to silver).

Electrochemists have defined a standard terminology and notation that applies to both galvanic and electrolytic cells. The **anode** is always the electrode at which oxidation occurs, and the **cathode** is always the electrode at which reduction occurs; these names were coined by Michael Faraday, along with many other terms used in electrochemistry. The components of electrochemical cells are represented by a shorthand notation, which, for the cell just described, is written as

$$Cu|Cu^{2+}||Ag^+|Ag$$

in which the single vertical lines represent phase boundaries (between the metal electrodes and the electrolyte solution in this example) and the double lines represent the salt bridge. The oxidation (anode) half-reaction is always written on the left, by convention, irrespective of whether the cell is a galvanic cell or an electrolytic cell. Species in aqueous solution are written immediately adjacent to the double line. Commas are used to indicate the presence of different components in the same phase, an aqueous solution of hydrochloric acid being represented as $|H^+, Cl^-|$, for example. Finally, unless otherwise indicated, you may assume that all reactions are carried out

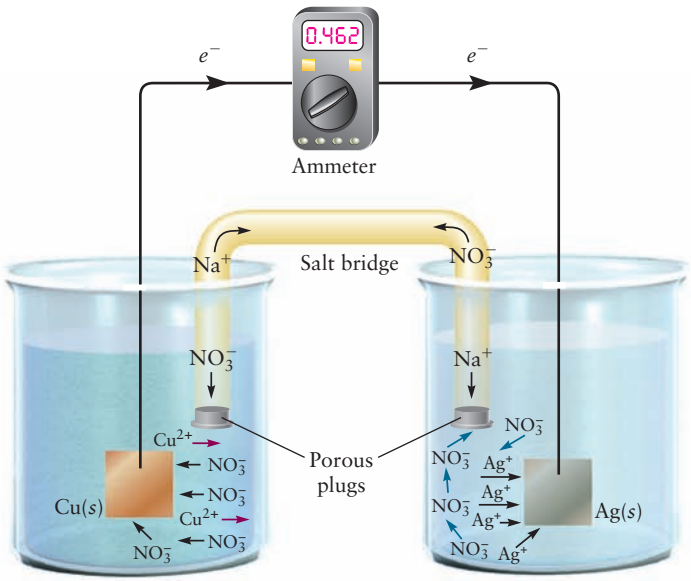

FIGURE 17.2 A schematic of the galvanic cell shown in Figure 17.1. Electrons flow from the copper electrode to the silver electrode through an external circuit and the current is measured with an ammeter. Anions migrate toward the copper electrode and cations move toward the silver electrode in the respective solutions with sodium and nitrate ions moving through the salt bridge to maintain electrical neutrality.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

in aqueous solution and that the shorthand notation used for the ions H^+, Ag^+, and Cl^- implies that we mean $H^+(aq)$, $Ag^+(aq)$, and $Cl^-(aq)$ respectively.

Electrolytic Cells

The galvanic cell reaction described above is spontaneous because the Gibbs free energy change for the reaction as written is negative. This thermodynamic driving force can be related to an electrostatic driving force as follows. We showed in Section 3.3 that systems composed of charged particles spontaneously seek states of the lowest electrostatic potential energy just like mechanical systems spontaneously seek states of the lowest mechanical potential energy. Electrons being transferred in a galvanic cell reaction spontaneously move from a region of higher electrostatic potential energy on the anode to a region of lower electrostatic potential energy on the cathode, in the same way that water flows downhill. Electrons will flow from the anode to the cathode until the potential energies of the electrons in both half-cells are equal to one another, at which point the system has reached equilibrium; there is no longer any electrostatic driving force for the reaction.

Galvanic cell reactions occur spontaneously as written; consequently, their reverse reactions are not spontaneous. The reverse reactions can be made to occur by applying an external driving force that increases the electrostatic potential energies of electrons on the cathode side of the reaction until they are higher than those on the anode side. The external driving force is provided by a power supply in electrolytic cells. Electrons flow in the opposite direction, the species being oxidized when the cell was operating as a galvanic cell is now being reduced, and the anode becomes the cathode and vice versa.

EXAMPLE 17.1

The final step in the production of magnesium from seawater is the electrolysis of *molten* magnesium chloride, with the overall reaction

$$Mg^{2+} + 2\ Cl^- \longrightarrow Mg(\ell) + Cl_2(g)$$

Write equations for the half-reactions occurring at the anode and at the cathode, and identify the direction in which electrons flow through the external circuit.

Solution

Oxidation, the loss of electrons, occurs at the anode, by the half-reaction

$$2\ Cl^- \longrightarrow Cl_2(g) + 2\ e^-$$

Reduction, the gain of electrons, occurs at the cathode, by the half-reaction

$$Mg^{2+} + 2\ e^- \longrightarrow Mg(\ell)$$

Electrons released at the anode, where chlorine is liberated, travel through the external circuit to the cathode, where molten magnesium is produced.

Related Problems: 1, 2

It is customary in electrochemistry to measure the difference between the **electrostatic potential** of the electrons at the cathode and the anode rather than the differences in their electrostatic potential energy. The electrostatic potential is defined as the electrostatic potential energy per unit positive charge:

$$E = E_P/e$$

where E is the symbol for the electrostatic potential (referred to simply as the potential from now on), E_P is the symbol for the electrostatic potential energy (referred to

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

simply as the potential energy from now on) and e is the elementary charge measured in coulombs (C). The SI unit for potential is the volt: $1\ \text{V} = 1\ \text{J C}^{-1}$. The change in the potential energy of a unit positive test charge (defined as $+e$) that results from a change in potential of 1 V is given by

$$\Delta E_P = e\Delta E = (1.602 \times 10^{-19}\ \text{C})(1\ \text{V}) = 1.602 \times 10^{-19}\ \text{J} = 1\text{eV}$$

and the corresponding change that accompanies the transfer of 1 C of charge through a potential difference of 1 V is

$$\Delta E_P = Q\Delta E = (1\ \text{C})(1\ \text{V}) = 1\ \text{J}$$

where we use the symbol Q to represent macroscopic quantities of charge, by analogy to our use of the symbol q to represent microscopic quantities of charge on electrons, nuclei, and ions in earlier chapters.

We now see why electron volts (eV) are such convenient units with which to express the energies of elementary particles or of individual atoms or molecules; they tend to be small numbers that we can talk about easily. The potential energy of a positive elementary charge *increases* by 1 eV when it moves through a potential difference of +1 V. The potential energy of an electron, however, decreases by 1 eV when it moves through a potential difference of +1 V, because the charge on the electron is negative.

$$\Delta E_P = -e\Delta E$$

The electrostatic driving force in electrochemistry is expressed in terms of the potential, rather than the potential energy. Electrons spontaneously move from regions of higher potential energy to regions of lower potential energy, as discussed earlier, or from more negative to more positive potentials. Spontaneous processes are those for which $\Delta E_P < 0$ or $\Delta E > 0$. These are equivalent statements, but you should be alert to the fact that the signs are opposites of one another and that spontaneous processes are characterized by *increases* in the potential, in contrast to what you have been used to seeing for spontaneous processes expressed in terms of changes in thermodynamic variables. We connect the two driving forces in the next section. **Voltmeters** measure the potential differences between two half-cells, the result being the **cell potential** (or voltage) as discussed later. Reversing the direction of a spontaneous process requires the application of an external potential that is greater in magnitude and opposite in sign to the potential of the spontaneous reaction. External potentials can be applied by inserting a power supply or a battery in the circuit of an electrolytic cell as shown in Figure 17.3.

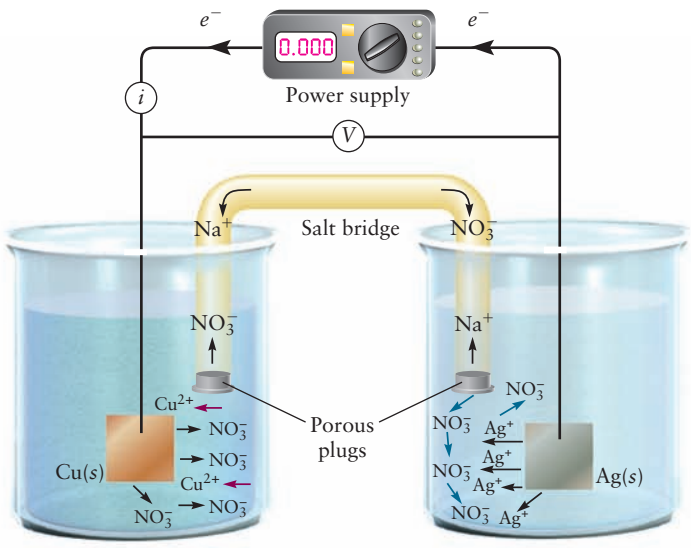

FIGURE 17.3 The spontaneous reaction in the galvanic cell shown in Figure 17.2 can be reversed by the application of an external potential from a power supply connected into the circuit as shown schematically. The power supply is in the off position in the figure; the meter would read either voltage or current during operation.

Faraday's Laws

Alessandro Volta discovered the galvanic cell in 1800 and constructed a "battery of cells" consisting of a number of platelets of silver and zinc that were separated from one another by porous strips of paper saturated with a salt solution. This voltaic pile, as it was then known, demonstrated that electricity could be produced by chemical reactions. By 1807, Sir Humphry Davy had prepared elemental sodium and potassium using a battery to electrolyze their respective hydroxides, demonstrating that electricity could drive chemical reactions. Michael Faraday was the first to demonstrate quantitative relationships between the amount of charge that flowed and the quantities of materials produced or consumed in electrochemical reactions, from which he asserted the fundamental duality of these processes: "the electricity which decomposes, and that which is evolved by the decomposition of, a certain quantity of matter, are alike." Faraday arranged a series of electrochemical cells through which the same amount of charge was passed and measured the quantities of the materials produced or consumed. The relationships he discovered are known as **Faraday's laws,** which we state as follows:

1. The mass of a given substance that is produced or consumed in an electrochemical reaction is proportional to the quantity of electric charge passed.
2. Equivalent masses[1] of different substances are produced or consumed in electrochemical reactions by a given quantity of electric charge passed.

These laws, which summarize the stoichiometry of electrochemical processes, were discovered by Michael Faraday in 1833, more than half a century before the electron was discovered and the nature of electricity was understood on the atomic scale. Faraday also measured, for the first time, the charge to mass ratio of the hydrogen ion, long before its chemical nature had been definitively established, by measuring the amount of charge required to generate 1 g of hydrogen gas. The value he obtained (about 1000 times smaller than e/m_e) provided a benchmark against which J. J. Thomson would later compare the charge to mass ratio of the electron and conclude that "the charge on the electron must be very large or the mass of the electron must be very small, compared to the hydrogen ion."

Let's express Faraday's laws in modern terms and relate the changes in masses observed to the charge that flows in electrochemical experiments. The charge e on a single electron (expressed in coulombs) has been very accurately determined to be

$$e = 1.60217646 \times 10^{-19}\ \text{C}$$

so the charge of one mole of electrons is equal to

$$\begin{aligned} Q &= (6.0221420 \times 10^{23}\ \text{mol}^{-1})(1.60217646 \times 10^{-19}\ \text{C}) \\ &= 96{,}485.34\ \text{C} \end{aligned}$$

which is an enormously large quantity of charge, as shown in the chapter opening photograph on page 763. The charge of one mole of electrons has been given a special name and symbol, the **Faraday constant,**

$$F = 96,485.34\ \text{C mol}^{-1}$$

in recognition of the central importance of the mole concept in chemistry.

[1]The electron had not yet been discovered at the time of Faraday's experiments and so he was only able to assert that there were "equivalent masses" produced or consumed when a certain amount of charge was passed. The modern definition of the equivalent mass of an element or a compound in a redox reaction is its molar mass divided by the number of moles of electrons transferred per mole of substance in the corresponding half-reaction.

We typically measure the total charge passed in electrochemical experiments by measuring the current and the time. The **electric current** is the amount of charge that flows through a circuit per second, measured in the SI base unit, the ampere (A). The coulomb (C), a derived unit, is defined as the total charge transferred by 1 A of current flowing for one second.

$$1\ \text{C} = (1\text{A})(1\ \text{s}) \qquad [17.1]$$

We can use Equation 17.1 to calculate the total charge that has passed when a current of i amperes has flowed for t seconds as

$$Q = it$$

or express the number of moles of electrons n transferred as

$$n = \frac{it}{96{,}485\ \text{C mol}^{-1}}$$

We can calculate the number of moles (and therefore the number of grams) of reactants consumed and products formed in electrochemical reactions if we know how many electrons are transferred in a particular reaction and how many moles of electrons have passed through the cell. Suppose, for example, that we have a zinc–silver galvanic cell in which the anode half-reaction is

$$\text{Zn}(s) \longrightarrow \text{Zn}^{2+}(aq) + 2\ e^-$$

and the cathode half-reaction is

$$\text{Ag}^+(aq) + e^- \longrightarrow \text{Ag}(s)$$

Each mole of electrons produced arises from the oxidation of 1/2 mol of zinc metal (because each Zn atom gives up two electrons) and causes the reduction of 1 mol of silver ions. From the molar masses of silver and zinc, we calculate that (65.38)/2 = 32.69 g of zinc is dissolved at the anode, and 107.87 g of silver is deposited at the cathode. The same relationships hold if the cell is operated as an electrolytic cell, but in that case silver is dissolved and zinc is deposited.

EXAMPLE 17.2

An electrolytic cell is constructed in which the silver ions in silver chloride are reduced to silver at the cathode and copper is oxidized to $\text{Cu}^{2+}(aq)$ at the anode. A current of 0.500 A is passed through the cell for 101 minutes. Calculate the mass of copper dissolved and the mass of silver deposited.

Solution

$$t = (101\ \text{min})(60\ \text{s min}^{-1}) = 6.06 \times 10^3\ \text{s}$$

The number of moles of electrons passed through the circuit during this time is given by

$$n = \frac{(0.500\ \text{C s}^{-1})(6.06 \times 10^{-3}\text{s})}{96{,}485\ \text{C mol}^{-1}} = 3.14 \times 10^{-2}\ \text{mol}\ e^-$$

The half-cell reactions are

$$\text{AgCl}(s) + e^- \longrightarrow \text{Ag}(s) + \text{Cl}^-(aq) \qquad \text{(cathode)}$$

$$\text{Cu}(s) \longrightarrow \text{Cu}^{2+}(aq) + 2\ e^- \qquad \text{(anode)}$$

so the masses of silver deposited and copper dissolved are

$$\text{mass Ag} = (3.14 \times 10^{-2}\ \text{mol } e^-) \times \left(\frac{1\ \text{mol Ag}}{1\ \text{mol } e^-}\right) \times (107.78\ \text{g mol}^{-1})$$

$$\text{mass Ag} = 3.39\ \text{g Ag deposited}$$

$$\text{mass Cu} = (3.14 \times 10^{-2}\ \text{mol } e^-) \times \left(\frac{1\ \text{mol Cu}}{2\ \text{mol } e^-}\right) \times (63.55\ \text{g mol}^{-1})$$

$$\text{mass Cu} = 0.998\ \text{g Cu dissolved}$$

Related Problems: 3, 4, 5, 6

17.2 CELL POTENTIALS AND THE GIBBS FREE ENERGY

We discussed pressure–volume work in Chapters 12 and 13 and, in particular, demonstrated that the maximum work done either on or by the system occurs for reversible processes. We now consider a different kind of work, **electrical work,** which is fundamental in electrochemistry, and we investigate its properties. We showed earlier that the change in the potential energy associated with the transfer of $\mathcal{Q}$ coulombs of *negative* charge through a potential difference ΔE is given by

$$\Delta E_P = -\mathcal{Q}\Delta E$$

It is customary in electrochemistry to refer to the difference in the potential simply as the cell potential E_{cell} so the change in the potential energy is written as

$$\Delta E_P = -\mathcal{Q}E_{cell}$$

where E_{cell} is measured in volts and ΔE_P is measured in joules. The change in the potential energy *of the electrons* is defined as the **electrical work**

$$w_{elec} = \Delta E_P = -\mathcal{Q}E_{cell} \qquad [17.2]$$

where $E_{cell} = E_{cathode} - E_{anode}$, by convention.

We can also write Equation 17.2 in terms of the current and the time as

$$w_{elec} = -itE_{cell}$$

Work is done *on* the system when electrons move from regions of more positive potentials to regions of more negative potentials (increasing their potential energy) and work is done *by* the system when electrons move from regions of more negative potentials to regions of more positive potentials (decreasing their potential energy). The cell potential E_{cell} is positive for galvanic cells, which can produce electrical work, and negative for electrolytic cells in which electrical work is done *on* the system by an external power supply.

EXAMPLE 17.3

A 6.00 V battery delivers a steady current of 1.25 A for a period of 1.50 hours. Calculate the total charge $\mathcal{Q}$, in coulombs, that passes through the circuit and the electrical work done *by* the battery.

Solution

Recalling that 1 A = 1 C s^{-1} and 1 V = 1 J C^{-1} we calculate the total charge as

$$\mathcal{Q} = it = (1.25\ \text{C s}^{-1})(1.50\ \text{hr})(3600\ \text{s hr}^{-1}) = 6750\ \text{C}$$

and the electrical work as

$$w_{elec} = -QE_{cell} = -(6750\ C)(6.00\ J\ C^{-1}) = -4.05 \times 10^4\ J$$

This is the work done *on* the battery, so the work done *by* the battery is the negative of this quantity, or +40.5 kJ.

The change in the Gibbs free energy not only predicts the direction of spontaneous change but is also equal to the reversible work done (other than pressure–volume work) on or by the system at constant temperature and pressure, which we identify as the electrical work w_{elec} as follows:

$$w_{elec,rev} = \Delta G \qquad \text{(at constant } P \text{ and } T\text{)} \qquad [17.3]$$

We derive this result beginning with the definition of the Gibbs free energy function *G:*

$$G = H - TS = U + PV - TS$$

For processes occurring at constant pressure P and constant temperature T (the usual case in electrochemical cells),

$$\Delta G = \Delta U + P\Delta V - T\Delta S$$

The first law of thermodynamics is

$$\Delta U = q + w$$

which may be rewritten as

$$\Delta U = q + w_{elec} - P\Delta V$$

to explicitly identify electrical work w_{elec} and pressure–volume work, which is $-P_{ext}\Delta V = -P\Delta V$ at constant pressure. Substituting for ΔU into the equation for the change in the Gibbs free energy gives

$$\Delta G = q + w_{elec} - P\Delta V + P\Delta V - T\Delta S = q + w_{elec} - T\Delta S$$

For electrochemical reactions that are run reversibly (which is rather easy to achieve in practice by controlling the current)

$$q = q_{rev} = T\Delta S$$

allowing us to show that reversible electrical work is equal to the change in the Gibbs free energy

$$w_{elec,rev} = \Delta G$$

The change in the Gibbs free energy of the system is negative for a galvanic cell, and so the electrical work is done *by* the system. Energy, in the form of useful electrical work, is extracted *from* the system and made available to do work *on* the surroundings. The opposite is true for electrolytic cells. Work is done *on* the system, increasing its Gibbs free energy, most commonly as an increase in the potential energy of the electrons. The maximum work done on or by electrochemical cells is done when they operate reversibly, because they are working against the maximum possible opposing force at all times, just like for reversible PV work. Cells operating irreversibly (in other words, with large currents permitted to flow) produce less electrical work than those operating reversibly.

The electrical work w_{elec} is also equal to the product of the charge transferred and the difference in the electrostatic potential energy, which can be calculated as follows

$$w_{elec,rev} = \Delta G = -nFE_{cell}$$

for n moles of electrons moving through a potential difference ΔE_{cell}. Galvanic cells, for which $E_{cell} > 0$, can produce electrical work, whereas electrolytic cells, for which $E_{cell} < 0$, consume electrical work.

The preceding two paragraphs appear to contradict one another; they do, in principle, but not in practice. No current flows when cells operate reversibly, by definition; infinitesimal changes in conditions cause small currents to flow in one direction or the other, and reversibility can be achieved by controlling the conditions. Useful work can be extracted from galvanic cells, and the amount of work can be calculated using the preceding equation essentially because 1 mol of electrons is a very large number. A 1A current flowing for an hour, for example, transfers $\mathcal{Q} = (1\text{C s}^{-1})(3600\text{ s}) = 3600\text{ C} = 0.047$ mol, which is negligibly small for an electrochemical reaction in which 1A current is flowing.

Standard States and Standard Cell Potentials

Recall from Chapters 12 and 14 that the *standard states* of chemical substances are defined at 1 atm pressure and at a specified temperature. Electrochemists use *activities* (see Section 14.3) to define standard states, the standard states of gases and solutes being defined at unit activity. Recall that the standard state for solutes is defined to be a *hypothetical* state in which the solute concentration is 1 M, but the solute behaves as if it were ideal. The potential of the standard hydrogen electrode (SHE), the primary reference electrode used in electrochemistry (see p. 773), is defined under conditions of unit activity for the hydrogen ions in solution as well as unit activity for the hydrogen gas in equilibrium with the electrolyte. We specify concentrations in molarity in this chapter, but alert you to be mindful of the distinction when reading more advanced treatments of the subject. The standard free energy change ΔG^{o} for a reaction in which all reactants and products are in their standard states can be calculated from a table of standard free energies of formation ΔG_{f}^{o} of the reactants and the products (see Appendix D). We have shown that the cell potential is related to the change in the Gibbs free energy for reversible processes, allowing us to define a **standard cell potential** E_{cell}^{o} as

$$\Delta G^{o} = -nFE_{cell}^{o} \qquad \text{(reversible)} \qquad [17.4]$$

in which all reactants and products are in their standard states (gases at 1 atm pressure, solutes at 1 M concentration, pure metals in their most stable states and at a specified temperature). It is important to note that the condition of reversibility implies that no current is flowing. Standard cell potentials are measured using voltmeters having extremely high internal resistance to ensure that this is the case; these potentials are also referred to as *equilibrium* or *open-circuit* potentials. Standard cell potentials are intrinsic electrical properties of electrochemical cells that can be calculated from the associated standard free energy changes ΔG^{o} using Equation 17.4. Conversely, and perhaps more importantly, ΔG^{o} (and hence equilibrium constants) for a variety of chemical reactions can be determined simply by measuring the standard cell potentials ($\mathscr{E}_{cell}^{o}$) for reactions that can be carried out by electrochemical means. Many tabulated equilibrium constants have, in fact, been measured using electrochemical methods because they are more convenient and, often, more accurate than other methods. For example, the concentrations of ions in solutions of sparingly soluble salts (see Section 16.1) are quite low but can be readily determined by measuring cell potentials.

EXAMPLE 17.4

A $Zn^{2+}|Zn$ half-cell is connected to a $Cu^{2+}|Cu$ half-cell to make a galvanic cell, in which $[Zn^{2+}] = [Cu^{2+}] = 1.00$ M. The cell potential at 25°C is measured to be $E^{o}_{cell} = 1.10$ V, which corresponds to the overall cell reaction

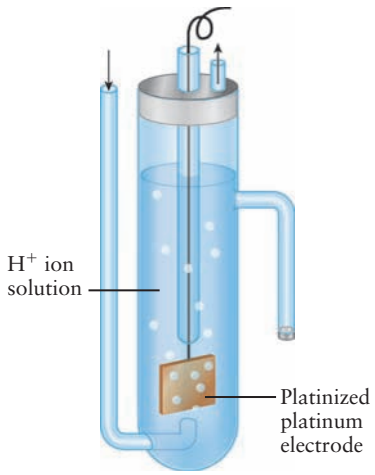
$$Zn(s) + Cu^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Cu(s)$$

Calculate ΔG^{o} for this reaction under the given conditions.

Solution

$$\Delta G^{o} = -nFE^{o}_{cell} = -(2.00 \text{ mol})(96{,}485 \text{ C mol}^{-1})(1.10 \text{ V})$$
$$= -2.12 \times 10^{5} \text{ J} = -212 \text{ kJ}$$

Related Problems: 11, 12



Standard Reduction Potentials

We could tabulate cell potentials for every conceivable electrochemical reaction, but the list would be very long. We can construct electrochemical cells in which one half-reaction has been chosen to be our reference half-reaction and then measure the cell potentials that result when this reference half-reaction is coupled to all other half-reactions of interest. This procedure is analogous to the one we used to find the changes in internal energy, enthalpy, entropy, and Gibbs free energy for chemical reactions using the standard energies and enthalpies of formation, absolute entropies, and standard Gibbs free energies of formation.

The primary reference electrode has been chosen, by convention, to be the **standard hydrogen electrode** (SHE), often called the **normal hydrogen electrode** (NHE) by electrochemists. The standard hydrogen electrode, as illustrated in Figure 17.4, consists of a platinum electrode immersed in a solution in which $[H_3O^+] = 1$ M $(a_{H_3O^+} = 1)$, under a hydrogen partial pressure $p_{H_2} = 1$ atm $(a_{H_2} = 1)$.

Cell potentials for a number of half-reactions have been measured with reference to the SHE, which has been defined to be 0.00 V, and the results tabulated as standard *reduction* potentials by convention (see Appendix E). Half-reactions with positive potentials, with respect to SHE, proceed as reductions whereas half-reactions with negative potentials, with respect to SHE, proceed as oxidations. Standard cell potentials for any electrochemical cell can be calculated from standard reduction potentials using

$$E^{o}_{cell} = E^{o}_{cathode} - E^{o}_{anode} \qquad [17.5]$$

Standard hydrogen electrode

FIGURE 17.4 Schematic of a standard hydrogen electrode.

where $E^{o}_{cathode}$ is the standard reduction potential for the reaction occurring at the cathode (reduction) and E^{o}_{anode} is the standard reduction potential for the reaction occurring at the anode (oxidation). The procedure for finding standard cell potentials for any cell is simple:

1. Identify the cathode half-reaction.
2. Identify the anode half-reaction.
3. $E^{o}_{cell} = E^{o}_{cathode} - E^{o}_{anode}$

Reactions for which $E^{o} > 0$ are spontaneous as written and can be used to construct galvanic cells; those for which $E^{o}_{cell} < 0$ are not spontaneous as written and can be driven only by applying an external potential in electrolytic cells. The procedure we just described for finding cell potentials *always works* and can help avoid confusion with sign conventions when working electrochemical problems.

Let's illustrate this procedure for calculating a standard cell potential using the $Zn|Zn^{2+}||Cu^{2+}|Cu$ cell described in Example 17.4. The overall reaction is

$$Zn(s) + Cu^{2+}(aq) \longrightarrow Cu(s) + Zn^{2+}(aq)$$

in which $Cu^{2+}(aq)$ is reduced at the cathode and $Zn(s)$ is oxidized at the anode. The standard reduction potentials of the two half-reactions obtained from Appendix E are:

$$Zn^{2+}(aq) + 2\,e^{-} \longrightarrow Zn(s) \qquad E^{o} = -0.76\ V$$

$$Cu^{2+}(aq) + 2\,e^{-} \longrightarrow Cu(s) \qquad E^{o} = \ \ 0.34\ V$$

and so the standard cell potential for the $Zn|Zn^{2+}||Cu^{2+}|Cu$ cell is

$$E^{o}_{cell} = E^{o}_{cathode} - E^{o}_{anode} = 0.34\ V - (-0.76\ V) = 1.10\ V$$

in agreement with the value measured in Example 17.4. Note that it is conventional in electrochemistry to write positive potentials without explicitly including the sign.

The standard reduction potentials tabulated in Appendix E are arranged in order, with the most positive potentials at the top and the most negative potentials at the bottom. We can determine immediately by inspection whether a given reaction will be spontaneous or not; galvanic cells are those for which the reduction potential of the cathode half-reaction is more positive (higher on the list) than the reduction potential of the anode half-reaction (lower on the list), as long as both half-cells are in their standard states.

The procedure we have just outlined can be used to find cell potentials from standard reduction potentials for any reaction of interest, even those for which it is necessary to multiply one half-reaction by an integer to balance the charge transferred in the overall cell reaction. Let's calculate the cell potential for the $Cu|Cu^{2+}||Ag^{+}|Ag$ cell we introduced at the beginning of the chapter. The reaction is

$$2\ Ag(s) + Cu^{2+}(aq) \longrightarrow 2\ Ag^{+}(aq) + Cu(s)$$

which we can represent as the sum of the following two half-reactions:

$$2\ Ag^{+}(aq) + 2\,e^{-} \longrightarrow 2\ Ag(s)$$

$$Cu(s) \longrightarrow Cu^{2+}(aq) + 2\,e^{-}$$

$$2\ Ag(s) + Cu^{2+}(aq) \longrightarrow 2\ Ag^{+}(aq) + Cu(s)$$

We identify the reduction of Ag^{+} as the cathode half-reaction and calculate the standard cell potential as before:

$$E^{o}_{cell} = E^{o}_{cathode} - E^{o}_{anode} = 0.799\ V - 0.34\ V = 0.459\ V$$

Note that we did *not* multiply the standard reduction potential for the half-reaction $Ag^{+}(aq) + e^{-} \longrightarrow Ag(s)$ by 2 when calculating the standard cell potential because potentials are intensive quantities that do not depend upon the quan-

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tity of material involved. The cell potential is simply the difference in the potentials of the two half-reactions. The change in potential energy, on the other hand, or that of any other extensive thermodynamic property of interest, does depend on the quantity of material involved. The change in the Gibbs free energy of the system discussed previously, for example, is

$$\Delta G^\circ = -nFE^\circ_{\text{cell}} = (-2 \text{ mol})(96{,}500 \text{ C mol}^{-1})(0.459 \text{ V}) = -0.886 \text{ kJ}$$

which also equals the electrical work done *by* the system.

Suppose we want to find the standard reduction potential for a half-reaction that is not listed in Appendix E. We could write the half-reaction of interest as the sum or difference of a pair of half-reactions tabulated in Appendix E. The number of electrons transferred in the reaction of interest, however, may be different than the numbers of electrons transferred in the standard reactions, and so we must first calculate the Gibbs free energy change for the reaction and then calculate the standard cell potential using Equation 17.4, as illustrated by the following example.

Suppose we want to find the standard reduction potential for the half-reaction

$$Cu^{2+} + e^- \longrightarrow Cu^+ \qquad E^\circ_3(Cu^{2+}|Cu^+) = ?$$

using the following standard reduction potentials from Appendix E.

$$Cu^{2+} + 2\,e^- \longrightarrow Cu \qquad E^\circ_1 = E^\circ(Cu^{2+}|Cu) = 0.340 \text{ V}$$

$$Cu^{+} + e^- \longrightarrow Cu \qquad E^\circ_2 = E^\circ(Cu^{+}|Cu) = 0.522 \text{ V}$$

We calculate the change in the Gibbs free energy as

$$\Delta G^\circ_3 = \Delta G^\circ_1 - \Delta G^\circ_2$$

$$-n_3FE^\circ_3 = -n_1FE^\circ_1 - (-n_2FE^\circ_2) = -n_1FE^\circ_1 + n_2FE^\circ_2$$

$$E^0_3 = \frac{n_1E^\circ_1 - n_2E^\circ_2}{n_3}$$

The standard reduction potential for the half-reaction

$$Cu^{2+} + e^- \longrightarrow Cu^+$$

therefore, is

$$E^\circ_3(Cu^{2+}|Cu^+) = \frac{(2 \text{ mol})(0.340 \text{ V}) - (1 \text{ mol})(0.522 \text{ V})}{1 \text{ mol}} = 0.158 \text{ V}$$

We can also use the procedure just described to calculate cell potentials for reactions of interest from standard reduction potentials, but the number of electrons in the numerator and the denominator will always be equal to one another and will cancel out; it is easier, therefore, to use the expression defined above:

$$E_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$$

EXAMPLE 17.5

An aqueous solution of potassium permanganate ($KMnO_4$) appears deep purple. The permanganate ion can be reduced to the pale-pink manganese(II) ion (Mn^{2+}) in aqueous acidic solutions. The standard reduction potential of an MnO_4^-, Mn^{2+} half-cell is $E^\circ_{\text{cell}} = 1.49$ V. Suppose this half-cell is combined with a $Zn^{2+}|Zn$ half-cell in a galvanic cell, with $[Zn^{2+}] = [MnO_4^-] = [Mn^{2+}] = [H_3O^+] = 1$ M.

(a) Write equations for the reactions at the anode and the cathode.

(b) Write a balanced equation for the overall cell reaction.

(c) Calculate the standard cell potential difference, E°_{cell}.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

(a) Permanganate ions will be reduced at the cathode because $E°(MnO_4^-, Mn^{2+}) = 1.49$ V is more positive than $E°(Zn^{2+}|Zn) = -0.76$ V. The balanced half-cell reaction requires the presence of H_3O^+ ions and water, giving

$$MnO_4^- + 8\ H_3O^+ + 5\ e^- \longrightarrow Mn^{2+} + 12\ H_2O$$

The anode half-reaction for the oxidation of Zn is

$$Zn \longrightarrow Zn^{2+} + 2\ e^-$$

(b) The number of electrons delivered to the cathode must equal the number of electrons released by the anode, so the first equation must be multiplied by 2 and the second equation by 5 before adding them together to give the overall reaction:

$$2\ MnO_4^- + 16\ H_3O^+ + 5\ Zn \longrightarrow 2\ Mn^{2+} + 24\ H_2O + 5\ Zn^{2+}$$

(c) The galvanic cell potential is the difference between the standard reduction potential for permanganate (at the cathode) and that for zinc (at the anode):

$$E° = E°(MnO_4^-, Mn^{2+}) - E°(Zn^{2+}|Zn) = 1.49 - (-0.76) = 2.25\ V$$

Note that the half-cell potentials are not multiplied by their coefficients (2 and 5) before subtraction. Half-cell potentials are *intensive* properties of a galvanic cell and are therefore independent of the amount of the reacting species.

Related Problems: 13, 14

Oxidizing and Reducing Agents

Strong **oxidizing agents** are chemical species that are themselves easily reduced. These species are characterized by large positive reduction potentials and appear at the top of the list in Appendix E. Fluorine has the most positive reduction potential listed, and fluorine molecules are extremely eager to accept electrons to become fluoride ions, as expected from fluorine's large electron affinity. Other strong oxidizing agents include hydrogen peroxide (H_2O_2) and aqueous solutions of permanganate ions (MnO_4^-). Strong **reducing agents,** on the other hand, are easily oxidized with very negative reduction potentials, and they are listed near the bottom of the table in Appendix E. The alkali and alkaline earth metals are especially good reducing agents, as expected from their low ionization potentials.

Oxygen itself is a good oxidizing agent in acidic solution at pH 0 because it has a reasonably positive standard reduction potential:

$$O_2 + 4\ H_3O^+ + 4\ e^- \longrightarrow 6\ H_2O \qquad E^o = 1.229\ V$$

Ozone (O_3) is an even stronger oxidizing agent than molecular oxygen, as shown by its more positive half-cell reduction potential in acidic aqueous solution:

$$O_3 + 2\ H_3O^+ + 2\ e^- \longrightarrow O_2 + 3\ H_2O \qquad E^o = 2.07\ V$$

Ozone is a stronger reducing agent than O_2 because its Gibbs free energy of formation (from O_2) is positive, which makes ΔG for the reduction of $H_3O^+(aq)$ by ozone more negative than for its reduction by O_2. The strong oxidizing power of ozone is exploited commercially as a bleach for wood pulp, and as a disinfectant and sterilizing agent for water, where it oxidizes algae and organic impurities but leaves no undesirable residue. The corresponding half-reactions in basic solutions are mediated by hydroxide ions, and the reduction potentials are different. Both oxygen and ozone are less effective oxidizing agents in basic solutions than in acidic solutions, as can be seen from their standard reduction potentials at pH 14 (stan-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

dard basic conditions), which are significantly less positive than those under acidic conditions.

$$O_2 + 2\ H_2O + 4\ e^- \longrightarrow 4\ OH \qquad E^o = 0.401\ V$$

$$O_3 + H_2O + 2\ e^- \longrightarrow O_2 + 2\ OH \qquad E^o = 1.24\ V$$

Reduction Potential Diagrams and Disproportionation

We can summarize the half-reactions of copper in a **reduction potential diagram** of the form

in which the species are arranged in sequence with the most oxidized form on the left and the most reduced form on the right. The standard reduction potential for each of the three half-reactions is written above the line that connects the half-reactions. Diagrams like these are very useful in helping us predict which ions are unstable with respect to *disproportionation,* a process in which a pair of ions in the same oxidation state are oxidized and reduced (see Example 11.10). Species will disproportionate if the driving force for reduction is greater than the driving force for oxidation; the decrease in the Gibbs free energy of the reduction half-reaction pays for the decrease in the Gibbs free energy of the oxidation half-reaction. The diagram is a useful way to quickly determine if this is the case. A species will undergo a disproportionation reaction if the reduction potential for the half-reaction connecting the species in the center to the one on the right is more positive than the half-reaction connecting the species in the center to the one on the left. The disproportionation reaction for Cu^+ is

$$2\ Cu^{2+} \longrightarrow Cu^+ + Cu \quad E^o = 0.552\ V - 0.158\ V = 0.324\ V$$

This spontaneous reaction ($E^o > 0$) is responsible for the negligible concentrations of Cu^+ found in aqueous solution. Interestingly enough, most transition metals, in fact, do not form stable M^+ ions in aqueous solution for this reason. The energy required to further ionize M^+ (essentially the second ionization energy, IE_2) is paid for by the large energy of hydration of M^{2+}, making the disproportionation reaction thermodynamically favorable overall.

EXAMPLE 17.6

Hydrogen peroxide, H_2O_2, is a possible product of the reduction of oxygen in acidic solution:

$$O_2 + 2\ H_3O^+ + 2\ e^- \longrightarrow H_2O_2 + 2\ H_2O \qquad E^o_3 = ?$$

It can then be further reduced to water:

$$H_2O_2 + 2\ H_3O^+ + 2\ e^- \longrightarrow 4\ H_2O \qquad E^o_2 = 1.77\ V$$

(a) Use the half-cell potential just given for the reduction of H_2O_2, together with that given earlier,

$$O_2 + 4\ H_3O^+ + 4\ e^- \longrightarrow 6\ H_2O \qquad E^o_1 = 1.229\ V$$

to calculate the standard half-cell potential for the reduction of O_2 to H_2O_2 in acidic solution.

(b) Write a reduction potential diagram for O_2, H_2O_2, and H_2O.

(c) Is H_2O_2 stable with respect to disproportionation in acidic solution?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution

(a) The desired half-cell reaction is obtained by *subtracting* the reaction with potential E_2° from that with potential E_1°. The half-cell reduction potentials are not subtracted, however, but rather combined as described earlier in this section. Taking $n_1 = 4$, $n_2 = 2$, and $n_3 = 2$ gives

$$E_3^\circ = \frac{n_1E_1^\circ - n_2E_2^\circ}{n_3}$$

$$= \frac{(4\text{ mol})(1.229\text{ V}) - (2\text{ mol})(1.77\text{ V})}{2\text{ mol}} = 0.69\text{ V}$$

(b) The reduction potential diagram is obtained by omitting the electrons, water, and H_3O^+ from the corresponding half-equations:

$$O_2 \xrightarrow{0.69\text{ V}} H_2O_2 \xrightarrow{1.77\text{ V}} H_2O$$

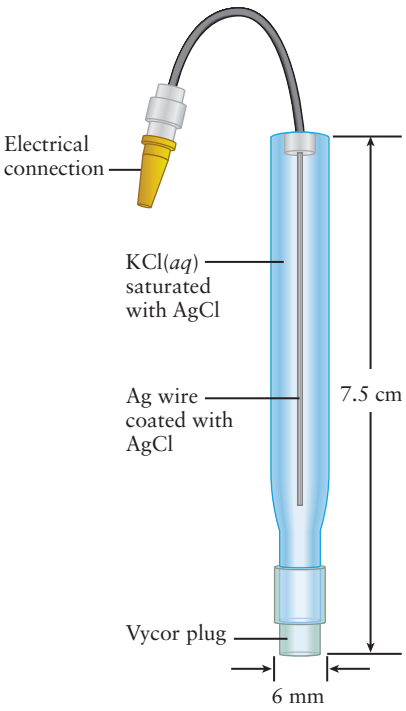
$$O_2 \xrightarrow{\qquad 1.229\text{ V} \qquad} H_2O$$

(c) H_2O_2 is thermodynamically unstable to disproportionation in acidic solution because the half-cell potential to its right (1.77 V) is higher than that to its left (0.69 V). The disproportionation of H_2O_2 is also spontaneous in neutral solution, but it is slow enough that aqueous solutions of hydrogen peroxide can be stored for a long time without deteriorating, as long as they are kept out of the light.

Related Problems: 23, 24, 25, 26

Alternative Reference Electrodes

The SHE is not particularly convenient to use in practice, so several alternative reference electrodes have been developed. The **saturated calomel electrode** (SCE) was the most popular alternative reference electrode for many years, but it is being phased out due to environmental concerns over mercury. The SCE consists of a platinum wire in electrical contact with a paste of liquid mercury, calomel [$Hg_2Cl_2(s)$], and a saturated solution of KCl. The reduction half-reaction is



$$Hg_2Cl_2 + 2\,e^- \longrightarrow 2\,Hg + 2\,Cl^-\ (\text{saturated})$$

with a reduction potential $E^\circ = 0.242$ V. The Ag/AgCl electrode, represented as Ag|AgCl|KCl (saturated, aqueous) electrode, which consists of a thick AgCl coating on a silver wire, is a very convenient alternative to both the SHE and SCE reference electrodes. A relatively thick coating of AgCl on Ag is prepared simply by oxidizing a silver wire in a solution that contains chloride ions. The reduction half-reaction is

$$AgCl + e \longrightarrow Ag + Cl^-$$

with a reduction potential $E^\circ = 0.197$ V.

It is convenient to represent the various standard reference potentials graphically so that we may easily convert cell potentials measured using different reference electrodes to the SHE reference potential. The connection is made most easily by representing potentials on a potential energy diagram, of the type we introduced in Section 5.4. We associate the potentials of redox couples with atomic and molecular energy levels in an approximate way as illustrated in the energy level diagram shown in Figure 17.5. An absolute potential for a given half-reaction may be defined with respect to the potential of a free electron at rest in a vacuum, which we set to zero. This reference state, with the electron infinitely far away from the

Schematic of a saturated calomel electrode.

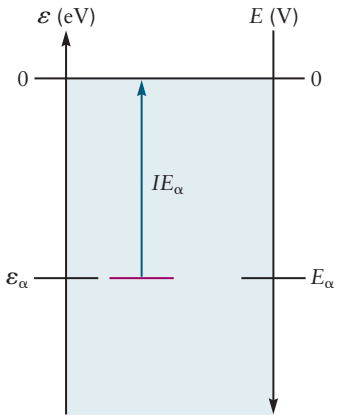

FIGURE 17.5 Relationship between orbital energy level (left) and potential (right). The arrows on both vertical axes indicate the direction in which the measured quantities are becoming more positive.

cation and with no kinetic energy, is exactly the same reference state that we chose to define the zero of energy with which to assign orbital energies, as determined using photoelectron spectroscopy. We plot energy, ε, in electron volts on the vertical axis on the left and potential, E, in volts on the vertical axis on the right. We chose ε to label the orbital energy in this plot to avoid confusion with E, the symbol we have reserved for potential in this chapter, as well as to be consistent with the energy level diagrams in Chapters 4 through 6.

Orbital energies are determined by measuring ionization potentials and invoking Koopman's approximation, $\varepsilon_\alpha = -IE_\alpha$, where ε_α is the energy of a particular orbital and IE_α is the energy required to remove an electron from that orbital. We have plotted a potential scale on the right-hand side of the diagram using the approximate (but reasonably accurate) relationship $\varepsilon_\alpha = -eE_\alpha$ that connects the energy of an orbital to a redox potential. The relationship is only approximately correct, however, because redox potentials are actually related to thermodynamic *free energies*, whereas orbital energies are just the *energies* of the various quantum states of the atoms or molecules that comprise the system. The approximation turns out to be a good one, for two reasons: (1) the change in entropy associated with simple redox reactions is much smaller than the change in enthalpy, so entropic contributions can be ignored, and (2) the change in enthalpy is very nearly the same as the change in energy for reactions carried out in solution (see Sec. 12.3). Making this approximation allows us to interpret the driving forces responsible for electrochemical processes in terms of the change in energy associated with the transfer of electrons between atomic and molecular energy levels. It also helps us visualize these processes at the molecular level, in the same way that we use energy level diagrams to help visualize physical processes, like ionization and electron attachment, and chemical bond formation.

An "absolute" potential scale for the SHE has been established by estimating the energy required to remove an electron from $Pt|H_2|H^+$ under standard conditions and transfer it to a vacuum at rest. The energy associated with this process can be thought of as the ionization energy of a hydrogen atom to produce an electron and H^+ under the standard conditions defined for the SHE. A value of 4.5 eV has been established for this ionization energy using a combination of theory (statistical mechanics, see Chapter 9) and experiment. We can now identify the energy of the associated orbital using Koopman's approximation as $\varepsilon_H = -IE_H = -4.5$ eV and define an absolute potential for this reference half-reaction as $E_H = \varepsilon_H/(-e) = 4.5$ V, equations that are illustrated in the energy level diagram shown in Figure 17.6. We can now represent the potentials of different half-reactions and different reference electrodes on a common energy level diagram, as shown in Figure 17.7. This diagram allows us

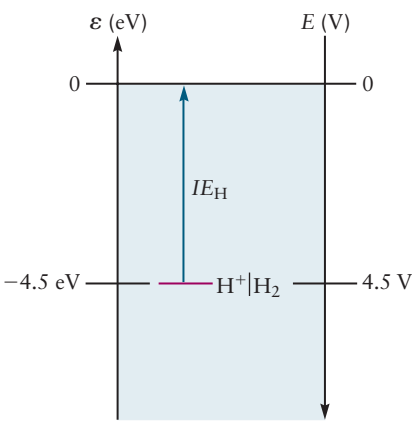

FIGURE 17.6 Orbital energy level for the SHE (left) and the "absolute" (vacuum) potential (right).

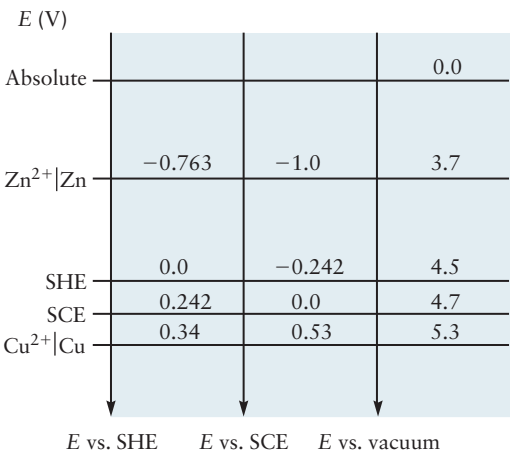

FIGURE 17.7 Relationships among SHE, SCE, and absolute (vacuum) potential scales.

to convert from one scale to another very quickly by inspection, for example, (E vs. SHE) = (E vs. SCE) + 0.242V if we wished to convert a potential that had been measured against SCE for convenience to the SHE reference that is preferred for reporting experimental results in the scientific literature.

17.3 MOLECULAR INTERPRETATION OF ELECTROCHEMICAL PROCESSES

Associating the potentials of redox couples with atomic and molecular energy levels helps us visualize how these processes occur on the molecular level. Figure 17.8 shows an energy level diagram for the $Cu|Cu^{2+}||Ag^{+}|Ag$ galvanic cell discussed earlier and illustrated in Figure 17.2.

The energies of the relevant orbitals are plotted along the vertical axis on the left, and the corresponding potentials are plotted along the vertical axis on the right. The energies of the orbitals of the copper metal electrode are represented by the solid blocks of color on the left-hand side of the diagram, and an orbital associated with the $Ag^{+}|Ag$ redox couple is represented by the single horizontal line on the right-hand side of the diagram. The energy levels of metals are spaced so closely together that they form a continuous **band** of levels (see Section 21.3). The orbitals of bulk metals are constructed from the orbitals of the individual metal atoms using LCAO MO theory, by analogy to the MOs constructed for 1,3-butadiene shown in Figure 7.15. Only half of the four butadiene orbitals are occupied because each orbital can accommodate two electrons. The same is true for metals; half of the orbitals are occupied for univalent metals that contribute one electron per atom to form a band. The solid block of color represents the occupied copper orbitals, whereas the unoccupied orbitals are represented by the more transparent block of color. We identify the highest occupied orbital (analogous to the HOMO—highest occupied molecular orbital—in organic chemistry) as the Fermi level with energy ε_F. The energy of the Fermi level, for a metal in vacuum, is given by $\varepsilon_F = -\Phi$, where Φ is the work function of the metal, as defined in our discussion of the photoelectric effect in Section 4.4.

We have plotted a potential scale on the right-hand side of the diagram using the approximate relationship $\varepsilon_\alpha = -eE_\alpha$ introduced in the previous section. We have not calibrated the energy or potential axes on this scale because we are using the figure only to represent the energy levels qualitatively and to help us visualize the directions in which electrons will flow spontaneously when the two electrodes are connected by a wire. We have located the energy of the orbital associated with the $Ag^{+}|Ag$ couple lower than the energy of the copper Fermi level because we know that this reaction is spontaneous as written. Electrons near the Fermi level in copper will travel spontaneously to the unoccupied orbitals of the Ag^{+} ions in solu-

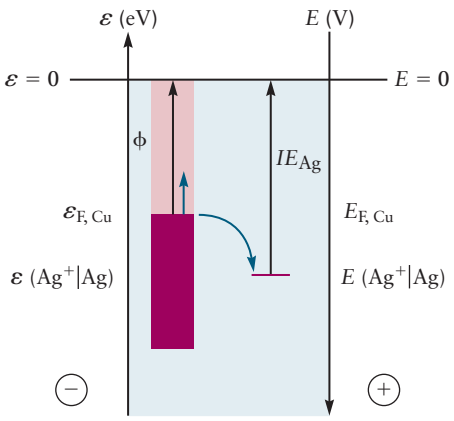

FIGURE 17.8 Electrons from the highest occupied metal orbital transfer spontaneously to unoccupied ion orbitals that lie at lower energies or more positive potentials.

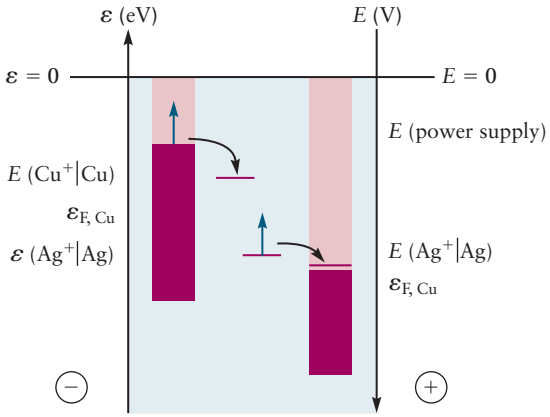

FIGURE 17.9 Electrode potentials and redox reactions for the electrolytic cell shown in Figure 17.3. The power supply withdraws electrons from the silver electrode and transfers them to empty copper orbitals at higher energies (more negative potentials). They reduce Cu^{2+} to Cu at the cathode when the potential becomes more negative than 0.34 V and Ag is oxidized to Ag^+ at the anode.

tion because they lie lower in energy. Electrons will continue to flow from Cu to Ag^+ until the energies of the electrons in both half-reactions have become equal to one another and there is no longer a driving force for the reaction to occur. We have identified the energy level of the Ag^+ ion with the potential of the redox couple for two reasons. First, recall that the energy of an atomic orbital does not depend on whether it is occupied or not (Koopman's approximation), and so we can represent the orbital energy of Ag and Ag^+ by a single level. Second (and this is more subtle), recall that we made the approximation that these energy levels really represent free energies; as such, the positions of these levels vary with the concentration of Ag^+ ions, but the variations are sufficiently small that we may ignore them.

These diagrams help us understand how applying an external potential can reverse the direction of a spontaneous reaction, and turn a galvanic cell into an electrolytic cell. The power supply shown in Figure 17.3 withdraws electrons from the silver electrode on the right (not shown) and increases their potential energy as they move to a region of more negative potential in the power supply (that's why the power supply is connected to the copper electrode by its negative terminal). Electrons will begin to flow from the power supply to fill the unoccupied levels of the copper electrode, making its potential more negative. Cu^{2+} will begin to plate out as metallic copper when the potential becomes more negative than 0.34 V, or when the energy of the electrons in the metal becomes greater than the energy of the unoccupied orbitals of the Cu^{2+} ions in solution, as shown in Figure 17.9. The half-reaction occurring at the silver electrode is also reversed because the potential has become more positive than the potential of the $Ag^+|Ag$ couple, making unoccupied Ag orbitals available into which electrons will transfer as silver metal oxidized into Ag^+ ions that enter solution.

The cell potential, whether established spontaneously in a galvanic cell or applied by an external power supply, determines the direction in which a particular electrochemical reaction proceeds. The cell potential also affects the rates of electrochemical reactions, as does the rate at which current is allowed to flow in particular processes. We show in Section 17.6 that measuring current as a function of applied potential allows electrochemists to determine the potentials of redox couples.

17.4 CONCENTRATION EFFECTS AND THE NERNST EQUATION

Concentrations and pressures are rarely fixed at their standard state values in real-world applications. It is therefore necessary to understand how concentration and pressure affect cell potentials by applying the thermodynamic principles presented

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

in Chapter 14 to electrochemical cells. In Chapter 14, we showed that the free energy change is related to the reaction quotient Q through

$$\Delta G = \Delta G° + RT \ln Q$$

Combining this equation with

$$\Delta G = -nFE_{cell}$$

and

$$\Delta G^{o} = -nFE^{o}_{cell}$$

gives

$$-nFE_{cell} = -nFE^{o}_{cell} + RT \ln Q$$

from which we get

$$E_{cell} = E^{o}_{cell} - \frac{RT}{nF} \ln Q \qquad [17.6]$$

which is known as the **Nernst equation.**

The Nernst equation can be rewritten in terms of common (base-10) logarithms by using the fact that

$$\ln Q \approx 2.303 \log_{10} Q$$

At 25°C (298.15 K), the combination of constants $2.303\ RT/F$ becomes

$$2.303 \frac{RT}{F} = (2.303) \frac{(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(298.15 \text{ K})}{96,485 \text{ C mol}^{-1}}$$

$$= 0.0592 \text{ J C}^{-1} = 0.0592 \text{ V}$$

because 1 joule per coulomb is 1 volt. The Nernst equation then becomes

$$E_{cell} = E^{o}_{cell} - \frac{0.0592 \text{ V}}{n} \log_{10} Q \quad \text{(at 25°C)} \qquad [17.7]$$

which is its most familiar form, with n being the number of moles of electrons transferred in the overall chemical reaction as written. We remind you that these measurements are made under conditions in which no current flows and that n appears only to relate the thermodynamic and electrostatic work to one another. In a galvanic cell made from zinc, aluminum, and their ions, for example

$$\begin{array}{r} 3\ Zn^{2+} + 6\ e^{-} \longrightarrow 3\ Zn \\ 2\ Al \longrightarrow 2\ Al^{3+} + 6\ e^{-} \\ \hline 3\ Zn^{2+} + 2\ Al \longrightarrow 2\ Al^{3+} + 3\ Zn \end{array}$$

$n = 6$ mol.

The Nernst equation is used to find the concentration dependence of half-cell potentials, as well.

$$E_{hc} = E^{0}_{hc} - \frac{0.0592 \text{ V}}{n_{hc}} \log_{10} Q_{hc}$$

for the potential of any half-cell reaction at 25°C, where n_{hc} is the number of moles of electrons appearing in the half-reaction and Q_{hc} is the reaction quotient for the half-cell reaction written as a reduction. Using the $Zn^{2+}|Zn$ half-cell as an example, the half-reaction written as a reduction is

$$Zn^{2+} + 2\ e^{-} \longrightarrow Zn$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

so $n_{hc} = 2$ and $Q_{hc} = 1/[Zn^{2+}]$. The cell potential for an electrochemical cell constructed from two half-cells that are not in their standard states is still calculated as before, $E_{cell} = E_{cathode} - E_{anode}$, but with the standard reduction potentials corrected to reflect the non-standard conditions using the Nernst equation.

EXAMPLE 17.7

Suppose the $Zn|Zn^{2+}||\ MnO_4^-|Mn^{2+}$ cell from Example 17.5 is operated at pH 2.00 with $[MnO_4^-] = 0.12$ M, $[Mn^{2+}] = 0.0010$ M, and $[Zn^{2+}] = 0.015$ M. Calculate the cell potential E_{cell} at 25°C.

Solution

Recall that the overall reaction is

$$2\ MnO_4^-(aq) + 5\ Zn(s) + 16\ H_3O^+(aq) \longrightarrow 2\ Mn^{2+}(aq) + 5\ Zn^{2+}(aq) + 24\ H_2O(\ell)$$

From Example 17.5, for every 5 mol of Zn oxidized (or 2 mol of MnO_4^- reduced), 10 mol of electrons passes through the external circuit, so $n = 10$. A pH of 2.00 corresponds to a hydronium ion concentration of 0.010 M. The easiest way to solve this problem is to calculate the potentials for each half-reaction using the Nernst equation and then calculate the cell potential in the usual way. The Nernst equation for a half-reaction is

$$E_{hc} = E^o_{hc} - \frac{0.0592\ V}{n_{hc}} \log_{10}\ Q_{hc}$$

Substituting the standard reduction potentials and concentrations given conditions for each half-reaction gives

$$E(MnO_4^-Mn^{2+}) = 1.49\ V - \frac{0.0592\ V}{10} \log_{10} \frac{(10^{-3})^2}{(0.12)^2(10^{-2})^{16}} = 1.33\ V$$

and

$$E(Zn|Zn^{2+}) = -0.76\ V - \frac{0.0592\ V}{2} \log_{10} \frac{1}{(0.15)^2} = -0.808\ V$$

giving

$$E_{cell} = E_{cathode} - E_{anode} = 1.33 - (-0.808) = 2.14\ V$$

Related Problems: 27, 28

Measuring Equilibrium Constants

Electrochemistry provides a convenient and accurate way to measure equilibrium constants for many solution-phase reactions; cell potentials are directly related to equilibrium constants as follows.

$$\Delta G° = -nFE^o_{cell}$$

and

$$\Delta G° = -RT \ln K$$

so

$$RT \ln K = nFE^o_{cell}$$

$$\ln K = \frac{nF}{RT} E^o_{cell}$$

and

$$\log_{10} K = \frac{n}{0.0592\ V} E^o_{cell} \qquad \text{(at 25°C)} \qquad [17.8]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The same result can be obtained in a slightly different way, by returning to the Nernst equation, which reads (at 25°C)

$$E_{cell} = E^{o}_{cell} - \frac{0.0592\ V}{n} \log_{10} Q$$

Suppose all species are initially present under standard-state conditions; $Q = 1$, and the cell potential E_{cell} is the standard cell potential E^{0}_{cell}. Q increases and E_{cell} decreases as the reaction proceeds, with E_{cell} approaching 0 V at equilibrium, at which point

$$E^{o}_{cell} = \frac{0.0592\ V}{n} \log_{10} K$$

which is the same as the relationship just obtained. This equation allows us to calculate equilibrium constants from standard cell potentials, as the following example illustrates.

EXAMPLE 17.8

Calculate the equilibrium constant for the redox reaction

$$2\ MnO_4^-(aq) + 5\ Zn(s) + 16\ H_3O^+(aq) \longrightarrow 2\ Mn^{2+}(aq) + 5\ Zn^{2+}(aq) + 24\ H_2O(\ell)$$

at 25°C using the cell potential calculated in Example 17.5.

Solution

$E^{o} = 2.25$ V and $n = 10$ for this reaction as shown in Examples 17.5 and 17.7. Therefore,

$$\log_{10} K = \frac{n}{0.0592\ V} E^{o}_{cell} = \frac{10}{0.0592\ V}(2.25\ V) = 380$$

$$K = 10^{380}$$

This overwhelmingly large equilibrium constant reflects the strength of permanganate ion as an oxidizing agent and that of zinc as a reducing agent. No MnO_4^- ions are present at equilibrium, for all practical purposes.

Related Problems: 35, 36

The foregoing example illustrates how equilibrium constants for redox reactions can be measured electrochemically. Related procedures can also be used to measure the solubility product constants of sparingly soluble ionic compounds or the ionization constants of weak acids and bases. The solubility product constant of AgCl can be measured electrochemically as follows. An electrochemical cell is constructed in which one half-cell contains solid AgCl and Ag metal, in equilibrium with a known concentration of $Cl^-(aq)$ (established with 0.001 M NaCl, for example) so that an unknown but definite concentration of $Ag^+(aq)$ is present. A silver electrode is used so that the half-cell reaction involved is either the reduction of $Ag^+(aq)$ or the oxidation of Ag. This is, in effect, an $Ag^+|Ag$ half-cell whose potential is to be determined. The second half-cell can be any cell whose standard reduction potential is accurately known, and its choice is a matter of convenience. The standard hydrogen electrode is the reference cell in the following example.

EXAMPLE 17.9

A galvanic cell is constructed from a half-cell containing silver and silver chloride and the SHE in order to determine an unknown concentration of Ag^+ ions. The cell diagram is

$$Pt|H_2(1\ atm)|H_3O^+(1\ M)||Cl^-(1.00 \times 10^{-3}\ M) + Ag^+(?\ M)|AgCl|Ag$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and the unknown concentration of Ag^+ is represented by $Ag^+(?\ M)$. The SHE is the anode, and the measured cell potential is $E_{cell} = 0.397$ V. Calculate the silver ion concentration in the cell and K_{sp} for AgCl at 25°C.

Solution

The half-cell reactions are

$$H_2 + 2\ H_2O \longrightarrow 2\ H_3O^+ + 2\ e^- \quad \text{(anode)}$$

$$2\ Ag^+ + 2\ e^- \longrightarrow 2\ Ag \quad \text{(cathode)}$$

$$E^\circ = E^\circ(\text{cathode}) - E^\circ(\text{anode}) = 0.800 - 0.000\ \text{V} = 0.800\ \text{V}$$

Note that $n = 2$ for the overall cell reaction, and the reaction quotient simplifies to

$$Q = \frac{[H_3O^+]^2}{[Ag^+]^2\ P_{H_2}} = \frac{1}{[Ag^+]^2}$$

because $[H_3O^+] = 1$ M and $P_{H_2} = 1$ atm. The Nernst equation is

$$E = E^\circ - \frac{0.0592\ \text{V}}{n}\ \log_{10}\ Q$$

$$\log_{10}\ Q = \frac{n}{0.0592\ \text{V}}(E^\circ - E) = \frac{2}{0.0592\ \text{V}}\ (0.800 - 0.397\ \text{V}) = 13.6$$

$$Q = 10^{13.6} = 4 \times 10^{13} = 1/[Ag^+]^2$$

This can be solved for the silver ion concentration $[Ag^+]$ to give

$$[Ag^+] = 1.6 \times 10^{-7}\ \text{M}$$

so that

$$[Ag^+][Cl^-] = (1.6 \times 10^{-7})(1.00 \times 10^{-3})$$

$$K_{sp} = 1.6 \times 10^{-10}$$

Related Problems: 41, 42

pH Meters

Cell potentials are sensitive to pH if one half-cell is the SHE. A simple cell can be constructed to measure pH as follows:

$$Pt|H_2(1\ \text{atm})|H_3O^+(1\ \text{M})||H_3O^+(\text{aqueous, variable})|H_2(1\ \text{atm})|Pt$$

If the half-cell reactions are written as

$$2\ H_3O^+(\text{var}) + 2\ e^- \longrightarrow H_2(1\ \text{atm}) + 2\ H_2O(\ell) \quad \text{(cathode)}$$

$$H_2(1\ \text{atm}) + 2\ H_2O(\ell) \longrightarrow 2\ H_3O^+(1\ \text{M}) + 2\ e^- \quad \text{(anode)}$$

then $n = 2$ and $Q = 1/[H_3O^+(\text{aqueous, variable})]^2$ because the other concentrations and gas pressures are unity. The cell potential calculated using the Nernst equation is

$$E_{cell} = E^\circ - \frac{0.0592\ \text{V}}{n} \log_{10}\ Q$$

which becomes

$$E_{cell} = -\frac{0.0592\ \text{V}}{2}\ \log_{10}\ 1/[H_3O^+]^2$$

$$= -0.0592\ \text{V}\ \log_{10}\ [H_3O^+] = -(0.0592\ \text{V})\ \text{pH}$$

because $E^\circ = 0$. The measured cell potential is directly proportional to the pH.

We have just described a simple **pH meter.** It is not convenient to bubble hydrogen gas through both the unknown and reference half-cells, however, so a smaller and more portable pair of electrodes is used to replace the hydrogen half-cells. The early commercial pH meters used two electrodes that were dipped into a solution of unknown pH. One of these, called the **indicator electrode** (because it indicates the unknown pH of the analyte), was made of an AgCl-coated silver electrode in contact with an HCl solution of known concentration (i.e., 1.0 M) contained in a glass tube terminated by a thin-walled, bulb-shaped, glass membrane. A pH-dependent potential develops across this thin glass membrane when the glass electrode is immersed in a solution of different, and unknown, $[H_3O^+]$ concentration. The reference electrode used was often the saturated calomel electrode discussed above. The overall cell (Fig. 17.10) can be represented as

$$Ag|AgCl|Cl^-(1.0\ M), H_3O^+(1.0\ M)|glass|H_3O^+(var)||Cl^-(sat)|Hg_2Cl_2(s)|Hg|Pt$$

with half-reactions

$$2\ Ag(s) + 2\ Cl^-(1.0\ M) \longrightarrow 2\ AgCl(s) + 2\ e^- \qquad \text{(anode)}$$

$$H_3O^+(1.0\ M) \longrightarrow H_3O^+(var)$$

$$Hg_2Cl_2(s) + 2\ e^- \longrightarrow 2\ Hg(\ell) + 2\ Cl^-(sat) \qquad \text{(cathode)}$$

The standard reduction potentials of the first and third half-reactions can be combined to give a constant reference potential E°_{ref}. The second reaction is the source of the variable potential in the cell, which corresponds to the free energy of dilution of H_3O^+ from a concentration of 1.0 M to an unknown concentration. That potential appears as a junction potential across the thin glass membrane of the indicator electrode. The Nernst equation for the overall cell can be written as

$$E = E_{ref} - \frac{0.0592\ V}{1} \log_{10} \frac{[H_3O^+(var)]}{1.00}$$

$$= E_{ref} + (0.0592\ V)\ pH$$

and the pH of the unknown solution is

$$pH = \frac{E - E_{ref}}{0.0592\ V}$$

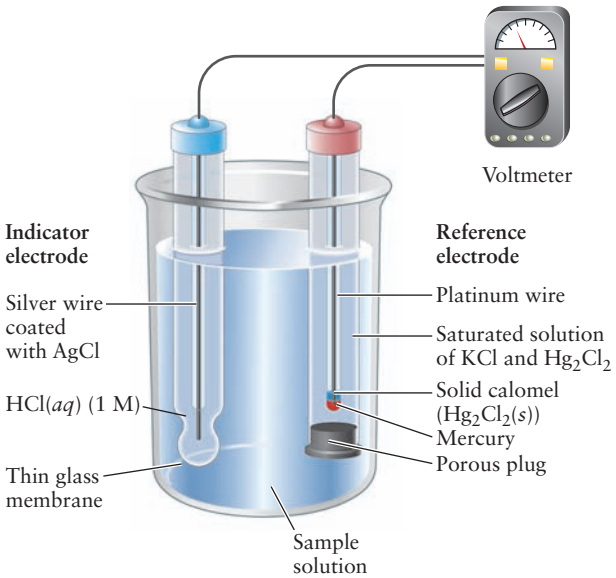

FIGURE 17.10 Schematic of an early pH meter.

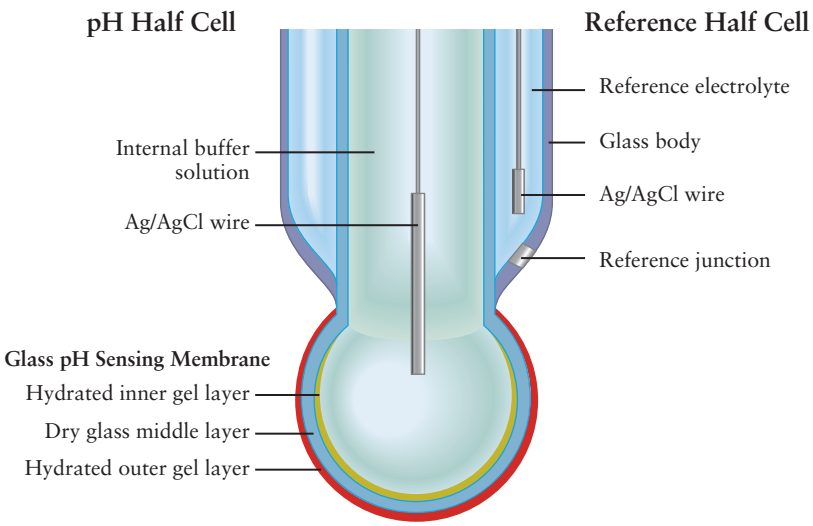

FIGURE 17.11 A combination pH probe.

The glass indicator electrode has a number of advantages over other possible pH electrodes. It responds only to changes in $[H_3O^+]$, and it does so over a wide range of pH. It is unaffected by strong oxidizing agents that would make hydrogen electrodes unreliable. Highly colored solutions that would render acid–base indicators useless do not interfere with the glass indicator electrode.

Most modern pH meters use a combination probe like the one shown in Figure 17.11, in which the indicator and reference electrodes are housed in one body. You are probably familiar with probes like this one from laboratory courses. Another significant advantage of the combination probe is that it can be miniaturized to permit insertion into individual living cells and probe pH in biological samples.

A number of **ion-selective electrodes** have been developed using similar principles to selectively measure ion concentrations to levels as low as 10^{-10} M. The simplest example of such an electrode would be the Ag/AgCl reference electrode already discussed, the potential being sensitive to the $Cl^-(aq)$ concentrations in the solution of interest. Modern ion selective electrodes are constructed from polymer membranes that have been tailored to transport only the ions of interest, greatly reducing background and improving sensitivity.

17.5 MOLECULAR ELECTROCHEMISTRY

The term **molecular electrochemistry** was coined recently to identify a branch of the broader field of electrochemistry that focuses on developing a molecular level understanding of electron transfer processes at electrodes and exploiting the interactions between molecules and electrode surfaces to optimize electrochemical reactions. Fundamental questions of interest include the coupling of electron and proton transfer, especially in biological systems; the way electron transfer reactions initiate bond breaking and formation; the role molecules play in catalyzing electrochemical reactions; and the way redox enzymes work. A wide range of applications is being pursued using this approach as well. The electrochemical synthesis of organic molecules, the development and application of biological sensors to problems of fundamental interest and medical diagnostics, the design of better catalysts for fuel cells, and the application of semiconductor photoelectrochemistry to problems as diverse as organic waste remediation and solar energy conversion are all active areas of research and development in this field. We discuss several of these applications in this section to illustrate the deeper insights this approach provides as well as to introduce you to some of the more exciting recent developments in electrochemistry.

Electrochemical Organic Synthesis

The large-scale commercial synthesis of organic compounds uses simple starting materials derived from petroleum and converts them into the desired products in reactions that are generally carried out at high temperatures and pressures using catalysts. Many of these reactions use H_2 and O_2 to reduce and oxidize hydrocarbons to produce intermediates or the desired products. It is interesting to think about these transformations as redox reactions and to compare the driving force available in the homogeneous gas phase reactions in electrochemical terms. The driving force for the gas phase oxidations and reductions is limited by the potentials for the reduction of oxygen or the oxidation of hydrogen, which is a range of about 1V under standard conditions, which corresponds to a change in the Gibbs free energy of about 100 kJ mol^{-1}. Synthetic organic reactions carried out electrochemically can be driven by potentials that range between −2.5 V to 3.5 V, providing much larger driving forces and the possibility of greater control over the thermodynamics and kinetics of reactions by controlling potential. This approach also has the advantage that it does not rely on powerful, but toxic and potentially dangerous, reducing agents like the alkali metals or oxidizing agents like Cl_2 or $Cr_2O_7^{2-}$. It has also been suggested that electrons are probably the least expensive and most widely available redox reagents on a per-mole basis.

The most famous example of a large-scale electrochemical organic synthesis is the Monsanto process for the production of adiponitrile, a precursor for hexamethylene diamine, which is one of the monomers used to make the large-volume commodity chemical nylon. The reaction mechanism is complex, but the following is one of the reactions that produces adiponitrile

$$CH_2{=}CHCN + 2e^- \longrightarrow 2(CH_2{=}CHCN)^- + 2\ H^+ \longrightarrow NC(CH_2)_4CN$$

which is then reduced in hydrogen to form the hexamethylenediamine monomer. The reaction is carried out in very large electrochemical reactors with steel electrodes coated by a thin film of Cd and the reactants, products, and electrolyte carried in an aqueous solution/organic solvent emulsion. This process produces some 200,000 tons of adiponitrile each year. Electrochemical organic synthesis has become increasingly popular in recent years for the synthesis of organic molecules on much smaller scales, such as pharmaceuticals, because of its speed and selectivity.

Enzyme-Based Electrochemical Sensors

Approximately 5% of the world's population, and nearly 8% of the population of the United States, are diabetic; they are unable either to produce insulin, or to respond to the insulin they do produce to regulate the absorption of glucose, a major source of energy, into cells. Diabetics must keep their blood sugar levels controlled pretty tightly to avoid serious medical problems, some of which are potentially life-threatening. They do so by monitoring their blood sugar several times daily and injecting themselves with synthetic human insulin to regulate glucose uptake. Synthetic insulin is made by inserting the human insulin gene into bacteria or yeast, which is produced in large amounts through fermentation, with the insulin being extracted from the hosts at the end of the growth process. There is an enormous market for devices that quickly and accurately measure blood sugar levels, portable devices that take samples from the skin by lancing with small needles as needed, and implantable ones that monitor blood sugar on a continuous basis. Both kinds of devices measure glucose levels electrochemically, making this assay undoubtedly one of the most important analytical applications of electrochemical methods in current use.

Glucose sensors monitor either the reduction of glucose by the enzyme glucose dehydrogenase GDH(FAD), or the oxidation of glucose by the enzyme glucose oxidase GOx($FADH_2$), where FAD and $FADH_2$ are the reduced and oxidized forms of cofactors (see Section 18.8) associated with the enzymes that provide the reducing

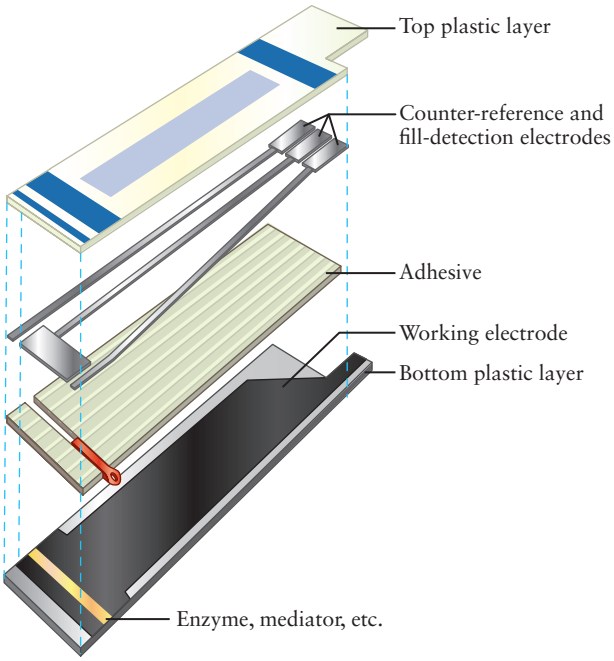

FIGURE 17.12 Glucose sensor test strip showing the capillary that fills with blood, the carbon working electrode and the counter-reference and fill-detection electrodes. The planar electrodes are separated from one another by 50 μm.

or oxidizing equivalents in the form of (H^+, e^-) pairs. The first reaction is used in test strips, whereas the second reaction is used in implantable devices; we discuss them separately, although they have many features in common.

The test strip, and associated meter, constitute a remarkable analytical device that measures the concentration of glucose from a 300 nL sample of blood in about 15 seconds. The strip, which is about 1" long and 1/4" wide, contains the following components: (1) a capillary that draws in the blood sample obtained by a skin prick, (2) a thin film carbon working electrode, (3) a thin film Ag/AgCl electrode that serves both as the counter and reference electrodes, and (4) two planar auxiliary electrodes that tell the main electrode when the capillary is filled and to start the analysis. As shown in Figure 17.12, the Ag/AgCl and auxiliary electrodes are part of the same structure, which faces the working electrode at a separation of 50 μm. The geometry of the strip was designed to facilitate the accurate and rapid measurement of blood glucose levels on the short time scale needed, but some very clever chemistry had to be developed in order for the sensor to meet its design objectives.

The particular test strip shown monitors the concentration of glucose by measuring the total charge transferred to the carbon electrode that results from the oxidation of glucose by an enzyme called glucose dehydrogenase (GDH), which converts an alcohol functional group into a ketone (see Section 7.6). The reduction half-reaction occurs at the Ag/AgCl reference electrode, and the overall set of reactions is summarized as follows.

$$2\ Ag^+ + 2\ e^- \longrightarrow 2\ Ag$$

$$\text{glucose} + \xrightarrow{\text{GDH}} \text{glucononlactone} + 2\ H^+ + 2\ e^-$$

$$\text{glucose} + 2\ Ag^+ \xrightarrow{\text{GDH}} \text{glucononlactone} + 2\ Ag + 2\ H^+$$

Electron transfer from the enzyme to the electrode surface is not very efficient, however, because the enzyme's active site is buried inside the protein and there is no easy path for the electrons to follow. The problem was solved by incorporating molecules called **mediators** into the device that facilitate electron transfer over large distances by a series of efficient electron transfer reactions. The design of the mediators is one part of the clever chemistry referred to earlier.

There are many classes of electron transfer mediators; they may be organic molecules, inorganic molecules, or coordination complexes (see Section 8.3). Good media-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tors for this application must have redox potentials located between the redox potential for the oxidation reaction and that of the electrode in order to drive the electrons toward the electrode, and the potential must be relatively insensitive to pH. They must also be stable molecules that are very soluble in water and diffuse rapidly to react with each other with very large rate constants for electron transfer. A schematic of the organization of the chemical components of this sensor is shown in Figure 17.13.

The mediators used in this particular sensor are coordination complexes of osmium, whose properties have been tuned for this particular application by varying the nature of the ligands attached, to avoid "shuttling" of the mediator back and forth between the electrodes without effecting the desired reaction. The Os^{2+}/Os^{3+} couple was simply oxidized at the working electrode and reduced at the reference electrode, contributing a large background signal that was unrelated to the oxidation of glucose. The problem was solved in a very clever way. The redox potential of the mediator was adjusted so that its oxidized form could be reduced by the enzyme, but not at the Ag/AgCl electrode.

Implantable sensors have different requirements than strips; they must measure glucose concentrations continuously and report both the concentrations and the changes in concentrations by transmitting signals to a monitor that is carried or worn by the diabetic. Dangerous or life-threatening changes in glucose levels trigger an alarm that requires action. A number of important features have been built into these devices, among the most interesting of which is the concept of "wired" enzymes. The first successful wired enzymes were coordination complexes containing the Fe^{2+}/Fe^{3+} redox couple that was covalently attached to the polypeptide chain of glucose oxidase (a different enzyme used for this application) at locations sufficiently close to each other that the electrons could be transferred between them as if they were in a wire. The current version of these devices incorporates the osmium-based redox couples that are covalently attached to a class of polymers called hydrogels that are very flexible and form open structures that are 99% water. The mediators are covalently attached to the flexible polymer background with separations that allow them to swing back and forth and collide with one another at rates that approach the diffusion rates of chloride ions in aqueous solution. Glucose oxidase is incorporated into the mediator-bearing polymer as they are deposited together on the electrode surface by controlling the electrode potential, in a process called *electrodeposition*. The end result is a thin film with a very high water content which conducts electrons and ions, and which is permeable to reactants, products, and electrolytes. None of the critical components can be leached out of the film because they are covalently bound, and the greatly improved current densities allow the development of much smaller sensors with high sensitivity. The present sensors are not felt by the user, provide five days of continuous monitoring, and are easily replaced by the users themselves.

Electrogenerated Chemiluminescence

Electrogenerated chemiluminescence (ECL) has become a very important analytical technique for detecting biologically important molecules, with applications in clinical diagnostics, food and water testing, the detection of biowarfare agents, and basic research. It is very sensitive (picomolar concentrations can be measured) and the response is linearly proportional to concentration. ECL generally results from charge transfer reactions between radical anions and radical cations that produce

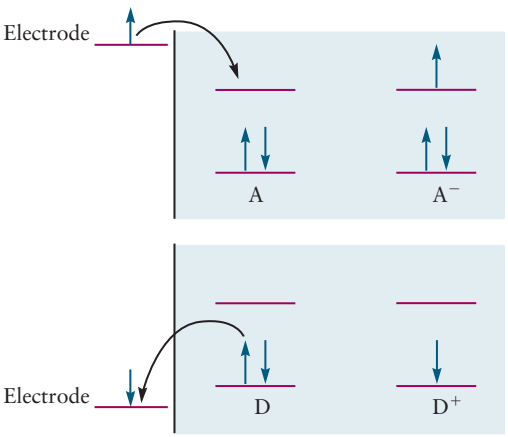

FIGURE 17.14 Generation of a radical cation and a radical anion in an ECL experiment. The radical anion of A is formed when the electrode potential is made more negative than the LUMO of A. The radical cation of D is formed when the electrode potential is made more positive than the HOMO of D.

excited molecular electronic states, which then emit light. The radicals are generated electrochemically, and the series of reactions can be written as

$$A + e^- \longrightarrow A^{-\bullet}$$

$$D \longrightarrow D^{+\bullet} + e^-$$

$$A^{-\bullet} + D^{+\bullet} \longrightarrow A^* + D$$

$$A^* \longrightarrow A + h\nu$$

in which A is the oxidized form of an electron acceptor and $A^{-\bullet}$ is its radical anion formed upon reduction; D is an electron donor and $D^{+\bullet}$ is its radical cation formed upon oxidation; A* is an electronically excited state of A and $h\nu$ is the energy of the emitted light. The electrochemical generation of the radical anion and radical cation is illustrated in Figure 17.14. The electron transfer reaction that produces A*, which subsequently returns to the ground state A by emitting a photon, is illustrated in Figure 17.15.

The ECL process is most easily illustrated using a specific example in which we identify the redox potentials of the donor and acceptor using an electrochemical technique known as cyclic voltammetry, and connect them to the absorption and emission spectra of the system. **Cyclic voltammetry** measures the current that flows as the electrode potential is scanned in the forward direction (typically toward more negative potentials) and then in the reverse direction. The cyclic nature of the scan gives the technique its name. Cyclic voltammetry is perhaps the electrochemists' most powerful method for the study of electrochemical processes. It can quickly identify redox active materials and locate the potentials at which various oxidations and reduction reactions occur. Cyclic voltammetry can also provide a great deal of information about the kinetics of electrochemical reactions, but that discussion is beyond the scope of this textbook. The application of cyclic voltammetry to ECL affords us the opportunity to introduce you to the technique at an elementary level as well as to illustrate how ECL experiments are actually carried out. Figure 17.16 shows the cyclic voltammogram of a redox-active dye molecule (PM 567) that has been tailored for ECL applications. The same molecule, in this example, is reduced to form the radical anion and oxidized to form the radical cation.

The potential is set initially to 0 V and then scanned through a cycle, first toward more negative potentials, then toward more positive potentials, and finally

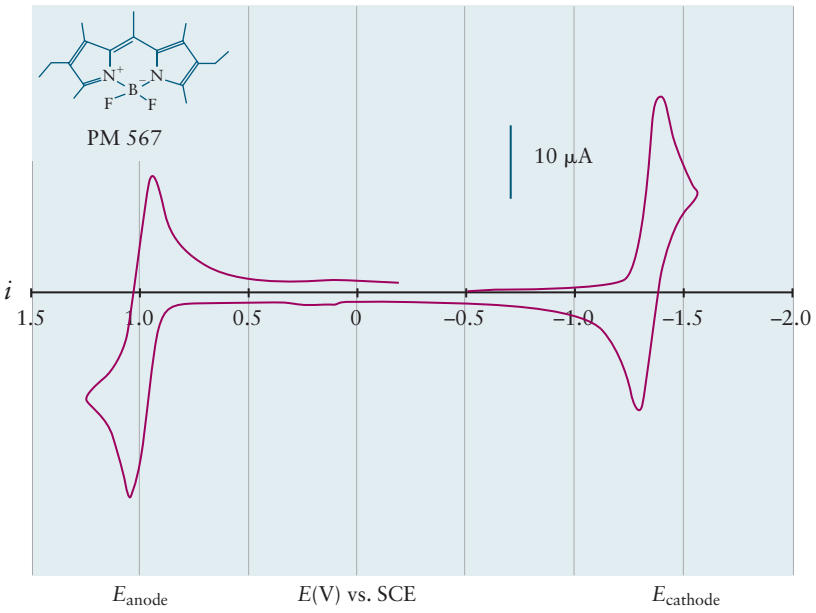

FIGURE 17.16 Cyclic voltammogram for an ECL dye.

returning to zero. As shown in the voltammogram in Figure 17.16, the current begins to rise as the potential reaches about −1.4 V, signifying the reduction of PM to $PM^{-\bullet}$ at the cathode.

The scan is reversed and current begins to flow in the opposite direction as $PM^{-\bullet}$ is oxidized back to PM. When the potential is scanned through potentials more positive than about 1 V, PM is oxidized to $PM^{+\bullet}$ and then reduced back to PM when the scan is reversed. The shapes of these curves contain a great deal of information about the kinetics of the reactions, with the current rising and then falling due to an increase and then a decrease in the rates of diffusion of reactants to the electrode surface. The redox potential for the $PM|PM^{-\bullet}$ couple is located between the two peaks in the wave near −1.4 V, and the redox potential for the $PM^{+\bullet}|PM$ couple is located between the two peaks in the wave near 1 V. We can calculate the maximum amount of energy available to create an excited state, and the energy of the emitted photon from the reaction

$$PM^{-\bullet} + PM^{+\bullet} \longrightarrow PM + PM^* \longrightarrow PM + h\nu$$

as follows. We have associated the potential of the $PM^{+\bullet}|PM$ couple with the HOMO (highest occupied molecular orbital) and that of the $PM|PM^{-\bullet}$ couple

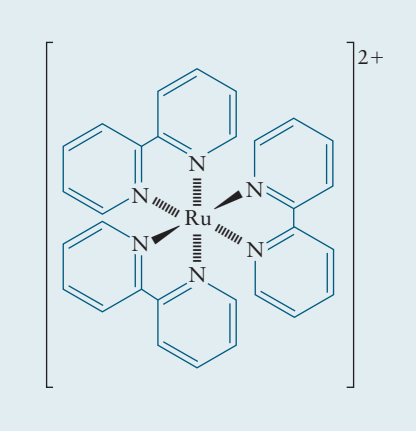
with the LUMO (lowest unoccupied molecular orbital), so the energy available is given by the potential difference between the two redox couples times the charge of the electron, giving $-e\Delta E = 2.4$ eV for this system. The absorption and fluorescence spectra of PM 567 are shown in Figure 17.17. The peak in the absorption spectrum appears at 514 nm, which corresponds to an energy of about 2.4 eV, so the energy available from the recombination reaction is sufficient to create the excited state. The maximum in the fluorescence spectrum is shifted to somewhat longer wavelengths, as is typical for molecules in solution, appearing at 567 nm.

EXAMPLE 17.10

Sketch and interpret the cyclic voltammogram you expect for the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ redox couple measured with respect to a Ag/AgCl reference electrode. The standard reduction potential for this system at pH = 7 is 0.43 V.

Solution



The cyclic voltammogram for this system is sketched above. The potential is set initially at 0.8 V and no current flows. A detectable current begins to flow as the potential is scanned to more negative values, the current beginning to appear at about 0.5 V. The current is due to the reduction of $[Fe(CN)_6]^{3-}$ to $[Fe(CN)_6]^{4-}$ at the cathode. The current peaks and then declines as the potential is scanned to more negative values. The direction of the potential scan is reversed at about 0 V and a current flowing in the opposite direction begins to appear at about 0.4 V, indicating the re-oxidation of $[Fe(CN)_6]^{4-}$ to $[Fe(CN)_6]^{3-}$. The current first increases and then decreases as the potential is scanned to more positive values. The redox potential is determined graphically by locating the midpoint between the two peaks, in this case 0.34 V.

Related Problems: 43, 44

We have illustrated the principles of ECL using as an example a molecule that serves as both the electron acceptor and the electron donor. Practical applications of ECL, however, require molecules both that are stable and that show ECL in *aqueous* solution. The discovery of ECL in the water-soluble coordination complex $Ru(bpy)_3^{2+}$, shown on the next page, was a promising development, but it turned out to be difficult, if not impossible, to find a suitable electron acceptor that could be reduced electrochemically in water. The difficulty arises because potentials more negative than the potential for water reduction are needed to produce species that can reduce $Ru(bpy)_3^{3+}$ generated electrochemically by oxidation of $Ru(bpy)_3^{2+}$ (see Section 17.9, *A Deeper Look . . .* Electrolysis of Water and Aqueous Solutions). The problem was solved by finding a way to produce reducing species by *oxida-*

tion, using molecules called coreactants that decompose upon oxidation to produce products with the required reducing power.

$Ru(bpy)_3^{2+}$

The molecule tripropylamine, $N(CH_2CH_2CH_3)_3$ abbreviated $Pr_2NCH_2CH_2CH_3$, is a particularly good coreactant for the efficient generation of ECL from $Ru(bpy)_3^{2+}$ in aqueous solution. $Ru(bpy)_3^{2+}$ and tripropylamine are simultaneously oxidized during a single potential step to produce $Ru(bpy)_3^{3+}$ and $Pr_2N(CH_2CH_2CH_3)^{+\bullet}$ respectively. The tripropylamine radical cation then loses a proton to form the strongly reducing free radical species $Pr_2N(^{\bullet}CHCH_2CH_3)$, which reacts with $Ru(bpy)_3^{3+}$ to produce an excited state of $Ru(bpy)_3^{2+}$ that emits light. The overall sequence is summarized as follows.

$$Ru(bpy)_3^{2+} \longrightarrow Ru(bpy)_3^{3+} + e^-$$

$$Pr_2N(CH_2CH_2CH_3) \longrightarrow Pr_2N(CH_2CH_2CH_3)^{+\bullet} + e^-$$

$$Pr_2N(CH_2CH_2CH_3)^{+\bullet} \longrightarrow Pr_2N(^{\bullet}CHCH_2CH_3) + H^+$$

$$Ru(bpy)_3^{3+} + Pr_2N(^{\bullet}CHCH_2CH_3) \longrightarrow (Ru(bpy)_3^{2+})^* + Pr_2N(^{+}CH_2CH_2CH_3)$$

ECL is used in a large number of clinically important assays. $Ru(bpy)_3^{2+}$ is covalent bound, using different linking molecules, to a probe that binds to target molecules of interest. The target molecules fall into major classes that include: antigens that trigger an immune response, producing antibodies, and the nucleic acids DNA and RNA. Antibody-based assays are used to measure estrogen and testosterone levels, detect the hepatitis and HIV viruses, and measure insulin levels, for example. Antibodies to a particular antigen are covalently attached to a solid surface, and $Ru(bpy)_3^{2+}$ –labeled antibodies and the sample of interest are placed in solution. Any antigen present will be recognized and bound to both the surface-bound antibodies and the solution-phase antibodies, linking them together. A number of schemes have been developed to present these samples to electrode surfaces for ECL analysis, magnetic beads that attach to electrode surfaces or miniature electrodes printed in arrays of small wells, for example. Assays based on the recognition of specific nucleic acid sequences proceed in an analogous way.

ECL has a number of significant advantages over other biological assays. First, the labels are completely stable until the potential is stepped to generate the reactive species. Second, and perhaps most importantly, there is no background emission like that found in fluorescence experiments. Light emission occurs in ECL only when the electrode is stepped through the potential region of interest. Third, it is a very sensitive technique because modern photomultipliers or other detectors can detect single photons. Detection limits for ECL have been demonstrated to be as low as 10^{-12} M, making it among the most sensitive analytical methods available.

EXAMPLE 17.11

Suppose that you were asked to synthesize a molecule for use in ECL that emits light at 600 nm and has a potential associated with the LUMO located at −1.05 V, for compatibility with other requirements in a particular analytical application. What is the redox potential associated with the HOMO?

Solution

The energy of a photon is related to its wavelength by $E = h\nu = hc/\lambda$, where λ is the wavelength, h is Planck's constant and c is the speed of light (see Equations 4.1 and 4.7). Solving for E gives

$$E = (6.626 \times 10^{-34}\ \text{J s})(3 \times 10^{8}\ \text{m s}^{-1})/(600 \times 10^{-9}\ \text{m})$$

$$= 3.3 \times 10^{-19}\ \text{J} = 2.06\ \text{eV}$$

which is equal to the difference in the energies of the two orbitals $\varepsilon_{\text{LUMO}} - \varepsilon_{\text{HOMO}}$. The energy of the LUMO with redox potential −1.05 V is 1.05 eV (with respect to SHE, not vacuum) so the energy of the HOMO must be −1.01 eV with an associated potential located at −1.01 V.

Related Problems: 45, 46

Photoelectrochemistry

The left-hand side of Figure 17.18 shows two energy levels of a molecule or a semiconductor that absorbs light (a **chromophore**) along with the redox levels of an electron acceptor A and an electron donor D on the right-hand side of the diagram. The lower energy level in the chromophore is called the HOMO (highest occupied molecular orbital), and the higher energy level is called the LUMO (lowest unoccupied molecular orbital); the corresponding levels in the semiconductor are called the **valence band (VB)** and the **conduction band (CB),** respectively. We treat the semiconductor bands as if they were molecular orbitals, and we do not consider how the energies of these bands bend as a function of distance from the surface, which is an important consideration in more advanced work. We refer to the energy level splitting as the bandgap for molecular systems as well as semiconductors, for convenience and consistency. Redox potentials (also represented as orbital energy levels) for two different redox reactions, $A + e^- \longrightarrow A$ and $D^- \longrightarrow D + e^-$, are located on the right-hand side of the diagram; we have chosen the energy levels associated with these reactions to lie between the energy levels of the chromophore for the purpose of this discussion. Values of the potential and the potential energy, referenced to the SHE, are both given on the vertical axis.

Let's use this energy level diagram to understand the mechanism by which light absorption drives redox reactions that are not normally spontaneous. Light ab-

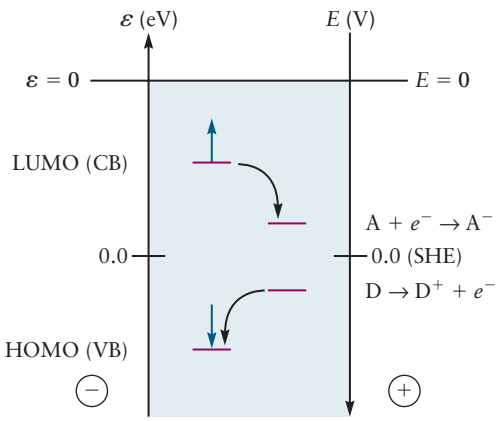

FIGURE 17.18 Photoexcitation promotes electrons to higher energies (more negative potentials), which make them stronger reducing agents, capable of reducing an acceptor A to A^-. The vacancies (holes) left behind can now accept electrons, which make them stronger oxidizing agents, capable of oxidizing a donor D to D^+.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

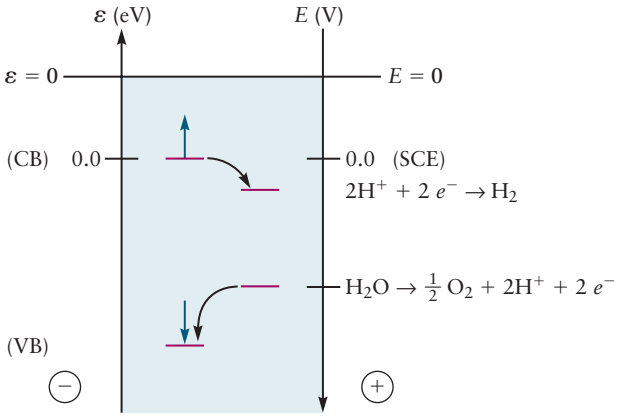

FIGURE 17.19 The potential of the conduction band of wide bandgap semiconductors is sufficiently negative to reduce hydrogen ions and that of the valence band sufficiently positive to oxidize water.

sorption promotes electrons from the lower level (the valence band) to the upper level (the conduction band), increasing their potential energy. The potential of these electrons is more negative than when they were in the HOMO, so these excited states have become stronger reducing agents than the ground state of the system. Vacancies (holes) left in the conduction band are now free to accept electrons from other species, making excited states more powerful oxidizing agents than ground states. Photoexcitation, therefore, has created excited states in which the electrons and the holes are simultaneously more strongly reducing and more strongly oxidizing, respectively, than the ground state molecules.

Let's now consider direct photoelectrochemical water splitting by wide bandgap semiconductors such as TiO_2 or $SrTiO_3$, with conduction bands located at about 3 V and valence bands very close to 0 V, as shown in Figure 17.19. The standard reduction potentials for the $H_2|H^+$ and $O_2|H_2O$ couples are 0.0 (by definition) and 1.229 V, respectively, so the potential of the conduction band must be more negative than 0.0 V to reduce H^+, and the potential of the valence band must be more positive than 1.229 V to oxidize water. The potential of the valence band is clearly sufficiently positive to oxidize water, but the potential of the conduction band is so close to the potential required for H^+ reduction that practical systems must be modified to make the potential sufficiently negative for reduction to occur.

The figure illustrates the overall process schematically with conduction band electrons reducing protons and valence band holes oxidizing water by the following reactions:

$$4\ H^+(aq) + 4\ e^- \longrightarrow 2\ H_2(g)$$

$$2\ H_2O(\ell) \longrightarrow O_2(g) + 4\ H^+(aq) + 4\ e^-$$

The energy level diagram suggests that a single excited state can reduce one proton and partially oxidize one water molecule, but we must look a bit more closely at the overall thermodynamics of the system as well as the stoichiometry of the reaction on the molecular level to understand the energy required for the overall reaction. The standard Gibbs free energy of formation of water is

$$H_2(g) + \tfrac{1}{2}\,O_2(g) \longrightarrow H_2O(\ell) \qquad \Delta G_f^\circ = -237.18\ \text{kJ mol}^{-1}$$

so the light absorbed must provide at least that much energy to decompose 1 mol of water. The energy absorbed by chromophores is partially degraded into heat, unfortunately, before ultimately being made available to drive the water splitting redox reactions. The maximum amount of energy available then becomes the difference in the energies of the hydrogen and oxygen redox levels, which is

$$\Delta G^\circ = -nFE^\circ = -(1\ \text{mol})(1.299\ \text{eV})(96.585\ \text{kJ mol}^{-1}\ \text{eV}^{-1}) = -125.3\ \text{kJ}$$

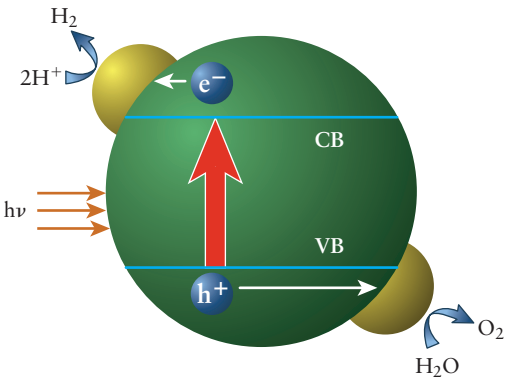

FIGURE 17.20 Direct photoelectrochemical water splitting by colloidal TiO_2, shown with hydrogen and oxygen evolution catalyst particles attached.

per mol of photons absorbed, which is clearly insufficient. Two moles of electrons would provide enough energy to decompose 1 mol of water, but there is no molecular mechanism that would produce one oxygen *molecule,* as required. Water splitting, therefore, is a four-electron redox process that proceeds through a series of electron transfer reactions that involve several intermediates.

The energetic considerations discussed above have important consequences for the design of practical systems for photoelectrochemical water splitting. Colloidal semiconductors like TiO_2 (illustrated in Figure 17.20) or $SrTiO_3$ have become the leading candidates for practical systems. They are more stable than molecular systems, and they have high surface-area-to-volume ratios that support the catalysts required to achieve acceptable reaction rates.

The water splitting reaction is thermodynamically allowed, but too slow for practical applications unless hydrogen reduction catalysts, like Pt, and oxidation catalysts, like RuO_2, are used. The wide bandgap semiconductors used for purposes of illustration are not suitable for practical applications because they absorb radiation only in the ultraviolet region of the spectrum, which accounts for less than 10% of the energy provided by sunlight. In addition, most of the energy of any ultraviolet radiation that is absorbed would be lost as heat; the fraction ultimately available is the ratio of the water oxidation potential energy to the energy of the bandgap, or about 40% (1.3 eV/3 eV). Most of the energy that is lost is due to the fact that the valence band in these wide bandgap materials is much more positive than that required to oxidize water, and so much current research in this area has been devoted to discovering new materials with smaller bandgaps and with valence bands at more negative potentials. Unfortunately, most materials with these properties decompose under illumination because the holes generated oxidize the semiconductors themselves; for example, metal sulfides and metal selenides decompose as

$$S^{2-} \xrightarrow{h\nu} S + 2\,e^- \quad \text{and} \quad Se^{2-} \xrightarrow{h\nu} Se + 2\,e^-.$$

EXAMPLE 17.12

Would GaAs be a suitable candidate as a semiconductor electrode for direct photoelectrochemical water splitting? The valence band lies at 0.350 V and the conduction band lies at −0.65 V. Why or why not?

Solution

The redox potential of the conduction band is sufficiently negative to reduce water to H_2 but the potential of the valence band is not sufficiently positive to oxidize water to O_2.

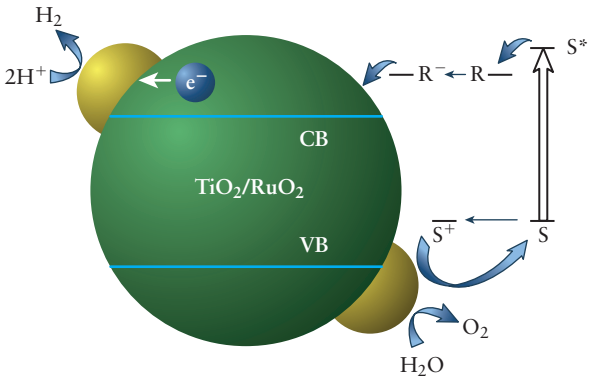
CONNECTION TO ENERGY



Solar Energy Conversion

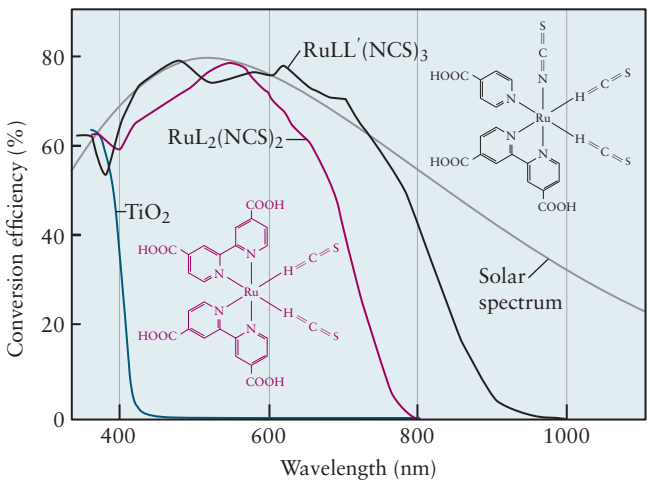
The sun is the ultimate source of energy for the earth; some of that energy is stored in plants, which provide food and energy for current needs. Plants were also the precursors to fossil fuels, our main source of energy for electrical power generation, transportation, and manufacturing. The finite supply of fossil fuels, combined with a growing population and increasing energy requirements in developing countries, has stimulated tremendous interest in new sources of renewable energy such as solar, wind, and biomass. We describe two approaches to solar energy conversion and storage that are based upon photoelectrochemical reaction schemes: one to produce fuel, the other to produce electricity.

Artificial Photosynthesis

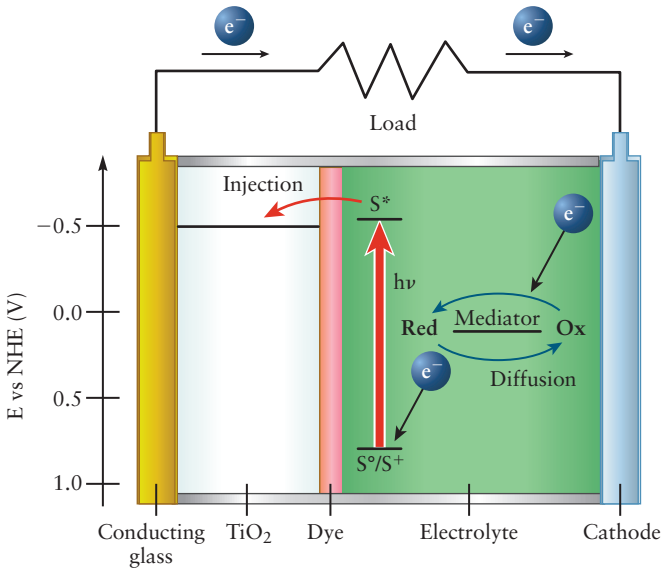
Photosynthesis, which occurs in plants and some bacteria, converts solar energy into chemical potential energy that is stored in the bonds of carbohydrates (see Section. 20.6). We recover this energy when metabolizing food or from the combustion of fossil fuels or biomass. Sunlight is the source of the Gibbs free energy required to drive these thermodynamically uphill reactions by creating excited states that are strong oxidizing and reducing agents (see Fig. 17.18). Natural photosynthetic systems are highly organized arrays of molecules that absorb much of the available sunlight and transfer it efficiently to the photosynthetic reaction centers that catalyze the redox reactions.

The goal of *artificial photosynthesis* is to design simpler synthetic systems that perform the same functions as natural photosynthesis, the conversion and storage of solar energy as fuel, with a focus on hydrogen. The adjacent figure shows how the addition of a dye sensitizer and a mediator to the system illustrated in Figure 17.20 enables water splitting at visible wavelengths. The basic idea is fairly straightforward but producing practical devices remains a daunting challenge. Light absorbed by sensitizers generates excited states that can inject electrons into the conduction band of the semiconductor particle, with the electrons ultimately reducing water (represented here as H^+) to generate H_2 gas that may be stored and used as a fuel. The LUMO of the sensitizer must lie at higher energy than that of the conduction band to allow electron injection and the redox potential associated with the HOMO must be sufficiently positive to oxidize water. Redox mediators (if used) must have a wider "bandgap" than the sensitizer. Small Pt and RuO_2 particles (gold spheres) catalyze the reduction and oxidation reactions, respectively. We introduce this single-component model system because it is easy to visualize and illustrates principles that underlie one approach to develop more efficient solar cells.

Dye Sensitized Solar Cells



The vast majority of solar cells in current use are Si-based photovoltaic devices in which light absorption excites electron-hole pairs in *p-n* junctions (see Section 22.7), generating electrons that flow through external circuits producing electrical work. These cells can be very efficient (more than 20%) but they are also very expensive due to demanding material requirements.



Considerable effort has been devoted to the development of dye-sensitized semiconductor solar cells (DSC) over the past several decades. Research in this area was pioneered in large part by the Swiss physical chemist Michael Grätzel, who has made important contributions to the development of systems for direct water splitting as well as for electricity generation. A schematic of the Grätzel cell is shown on p. 799; it has many of the characteristics of the dye-sensitized semiconductor system discussed earlier. Sensitizing dyes are adsorbed on, or chemically bound to, the surfaces of wide bandgap semiconductor nanoparticles. Light absorbed by the dyes excites electrons into the LUMO from

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

which they are injected into the conduction band of the semiconductor.

Unlike in the previous example, however, electrons flow through an external circuit where they can do work. The electrons reenter the cell at the cathode and reduce the oxidized form of a redox mediator, which is then oxidized by the hole left behind in the sensitizer. A number of factors have been carefully considered to design cells with conversion efficiencies as high as 12% and projected lifetimes as long as 10 years. The morphology of the semiconductor nanoparticles, the electronic energy level structures of the dye molecules, the coverage of dye molecules on each nanoparticle and the way in which these nanoscopic structures are assembled have been carefully chosen to provide very large surface areas for efficient light absorption and electron injection. Dyes have been synthesized with LUMOs located slightly above the energy of the semiconductor conduction band to ensure efficient injection and with HOMOs located at the lowest possible energies to maximize the fraction of the incident light absorbed as well as to be compatible with the redox potential of the mediator. Examples of sensitizers include derivatives of $Ru(bpy)_3$ in which one or more of the bipyridine ligands have been replaced by isothiocyante (—N=C=S) ligands to extend the absorption onset to longer wavelengths, as shown in the figure. The solar spectrum is represented in the figure by the spectrum of a blackbody at the temperature of the sun to give you a sense of how much of the available radiation is absorbed by these dyes. The vertical axis is the percent conversion efficiency (incident photons to electrons).

Schematic of a Grätzel cell

The redox mediator transports electrons from the cathode to the radical cation created by photoexcitation and charge injection, regenerating the ground state of the sensitizer and preventing direct electron-hole pair recombination, an undesirable competing reaction. The relevant reactions are

$$S \xrightarrow{h\nu} S^+ + e^-(TiO_2^{cb}) \quad \text{charge injection}$$

$$I + e^- \longrightarrow I^- + I_2 \longrightarrow I_3^- \quad \text{mediator reduction}$$

$$S^+ + I_3^- \longrightarrow S + I_2 + I \quad \text{sensitizer regeneration}$$

The iodide/triodide redox couple has been the mediator of choice because it is sufficiently soluble, does not absorb significant amounts of light, has appropriate redox potentials, rapid dye regeneration kinetics and, most importantly, very slow rates for the direct recombination of the conduction band electrons with triodide, another undesirable competing reaction. The choice of redox mediator is critical; the performance of the iodide/triiodide couple is unmatched to date but there is considerable interest in finding other mediators that would increase efficiency. The standard reduction potential for the I/I_3^- couple is 0.35 V (SHE) and that of the radical cation is about 1.1 V (see figure). The energy difference is lost as heat; designing systems with more closely matched energy levels could greatly improve the efficiencies of these devices.

Improving the efficiencies of semiconductor-based solar cells is a topic of great current research interest, motivated both by a desire to more fully understand the basic physical and chemical processes involved as well as to guide the design of practical cells. Wide bandgap semiconductors like TiO_2 and $SrTiO_3$ have conduction bands with potentials sufficiently negative to reduce water but their valence bands are located at much more positive potentials than necessary to oxidize water, resulting in most of the energy absorbed being lost as heat. Photosynthesis, the process in nature by which solar energy is captured and stored, uses coupled systems to absorb light over a significant wavelength range and efficiently transfer energy to the sites where oxidation reduction reactions occur. Considerable effort is currently being devoted to develop semiconductor-based solar cells that operate using principles inspired by the natural photosynthetic systems. The accompanying *Connection to Energy:* Solar Energy Conversion introduces you to one approach that has been developed to increase the efficiency of direct photoelectrochemical water splitting as well as to generate electricity, using dye-sensitized semiconductor solar cells.

EXAMPLE 17.13

What properties should you specify for a dye to be used as a sensitizer in a dye-sensitized solar cell used for direct photoelectrochemical water splitting or for generating electricity directly in a cell like the Graetzel cell discussed in the *Connection to Energy:* Solar Energy Conversion?

Solution

The LUMO of the dye must lie at higher energy than the conduction band of the semiconductor in order for electron injection to occur; this requirement must be met for both applications.

17.6 BATTERIES AND FUEL CELLS

Batteries and fuel cells are examples of galvanic cells that convert chemical energy into electrical energy, the difference being that batteries carry all of their fuel with them and must be replaced or recharged, whereas fuel cells operate continuously as long as fuel and oxygen are being supplied. You are familiar with the batteries you use in cell phones, laptops, and other consumer products, but applications of batteries and fuel cells for transportation and energy storage are becoming increasingly important as well, driven primarily by energy and environmental concerns. We discuss the chemistry of several of the most common battery systems in current use and introduce you to fuel cells in this section.

Batteries

The origin of the **battery** is lost in history, but it could very well date back some 2000 years. A jar discovered near Baghdad in 1936 has all of the elements needed to generate a voltage, and replicas of the "Baghdad Battery" have produced about 2 V, using common electrolytes available in ancient times, like grape juice. Whether the jar was indeed used to electroplate objects with gold remains a matter of speculation. The development of the modern battery began with the invention of the voltaic pile in 1800, as mentioned earlier. The pile was a collection of galvanic cells (a battery of cells) connected in series (cathode to anode) so that the individual cell voltages added together; enough cells added together could produce a battery that

Batteries vary in size and chemistry. Shown here are an automobile lead-storage battery, rechargeable nickel–cadmium cells, alkaline cells, and zinc–carbon dry cells.

could deliver quite a shock. Modern usage makes no distinction between a single cell and the voltaic pile, and the word *battery* has come to mean the cell itself. Cells that are discarded when their electrical energy has been spent are called **primary** cells, and those that can be recharged are called **secondary** cells.

The most familiar primary cell is the **Leclanché cell** (also called a *zinc–carbon dry cell*) used for flashlights, portable radios, and a host of other purposes. More than five billion such dry cells are used worldwide each year, and estimates place the quantity of zinc consumed for this purpose at more than 30 metric tons per day. The "dry cell" is not really dry at all. Rather, its electrolyte is a moist powder containing ammonium chloride and zinc chloride. Figure 17.21 is a cutaway illustration of a dry cell, which consists of a zinc shell that serves as the anode (negative terminal) and an axial graphite rod for a cathode (positive terminal), with the rod surrounded by a densely packed layer of graphite and manganese dioxide.

Each of these components performs an interesting and essential function. Oxidation occurs at the zinc anode:

$$\mathrm{Zn}(s) \longrightarrow \mathrm{Zn}^{2+}(aq) + 2\,e^- \quad \text{(anode)}$$

The moist salt mixture (like the salt bridge in Figure 17.2) enables ion exchange between the sites of the anode and cathode half-reactions to maintain electrical neutrality as electrons flow through the external circuit. Manganese dioxide, the ultimate electron acceptor, is reduced to Mn_2O_3 by $H_2(g)$, produced by the reduction of ammonium ions in the following series of reactions:

$$2\,\mathrm{NH_4^+}(aq) + 2\,e^- \longrightarrow \mathrm{H_2}(g) + 2\,\mathrm{NH_3}(aq)$$

$$\mathrm{H_2}(g) + 2\,\mathrm{MnO_2}(s) \longrightarrow \mathrm{Mn_2O_3}(s) + \mathrm{H_2O}(\ell)$$

Mixing powdered graphite with powdered MnO_2 greatly increases the effective surface area of the cathode, reduces the internal resistance of the cell, and enables currents of several amperes to flow. The overall cell reaction is

$$\mathrm{Zn}(s) + 2\,\mathrm{MnO_2}(s) + 2\,\mathrm{NH_4^+}(aq) \longrightarrow \mathrm{Zn^{2+}}(aq) + \mathrm{Mn_2O_3}(s) + 2\,\mathrm{NH_3}(aq) + \mathrm{H_2O}(\ell)$$

The cell components are hermetically sealed (airtight) in a steel shell that is in contact with the zinc anode and thus acts as the negative terminal of the battery. Zinc–carbon dry cells produce 1.5 V when new.

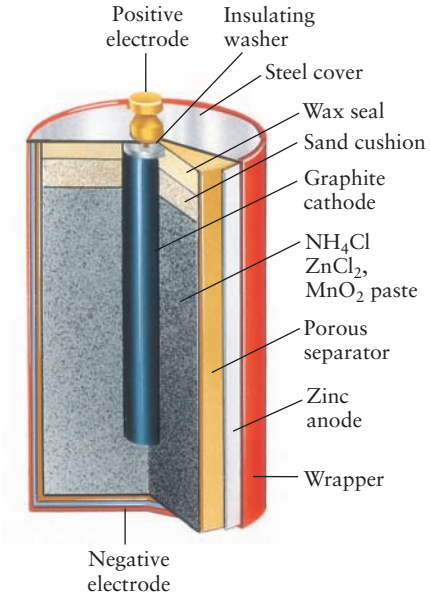

FIGURE 17.21 Leclanche "dry"cell. Electrons produced by oxidation of zinc metal at the anode flow through an external circuit and return at the cathode, where the reduction of MnO_2 occurs.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The disadvantage of the Leclanché cell is that the concentration of protons (available as $NH_4^+(aq)$) decreases with time, and the battery's voltage falls as it is used. The zinc anode also corrodes as it oxidizes, and the electrolyte leaks out. The **alkaline dry cell** has largely replaced the Leclanché cell as the dominant primary cell for consumer applications; potassium hydroxide replaces ammonium chloride, and the half-cell reactions are

$$Zn(s) + 2\ OH^- \longrightarrow Zn(OH)_2(s) + 2\ e^- \qquad \text{(anode)}$$

$$2\ MnO_2(s) + H_2O(\ell) + 2\ e^- \longrightarrow Mn_2O_3(s) + 2\ OH^- \qquad \text{(cathode)}$$

The overall cell reaction is then

$$Zn(s) + 2\ MnO_2(s) + H_2O(\ell) \longrightarrow Zn(OH)_2(s) + Mn_2O_3(s)$$

All of the reactants and products in alkaline cells are pure solids or liquids whose concentrations are fixed, and so the cell voltage remains stable over time.

The third primary cell we discuss is the **zinc–mercuric oxide cell** shown in Figure 17.22. It is commonly packaged in the shape of a small button that is convenient for use in automatic cameras, hearing aids, digital calculators, and quartz–electric watches. The anode is a mixture of mercury and zinc, and the cathode is made of steel in contact with solid mercury(II) oxide (HgO). The electrolyte is a 45% KOH solution that saturates an absorbent material. The anode half-reaction is the same as that in an alkaline dry cell,

$$Zn(s) + 2\ OH^- \longrightarrow Zn(OH)_2(s) + 2\ e^- \qquad \text{(anode)}$$

but the cathode half-reaction is now

$$HgO(s) + H_2O(\ell) + 2\ e^- \longrightarrow Hg(\ell) + 2\ OH^- \qquad \text{(cathode)}$$

The overall reaction is

$$Zn(s) + HgO(s) + H_2O(\ell) \longrightarrow Zn(OH)_2(s) + Hg(\ell)$$

The voltage (1.34 V) produced by these batteries is very stable over time, which made them especially valuable for use in communication equipment and scientific instruments.

Environmental concerns about mercury led federal regulators to ban their manufacture, however, and they have been replaced by lithium batteries (not lithium-ion batteries, discussed next) for portable electronics applications in cameras, watches, and calculators, for example. Lithium metal is the anode and MnO_2 is the cathode, with lithium perchlorate dissolved in a mixture of propylene carbonate and 1,2-dimethoxyethane as the electrolyte. The half-cell and overall cell reactions, which produce a nominal battery voltage of 3 V, are:

$$Li \longrightarrow Li^+ + e^-$$

$$\underline{(Mn^{4+})O_2 + Li^+ + e^- \longrightarrow (Mn^{3+})O_2\,(Li^+)}$$

$$Li + (Mn^{4+})O_2 \longrightarrow (Mn^{3+})O_2\,(Li^+)$$

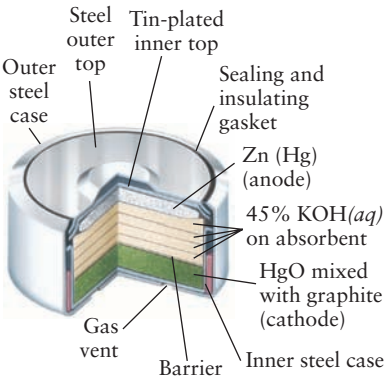

FIGURE 17.22 A zinc–mercuric oxide dry cell, used in electric watches and cameras.

Rechargeable Batteries

Rechargeable batteries have become very important in recent years for use in consumer products and transportation. The lithium-ion battery has become the dominant battery for use in laptops and cell phones. The lead acid battery has long been used in automotive applications with the nickel metal hydride (NiMH) battery having been developed as a rechargeable alternative for applications in hybrids and plug-in electric vehicles. Nickel metal hydride batteries are also popular alternatives to alkaline batteries for consumer applications because they can be recharged; they are

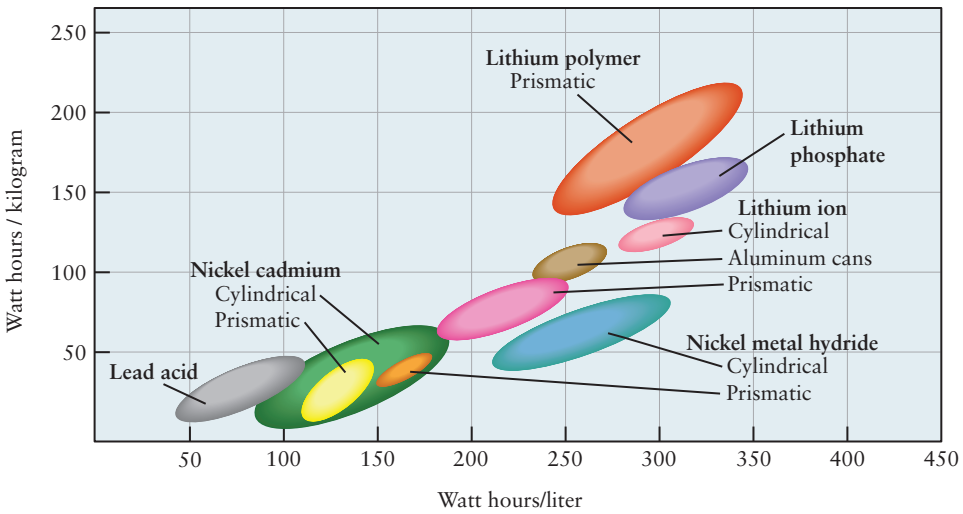

FIGURE 17.23 Ranges of typical energy densities for different classes of batteries.

manufactured in the same standard sizes. Batteries are recharged by applying an external potential that is greater in magnitude and opposite in sign to the galvanic cell potential, which causes the redox reactions to run in reverse, regenerating the reactants. Not all redox reactions are chemically reversible, however, which limits the choices for constructing rechargeable batteries. The Leclanché cell, for example, is not chemically reversible because the primary products are gases, hydrogen and ammonia, which are irreversibly bound up as water and $[Zn(NH_3)_2]^{2+}(aq)$ ions.

Rechargeable batteries are characterized by their voltages, the maximum current available (sustained for laptops or peak for camera flashes) and the total energy stored. The amount of charge available in a battery before it must be recharged is called its capacity, which for consumer applications has been defined as the maximum current that can be sustained for 20 hours of operation without dropping the voltage below an acceptable value. A 100 watt hour (Whr) battery, for example, will deliver 5 A for 20 hours. The battery in your laptop might have a rating of 3500 mAhr, meaning that it will provide 3.5 A for an hour or 1 A for 3.5 hours. The energy available from a battery before it must be recharged is given by the capacity times the voltage, so your laptop might provide itV = (3500 mAh)(10 V) = 35 J of energy before it needs to be recharged. Battery manufacturers continue to strive to develop batteries that deliver the most energy per unit volume of per-unit weight, depending upon their applications. These quantities are called the volumetric or gravimetric energy densities, measured in units Wh/L or Wh/kg, respectively. Modern Li-ion (see next page) laptop batteries achieve about 200 Wh/kg. Light metals such as lithium and magnesium are the most attractive cations for battery applications with hydroxide being among the most attractive anions. Figure 17.23 shows representative energy densities currently available in various classes of batteries.

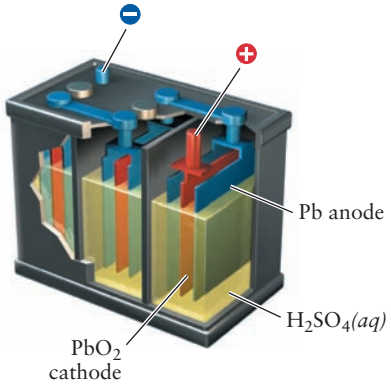

FIGURE 17.24 A lead–acid storage battery consists of several cells connected in series. The electrodes are both constructed from lead grids filled with spongy Pb (cathode) and PbO_2 (anode) and the electrolyte is sulfuric acid.

The **lead–acid battery** is currently the most widely used rechargeable battery in vehicles. A 12-V lead storage battery consists of six 2.0-V cells (Fig. 17.24) connected in series (cathode to anode) and housed in a hard rubber or plastic case. The anodes in each cell are made of lead grids filled with spongy lead to maximize the surface area in contact with the electrolyte; the cathodes are lead grids filled with PbO_2. The electrolyte is sulfuric acid solution (37% by mass).

Pb is oxidized to Pb^{2+} at the anode during discharge, while Pb^{4+} in PbO_2 is reduced to Pb^{2+} at the cathode; Pb^{2+} precipitates as lead sulfate on both electrodes. The half-cell reactions for the galvanic cells are

$$Pb(s) + SO_4^{2-} \longrightarrow PbSO_4(s) + 2\,e^- \qquad \text{(anode)}$$

$$PbO_2(s) + SO_4^{2-} + 4\,H_3O^+ + 2\,e^- \longrightarrow PbSO_4(s) + 6\,H_2O(\ell) \qquad \text{(cathode)}$$

$$Pb(s) + PbO_2(s) + 2\,SO_4^{2-} + 4\,H_3O^+ \longrightarrow 2\,PbSO_4(s) + 6\,H_2O(\ell)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The anode and cathode have both been largely converted to $PbSO_4(s)$ when the storage battery is fully discharged, and the concentration of sulfuric acid has fallen, because it is a reactant. Measuring the density of the electrolyte is a quick way to estimate the amount of charge available in the battery because the density of pure sulfuric acid is almost twice the density of water.

The lead–acid battery is recharged by applying a voltage greater than 12 V with the opposite polarity, which returns the battery to its initial state. One of the attractive features of lead–acid batteries is their ability to undergo thousands of charge/discharge cycles before they ultimately fail because $PbSO_4$ flakes fall off from the electrodes (preventing regeneration of Pb and PbO_2) or they develop internal short circuits. Lead–acid batteries designed for use in vehicles are not allowed to discharge completely. An alternator driven by the engine charges the battery continuously, or at least intermittently. About 1.8×10^7 J can be provided by an average automobile battery before it needs recharging, and currents as large as 100 A are available for the short time needed to start the engine.

A drawback of the lead–acid storage battery is its low energy density, the amount of energy obtainable per kilogram of battery mass. This limitation is not important when a battery is used primarily to start a gasoline-powered automobile, but it precludes the battery's use in vehicles driven by electric motors. The low energy density of the lead–acid battery limits the range of electric vehicles, and it has stimulated electrochemists to develop secondary batteries that have much higher energy densities.

Lithium-ion batteries are currently the most widely used rechargeable batteries for portable electronics applications. They have very high energy densities, due to lithium's low atomic mass, and are much safer than lithium batteries because they do not contain elemental lithium, which is very reactive. The chemistry of the lithium-ion battery is quite interesting, as shown schematically in Figure 17.25 and summarized by the reactions shown below. Lithium ions shuttle back and forth through an electrolyte between a $LiCoO_2$ cathode and a graphite anode represented as Li_yC_6 (we represent graphite by the symbol C_6 to remind you that it is a two-dimensional sheet of benzene rings).

Li^+ ions intercalate (insert) between the atomic planes of these layered structures, and electrons flow through the external circuit to balance charge. Other transition metals are being used in newer versions of this technology, so the general half-cell and the overall cell reactions may be written as:

$$\begin{aligned} Li_yC_6 &\longrightarrow y\ Li^+ + y\ e^- && \text{(anode)} \\ Li_{1-y}MO_2 + y\ Li^+ + y\ e^- &\longrightarrow LiMO_2 && \text{(cathode)} \\ \hline Li_yC_6 + Li_{1-y}MO_2 &\longrightarrow LiMO_2 \end{aligned}$$

The simplest way to think of this reaction is to consider what happens when single Li^+ ions shuttle back and forth. We can represent that situation by the reactions

$$\begin{aligned} LiC_6^- &\longrightarrow Li^+ + e^- && \text{(anode)} \\ LiM^{n+}O_2 + Li^+ + e^- &\longrightarrow LiM^{(n-1)+}O_2 && \text{(cathode)} \\ \hline LiC_6 + LiM^{n+}O_2 &\longrightarrow LiM^{(n-1)+}O_2 \end{aligned}$$

in which an electron occupies an antibonding orbital of one graphite ring to form a (localized) anion for every Li^+ ion intercalated into graphite. Graphite is oxidized when lithium migrates to the cathode and electrons travel through the external circuit to reduce M^{n+} to $M^{(n-1)+}$.

Nickel metal hydride (NiMH) batteries have replaced NiCd batteries as the rechargeable battery of choice for consumer applications like flashlights and have also begun to displace lead storage batteries from automotive applications, particularly for hybrid vehicles. The anodes in nickel metal hydride batteries are constructed from a variety of complex rare earth or nickel alloys, the hydrides of which are oxidized at the anode to form the elemental metals. The cathode is NiOOH

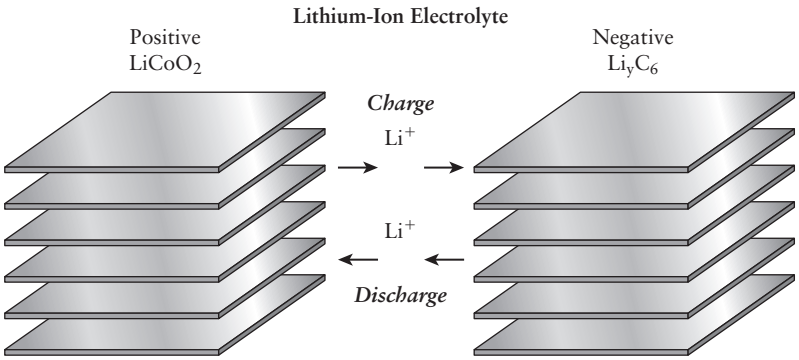

FIGURE 17.25 Lithium-ion battery schematic.

(nickel oxyhydride), at which the nickel is reduced from Ni^{3+} to Ni^{2+}. The electrolyte is typically KOH. The half-cell reactions and overall cell reaction are:

$$\begin{aligned} MH + OH^- &\longrightarrow M + H_2O + e^- \qquad \text{(anode)} \\ NiOOH + H_2O + e^- &\longrightarrow Ni(OH)_2 + OH^- \qquad \text{(cathode)} \\ \hline MH + NiOOH &\longrightarrow M + Ni(OH)_2 \end{aligned}$$

Another class of interesting batteries with high energy densities uses alkali metals (lithium or sodium) as anodes and sulfur as the electron acceptor. Sulfur does not conduct electricity, so graphite is used as the cathode. These batteries operate at high temperatures because the elements must be liquids for efficient electrical conduction (sulfur melts at 112°C, lithium at 186°C, and sodium at 98°C). The sodium–sulfur cell (Fig. 17.26), for example, has an optimal operating temperature of 250°C. The half-cell reactions are

$$\begin{aligned} 2\,Na &\longrightarrow 2\,Na^+ + 2\,e^- \qquad \text{(anode)} \\ S + 2\,e^- &\longrightarrow S^{2-} \qquad \text{(cathode)} \\ \hline 2\,Na + S &\longrightarrow 2\,Na^+ + S^{2-} \end{aligned}$$

The cathode reaction shown is an oversimplification because sulfide ions react with sulfur to form polysulfides:

$$S^{2-} + nS \longrightarrow S_{n+1}^{2-}$$

but the fundamental principles of the cell operation are the same.

What makes the sodium–sulfur cell possible is a remarkable property of a compound called beta-alumina, which has the composition $NaAl_{11}O_{17}$. Beta-alumina allows sodium ions to migrate through its structure very easily, but it blocks the passage of polysulfide ions. Therefore, it functions as a semipermeable medium like the membranes used in osmosis (see Section 11.5). This ionic solid electrolyte serves to physically separate the reactants from one another while permitting the transport of the redox-active species $Na^+(aq)$; the lithium–sulfur battery operates on similar principles.

Sodium–sulfur batteries, with their high energy densities, were originally developed with transportation applications in mind. NiMH batteries have become the current favorite for automotive applications, but the sodium–sulfur battery has found an important application in large-scale energy storage, where the high operating temperatures are less problematic. The city of Presidio, Texas (population ca. 4000), has suffered intermittent power outages over the years because it has been connected to the electric power grid by a single transmission line. The city has recently installed a sodium–sulfur battery that is about the size of a house (BOB—Big Old Battery) that will provide up to 4 MW of power for 8 hours, enough to power the entire town overnight. These batteries are also being used in remote locations to store energy generated from wind turbines or photovoltaic systems, making these locations independent of the electric utility grid.

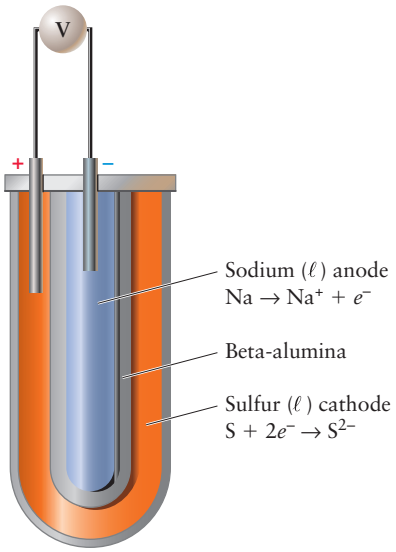

FIGURE 17.26 Schematic of a sodium–sulfur battery. Na^+ ions generated by oxidation at the anode also serve to neutralize charge as they migrate through beta-alumina to the cathode.

Fuel Cells

Fuel cells convert chemical potential energy into electrical energy using coupled redox reactions, like batteries, but they operate as long as they are being supplied with fuel. Batteries carry all of their "fuel" with them and must be replaced or recharged to continue to provide energy. Fuel cells operate using the same oxidation reactions as combustion but are much more efficient, in principle, because different thermodynamic considerations apply. We discuss two classes of fuel cells: polymer electrolyte membrane (PEM) fuel cells that have been developed for transportation and solid oxide fuel cells (SOFC) that are currently the dominant technology for large-scale stationary power generation. We focus on hydrogen fuel cells because of the attractive features they offer, but fuel cells that use methane or methanol as fuels have been developed and may have advantages in certain applications, for example, in areas where natural gas is readily available. However, carbon-based fuels, of course, emit CO_2 and contribute to climate change (see Section 20.6)

The basic components and operation of a PEM fuel cell are shown in Figure 17.27. The hydrogen fuel, entering from the left, is dissociated catalytically and ionized at the anode to produce protons and electrons. The electrons travel through the external circuit, producing work, while the protons move through the membrane toward the cathode. The electrons and protons react catalytically with molecular oxygen at the cathode in a four-electron reduction to produce water.

The overall cell reaction is

$$2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(\ell)$$

with a standard cell potential $E^\circ_{cell} = 1.229$ V. The polymer membranes in current use are fluorocarbons (hydrocarbons in which all of the hydrogen atoms have been replaced by fluorine) with sulfonic acid $-(SO_3H)$ functional groups attached. Protons transfer by hopping between the sulfonic acid groups' side groups along and between the polymer chains. The operating temperature of current PEM fuel cells is limited to about 80°C because the polymer membranes must remain hydrated for this proton transfer mechanism to work. Developing alternative membrane materials that transport protons at higher temperatures is an active area of research in materials science and engineering. Increasing the activity and reducing the cost of the oxygen reduction catalysts is also another area of intense current interest. Present generation PEM fuel cells use finely divided Pt nanoparticles supported on carbon substrates. A factor of 10 improvement in oxygen reduction activity has been demonstrated recently by controlling the surface morphology and subsurface electronic structure of platinum nanocrystals that have been alloyed with other metals

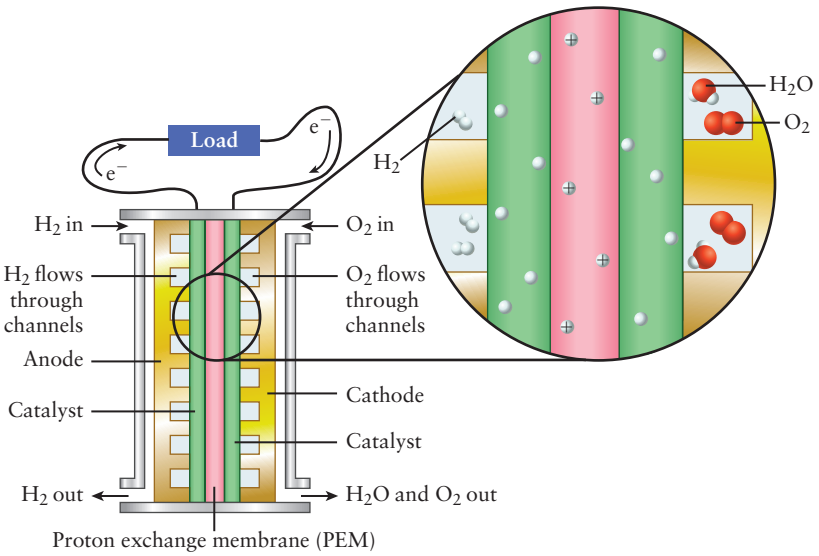

FIGURE 17.27 Polymer electrolyte membrane (PEM) fuel cell.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

such as nickel. The surface layer of these particles is pure Pt, which has long been known to be effective at breaking O–O bonds and forming O–H bonds. A subsurface alloy with nominal composition, $PtNi_3$ alters the electronic structure of the surface layer to make it an even more effective catalyst for oxygen reduction. Collaboration between experimental and computational materials scientists on the development of new catalysts for oxidation–reduction and other important catalytic reactions is a particularly exciting area of current research.

To better understand the attractive characteristics of fuel cells, let's compare the energy available from the hydrogen oxygen PEM fuel cell with that available from the combustion of hydrogen in an internal combustion engine. The relevant reaction for transportation is

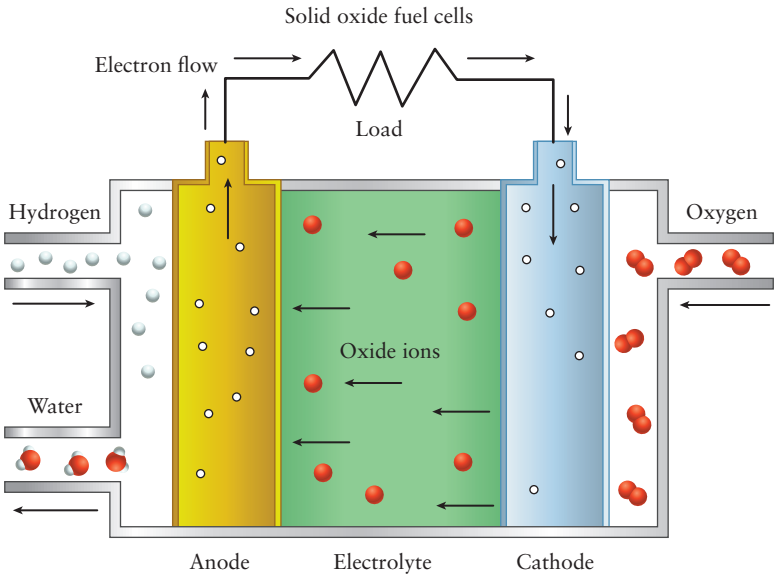
$$H_2(g) + \tfrac{1}{2}\ O_2(g) \longrightarrow H_2O(g) \qquad \Delta H_f^o = -241.8\ \text{kJ mol}^{-1}$$

because water is produced as a high-temperature exhaust gas. We calculate the maximum work available from combustion as follows:

$$-w_{max} = \epsilon q_p = (1 - T_l/T_h)\Delta H_f^o$$

where ϵ is the Carnot efficiency, q_p is the heat transferred at constant pressure, T_l is the temperature of the exhaust gas, and T_h is the operating temperature of the internal combustion engine. The Carnot efficiency of an internal combustion engine is about 45%, so the maximum theoretical work available from hydrogen used as a fuel in such an engine is

$$-w_{max} = (-0.4)(-241.8\ \text{kJ mol}^{-1}) = +96\ \text{kJ mol}^{-1}$$



Note that we have used the chemist's thermodynamic sign convention in which work done *by* the system is negative; work done *on* the surroundings is therefore positive. The maximum work available if the same reaction is carried out in a fuel cell is $-w_{max} = \Delta G_f^o = -228.6\ \text{kJ mol}^{-1}$, which is more than twice that available, in principle, from the internal combustion engine. $\Delta G^o \approx \Delta H^o$ for combustion reactions, so finding ways to capture that energy without suffering the losses imposed by the Carnot efficiency is an important goal. Electric vehicles powered by fuel cells are also significantly more efficient than those powered by internal combustion engines, not only because of the more favorable thermodynamic considerations but also because electric motors are mechanically more efficient than internal combustion engines, the former being about 90% efficient compared with 75% efficiency for the latter. We can compare the so-called "tank-to-wheel" efficiencies of a vehicle powered by a hydrogen fuel cell to one powered by a hydrogen-fueled internal combustion engine by multiplying the work available by the mechanical efficiencies of each engine and taking the ratio.

$$\frac{\text{Overall efficiency fuel cell vehicle}}{\text{Overall efficiency internal combustion engine vehicle}} = \frac{(0.9)(228.6\ \text{kj mol}^{-1})}{(0.75)(96\ \text{kj mol}^{-1})} = 2.89$$

The U.S. Department of Energy has been evaluating a fleet of fuel cell vehicles for several years now and reports an average efficiency for the fuel cells in the 53–58% range, which is very close to their target of 60%. (Efficiency is defined as the ratio of the electrical power produced to the heating value of the fuel.) Honda has introduced a prototype hydrogen-powered fuel cell car called the FCX Clarity, which is undergoing real-world testing in California during 2009–2010. Honda reports a tank-to-wheel efficiency of 60%, which is, indeed, about three times higher than that of vehicles powered by internal combustion engines. There are, of course, many practical issues that need to be addressed before vehicles powered by fuel cells are widely deployed, but we believe that this is a promising technology and one that clearly illustrates the advantages of capturing chemical energy directly as electrical energy, without the inevitable thermodynamic losses associated with combustion.

FIGURE 17.28 Solid oxide fuel cell.

Solid oxide fuel cells (SOFC) appear to be the current technology of choice for large-scale stationary power generation, whether to produce backup power for critical applications such as hospitals or for generating power in remote locations that are not served by the electrical power grid. A schematic of an SOFC is shown in Figure 17.28.

The electrolytes in these cells are oxide ceramics (see Section 22.2), an important example of which is zirconium oxide (ZrO_2) that has been doped with yttrium oxide, Y_2O_3. Doping replaces some of the Zr^{4+} ions with Y^{3+} ions, which creates oxide "vacancies" because only three oxide ions per Y^{3+} are required for charge neutrality. Oxide ions can move through the lattice at sufficiently high temperatures (1000 °C), which provides a mechanism for ionic conduction. The overall cell reaction for a typical solid oxide fuel cell that uses hydrogen is

$$H_2(g) + \tfrac{1}{2}\,O_2(g) \longrightarrow H_2O(\ell) \qquad \Delta H_f^\circ = -285.8\ \text{kJ mol}^{-1}$$

when the product is liquid water. Considerably more thermal energy is available from this reaction then when the product is steam because the heat stored in the steam is recovered, as it cools to the boiling point, from the enthalpy of condensation, and from cooling the liquid water further to ambient temperatures. The standard cell potentials are similar for both high-temperature and low-temperature products, but the waste heat can be captured in stationary solid oxide fuel cells, unlike those that power vehicles. The intrinsic overall efficiencies of solid oxide fuel cells have been demonstrated to be around 50%, increasing if the steam is used to drive turbines to around 70%, and up to 80% or so if the waste heat is recovered. These systems can be quite large; commercial versions can provide 250 kW to 1MW of power, which is sufficient for emergency backup at large installations like hospitals.

17.7 CORROSION AND CORROSION PREVENTION

The **corrosion** of metals is one of the most significant problems faced by advanced industrial societies (Fig. 17.29). It has been estimated that in the United States alone, the annual cost of corrosion amounts to tens of *billions* of dollars. Effects of corrosion are both visible (the formation of rust on exposed iron surfaces) and invisible (the cracking and resulting loss of strength of metal beneath the surface).

FIGURE 17.29 Rust.

The mechanism of corrosion must be understood before processes can be developed for its prevention.

Although corrosion is a serious problem for many metals, we focus on the spontaneous electrochemical reactions of iron. Corrosion can be pictured as a "short-circuited" galvanic cell, in which some regions of the metal surface act as cathodes and others as anodes, and the electric "circuit" is completed by electrons flowing through the iron itself. These electrochemical cells form in parts of the metal where there are impurities or in regions that are subject to stress. The anode reaction is

$$\mathrm{Fe}(s) \longrightarrow \mathrm{Fe}^{2+}(aq) + 2\ e^-$$

Various cathode reactions are possible. In the absence of oxygen (for example, at the bottom of a lake), the corrosion reactions are

$$\begin{aligned} \mathrm{Fe}(s) &\longrightarrow \mathrm{Fe}^{2+}(aq) + 2\ e^- && \text{(anode)} \\ 2\ \mathrm{H_2O}(\ell) + 2\ e^- &\longrightarrow 2\ \mathrm{OH}^-(aq) + \mathrm{H_2}(g) && \text{(cathode)} \\ \hline \mathrm{Fe}(s) + 2\ \mathrm{H_2O}(\ell) &\longrightarrow \mathrm{Fe}^{2+}(aq) + 2\ \mathrm{OH}^-(aq) + \mathrm{H_2}(g) \end{aligned}$$

These reactions are generally slow and do not cause serious amounts of corrosion. Far more extensive corrosion takes place when the iron is in contact with both oxygen and water. In this case the cathode reaction is

$$\tfrac{1}{2}\,\mathrm{O_2}(g) + 2\ \mathrm{H_3O}^+(aq) + 2\ e^- \longrightarrow 3\ \mathrm{H_2O}(\ell)$$

The Fe^{2+} ions formed simultaneously at the anode migrate to the cathode, where they are further oxidized by O_2 to the +3 oxidation state to form rust ($Fe_2O_3{\cdot}xH_2O$), a hydrated form of iron(III) oxide:

$$2\ \mathrm{Fe}^{2+}(aq) + \tfrac{1}{2}\,\mathrm{O_2}(g) + (6 + x)\mathrm{H_2O}(\ell) \longrightarrow \mathrm{Fe_2O_3}{\cdot}x\mathrm{H_2O} + 4\ \mathrm{H_3O}^+(aq)$$

The hydronium ions produced in this reaction allow the corrosion cycle to continue.

When a portion of the paint that protects a piece of iron or steel is chipped off (Fig. 17.30), the exposed area acts as the cathode because it is open to the atmosphere (air and water) and is therefore rich in oxygen, whereas oxygen-poor areas *under* the paint act as anodes. Rust forms on the cathode (the visible, exposed region), and pitting (loss of metal through oxidation of iron and flow of metal ions to the cathode) occurs at the anode. This pitting can lead to loss of structural strength in girders and other supports. The most serious harm done by corrosion is not the visible rusting but the damage done beneath the painted surface.

A number of factors speed corrosion. Dissolved salt provides an electrolyte that improves the flow of charge through solution; a well-known example is the rapid

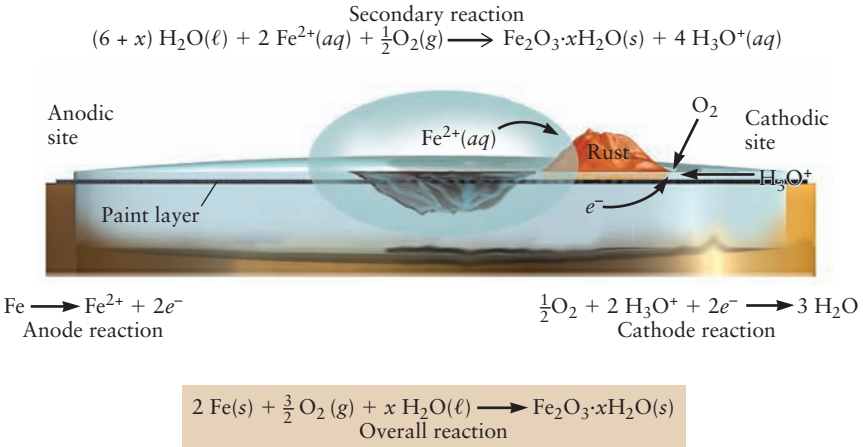

FIGURE 17.30 Schematic of iron corrosion. Pitting occurs in the anodic region, and rust appears in the cathodic region. The movement of hydronium ions through the hydrated rust pile is not shown.

rusting of cars in areas where salt is spread on icy roads. Higher acidity also increases corrosion, as seen by the role of H_3O^+ as a reactant in the reduction process at the cathode. Acidity is enhanced by the presence of dissolved CO_2 (which produces H_3O^+ and HCO_3^- ions) and by air pollution from oxides of sulfur, which leads to the formation of dissolved sulfuric acid in acid precipitation.

Corrosion of iron can be inhibited in a number of ways. Coatings of paint or plastics obviously protect the metal, but they can crack or suffer other damage, thereby localizing and accentuating the process. An important method of protecting metals arises from the phenomenon of **passivation,** in which a thin metal oxide layer forms on the surface and prevents further electrochemical reactions. Some metals become passivated spontaneously upon exposure to air; aluminum, for example, reacts with oxygen to form a thin protective layer of Al_2O_3. Special paints designed to prevent rusting contain potassium dichromate ($K_2Cr_2O_7$) and lead oxide (Pb_3O_4), which cause the superficial oxidation and passivation of iron. Stainless steel is an alloy of iron with chromium in which the chromium leads to passivation and prevents rusting.

A different way of preventing iron corrosion is to use a **sacrificial anode.** A comparison of the standard reduction potentials of iron and magnesium

$$Fe^{2+} + 2\,e^- \longrightarrow Fe(s) \qquad E° = -0.41\ V$$

$$Mg^{2+} + 2\,e^- \longrightarrow Mg(s) \qquad E° = -2.39\ V$$

shows that Mg^{2+} is much harder to reduce than Fe^{2+} or, conversely, that Mg(s) is more easily oxidized than Fe(s). A piece of magnesium in electrical contact with iron is oxidized in preference to the iron, and the iron is therefore protected. The magnesium is the sacrificial anode, and once it is consumed by oxidation it must be replaced. This method is used to protect ship hulls, bridges, and iron water pipes from corrosion. Magnesium plates are attached at regular intervals along a piece of buried pipe, and it is far easier to replace them periodically than to replace the entire pipe.

17.8 ELECTROMETALLURGY

The recovery of metals from their sources in the earth is the science of **extractive metallurgy,** a discipline that draws on chemistry, physics, and engineering for its methods. As a science it is a comparatively recent subject, but its beginnings, which were evidently in the Near East about 6000 years ago, marked the emergence of humanity from the Stone Age. The earliest known metals were undoubtedly gold, silver, and copper because they could be found in their native (elemental) states (Fig. 17.31). Gold and silver were valued for their ornamental uses, but they are too soft to have been made into tools. Iron was also found in elemental form—although rarely—in meteorites.

© Cengage Learning/Charles D. Winters

FIGURE 17.31 A specimen of native copper.

Most metals in nature are combined with other elements, such as oxygen and sulfur in ores, and chemical processes are required to free them. As Table 17.1 shows, the free energies of formation of most metal oxides are negative, indicating that the reverse reactions, which would yield the free metal and oxygen, have positive free energy changes. Scientists can carry out one of these reverse reactions to obtain the free metal only by coupling it with a second, spontaneous chemical reaction. The greater the cost in free energy, the more difficult the production of the free metal. Thus, silver and gold (at the bottom of Table 17.1) exist in nature as elements, and mercury can be released from its oxide or sulfide ore (cinnabar) merely by moderate heating (see Fig. 1.6). Extracting pure copper, zinc, and iron requires more stringent conditions; the ores of these metals are reduced in chemical reactions at high temperatures, collectively called **pyrometallurgy.** These reactions are carried out in huge furnaces, in which a fuel such as

TABLE 17.1

Metal Oxides Arranged According to Ease of Reduction

Metal Oxide	Metal	$n^\dagger$	$\Delta G_f^\circ/n^\dagger$ (kJ mol^{-1})	A Method of Production of the Metal
MgO	Mg	2	−285	Electrolysis of $MgCl_2$
Al_2O_3	Al	6	−264	Electrolysis
TiO_2	Ti	4	−222	Reaction with Mg
Na_2O	Na	2	−188	Electrolysis of NaCl
Cr_2O_3	Cr	6	−176	Electrolysis, reduction by Al
ZnO	Zn	2	−159	Smelting of ZnS
SnO_2	Sn	4	−130	Smelting
Fe_2O_3	Fe	6	−124	Smelting
NiO	Ni	2	−106	Smelting of nickel sulfides
PbO	Pb	2	−94	Smelting of PbS
CuO	Cu	2	−65	Smelting of $CuFeS_2$
HgO	Hg	2	−29	Moderate heating of HgS
Ag_2O	Ag	2	−6	Found in elemental form
Au_2O_3	Au	6	>0	Found in elemental form

†The standard free energies of formation of the metal oxides in kJ mol^{-1} are adjusted for fair comparison by dividing them by n, the total decrease in oxidation state required to reduce the metal atoms contained in the oxide to oxidation states of 0. Thus, the reduction of Cr_2O_3 involves a change in the oxidation state of two chromium atoms from +3 to 0, so $n = 2 \times 3 = 6$.

coke (coal from which volatile components have been expelled) serves both as the reducing agent and as the source of heat to maintain the required high temperatures. The process, called **smelting,** involves both chemical change and melting. The combustion of carbon

$$C(s) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta G^\circ = -394 \text{ kJ mol}^{-1}$$

provides the driving force for the overall reaction.

Even smelting is not sufficient to recover the metals at the top of Table 17.1, which have the most negative free energies of formation for their oxides (and for their sulfides as well). These metals have particularly high values of free energy relative to their compounds found in readily available ores. **Electrometallurgy,** or electrolytic production, provides the best ways of recovering such elements from their ores. Electrochemical cells are also used to purify the metals produced by the techniques of pyrometallurgy.

Aluminum

Aluminum is the third most abundant element in the earth's crust (after oxygen and silicon), accounting for 8.2% of the total mass. It occurs most commonly in association with silicon in the aluminosilicates of feldspars and micas and in clays, the products of weathering of these rocks. The most important ore for aluminum production is bauxite, a hydrated aluminum oxide that contains 50% to 60% Al_2O_3; 1% to 20% Fe_2O_3; 1% to 10% silica; minor concentrations of titanium, zirconium, vanadium, and other transition-metal oxides; and the balance (20% to 30%) water. Bauxite is purified via the **Bayer process,** which takes advantage of the fact that the amphoteric oxide alumina is soluble in strong bases but iron(III) oxide is not. Crude bauxite is dissolved in sodium hydroxide

$$Al_2O_3(s) + 2\ OH^-(aq) + 3\ H_2O(\ell) \longrightarrow 2\ Al(OH)_4^-(aq)$$

and separated from hydrated iron oxide and other insoluble impurities by filtration. Pure hydrated aluminum oxide precipitates when the solution is cooled to supersaturation and seeded with crystals of the product:

$$2\ Al(OH)_4^-(aq) \longrightarrow Al_2O_3 \cdot 3H_2O(s) + 2\ OH^-(aq)$$

The water of hydration is removed by calcining at high temperature (1200°C).

Compared with copper, iron, gold, and lead, which were known in antiquity, aluminum is a relative newcomer. Sir Humphry Davy obtained it as an alloy of iron and proved its metallic nature in 1809. It was first prepared in relatively pure form in 1825 by H. C. Oersted through reduction of aluminum chloride with an amalgam of potassium dissolved in mercury

$$AlCl_3(s) + 3\ K(Hg)_x(\ell) \longrightarrow 3\ KCl(s) + Al(Hg)_{3x}(\ell)$$

after which the mercury was removed by distillation. Aluminum remained largely a laboratory curiosity until 1886, when Charles Hall in the United States (then a 21-year-old graduate of Oberlin College) and Paul Héroult (a Frenchman of the same age) independently invented an efficient process for its production. In the 1990s the worldwide production of aluminum by the **Hall–Héroult process** was approximately 1.5×10^7 metric tons per year.

The Hall–Héroult process involves the cathodic deposition of aluminum, from molten cryolite (Na_3AlF_6) containing dissolved Al_2O_3, in electrolysis cells (Fig. 17.32). Each cell consists of a rectangular steel box some 6 m long, 2 m wide, and 1 m high, which serves as the cathode, and massive graphite anodes that extend through the roof of the cell into the molten cryolite bath. Enormous currents (50,000 to 100,000 A) are passed through the cell, and as many as one hundred such cells may be connected in series.

Molten cryolite, which is completely dissociated into Na^+ and AlF_6^{3-} ions, is an excellent solvent for aluminum oxide, giving rise to an equilibrium distribution of ions such as Al^{3+}, AlF^{2+}, AlF_2^+, . . ., AlF_6^{3-}, and O^{2-} in the electrolyte. Cryolite melts at 1000°C, but its melting point is lowered by dissolved aluminum oxide, so the operating temperature of the cell is about 950°C. Compared with the melting point of pure Al_2O_3 (2050°C), this is a low temperature, and it is the reason the Hall–Héroult process has succeeded. Molten aluminum is somewhat denser than the melt at 950°C and therefore collects at the bottom of the cell, from which it is tapped periodically. Oxygen is the primary anode product, but it reacts with the graphite electrode to produce carbon dioxide. The overall cell reaction is

$$2\ Al_2O_3 + 3\ C \longrightarrow 4\ Al + 3\ CO_2$$

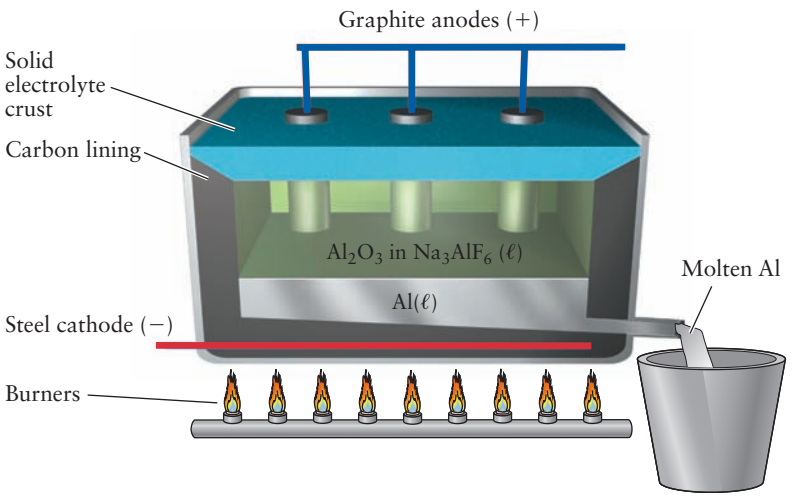

FIGURE 17.32 An electrolytic cell used in the Hall–Héroult process for the commercial production of aluminum.

TABLE 17.2

Densities of Selected Metals

Metal	Density (g cm^{-3}) at Room Conditions
Li	0.534
Na	0.971
Mg	1.738
Al	2.702
Ti	4.54
Zn	7.133
Fe	7.874
Ni	8.902
Cu	8.96
Ag	10.500
Pb	11.35
U	18.95
Au	19.32
Pt	21.45

Aluminum and its alloys have a tremendous variety of applications. Many of these make use of aluminum's low density (Table 17.2), an advantage over iron or steel when weight savings are desirable—such as in the transportation industry, which uses aluminum in vehicles from automobiles to satellites. Aluminum's high electrical conductivity and low density make it useful for electrical transmission lines. For structural and building applications, its resistance to corrosion is an important feature, as is the fact that it becomes stronger at subzero temperatures. (Steel and iron sometimes become brittle under these circumstances.) Household products that contain aluminum include foil, soft drink cans, and cooking utensils.

Magnesium

Like aluminum, magnesium is an abundant element on the surface of the earth, but it is not easy to prepare in elemental form. Although ores such as dolomite [$CaMg(CO_3)_2$] and carnallite [$KMgCl_3{\cdot}6(H_2O)$] exist, the major commercial source of magnesium and its compounds is seawater. Magnesium forms the second most abundant positive ion in the sea, and scientists separate Mg^{2+} from the other cations in seawater (Na^+, Ca^{2+}, and K^+, in particular) by taking advantage of the fact that magnesium hydroxide is the least soluble hydroxide of the group. Economical recovery of magnesium requires a low-cost base to treat large volumes of seawater and efficient methods for separating the $Mg(OH)_2(s)$ that precipitates from the solution. One base that is used in this way is calcined dolomite, prepared by heating dolomite to high temperatures to drive off carbon dioxide:

$$CaMg(CO_3)_2(s) \longrightarrow CaO \cdot MgO(s) + 2\ CO_2(g)$$

The greater solubility of calcium hydroxide ($K_{sp} = 5.5 \times 10^{-6}$) relative to magnesium hydroxide ($K_{sp} = 1.2 \times 10^{-11}$) leads to the reaction

$$CaO \cdot MgO(s) + Mg^{2+}(aq) + 2\ H_2O(\ell) \longrightarrow 2\ Mg(OH)_2(s) + Ca^{2+}(aq)$$

The magnesium hydroxide that is produced in this process includes not only the magnesium from the seawater but also that from the dolomite.

An interesting alternative to dolomite as a base for magnesium production is a process used off the coast of Texas (Fig. 17.33). Oyster shells (composed largely of $CaCO_3$) are calcined to give lime (CaO), which is added to the seawater to yield magnesium hydroxide. The $Mg(OH)_2$ slurry (a suspension in water) is washed and filtered in huge nylon filters.

After purification, $Mg(OH)_2$ can be reacted with carbon dioxide to give magnesium carbonate, used for coating sodium chloride in table salt to prevent caking and for antacid remedies. Another alternative is to add hydrochloric acid to the magnesium hydroxide to neutralize it and yield hydrated magnesium chloride:

$$Mg(OH)_2(s) + 2\ HCl(aq) \longrightarrow MgCl_2(aq) + 2\ H_2O(\ell)$$

After the water is evaporated, the solid magnesium chloride is melted (m.p. 708°C) in a large steel electrolysis cell that holds as much as 10 tons of the molten salt. The steel in the cell acts as the cathode during electrolysis, with graphite anodes suspended from the top. The cell reaction is

$$MgCl_2(\ell) \longrightarrow Mg(\ell) + Cl_2(g)$$

The molten magnesium liberated at the cathode floats to the surface and is dipped out periodically, while the chlorine released at the anodes is collected and reacted with steam at high temperatures to produce hydrochloric acid. This is recycled for further reaction with magnesium hydroxide.

Until 1918, elemental magnesium was used mainly in fireworks and flashbulbs, which took advantage of its great reactivity with the oxygen in air and the bright light given off in that reaction (see Fig. 11.6). Since then, many further uses for the metal and its alloys have been developed. Magnesium is even less dense than aluminum and is used in alloys with aluminum to lower density and improve resis-

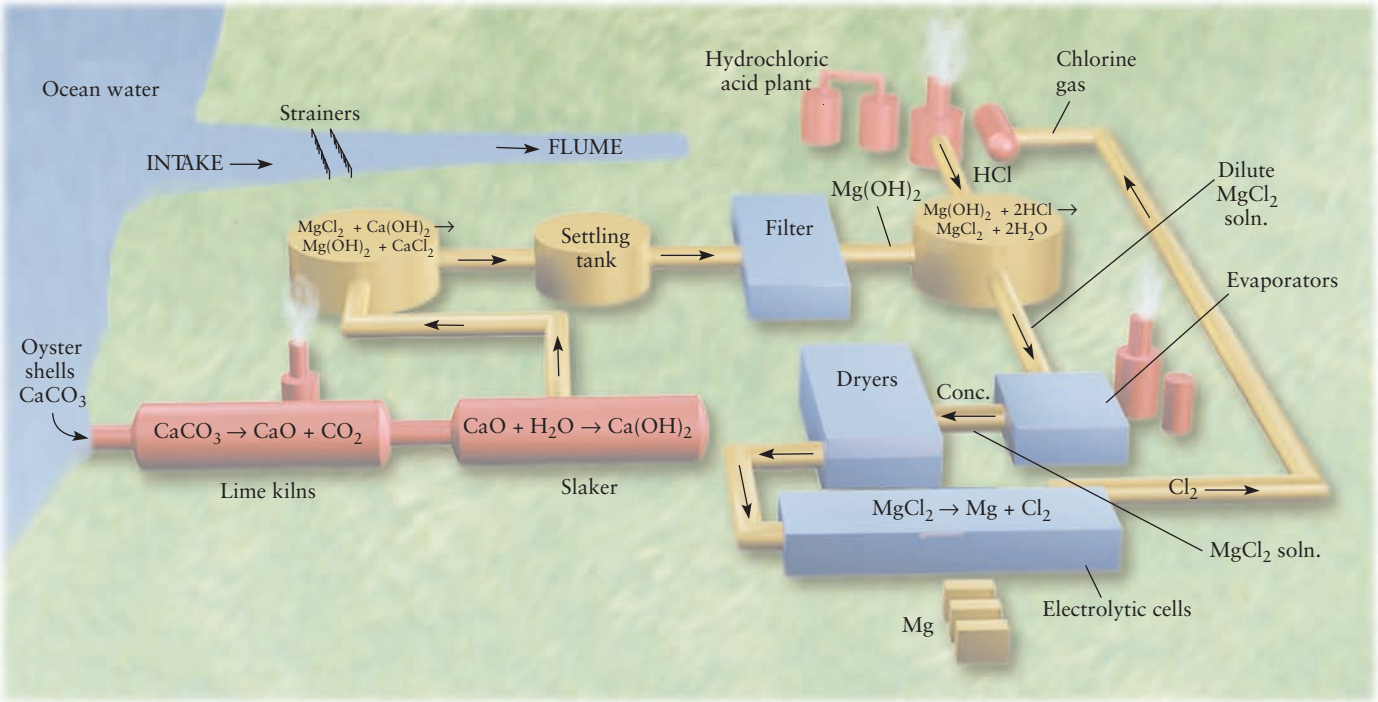

FIGURE 17.33 The production of magnesium hydroxide starts with the addition of lime (CaO) to seawater. Reaction of the magnesium hydroxide with hydrochloric acid produces magnesium chloride, which, after drying, is reduced electrolytically to produce magnesium metal.

tance to corrosion under basic conditions. As discussed in Section 17.7, magnesium is used as a sacrificial anode to prevent the oxidation of another metal with which it is in contact. It is also used as a reducing agent to produce other metals such as titanium, uranium, and beryllium from their compounds.

Electrorefining and Electroplating

Metals that have been produced by pyrometallurgical methods, such as copper, silver, nickel, and tin, are too impure for many purposes, and **electrorefining** is used to purify them further. Crude metallic copper is cast into slabs, which are used as anodes in electrolysis cells that contain a solution of $CuSO_4$ in aqueous H_2SO_4. Thin sheets of pure copper serve as cathodes, and the copper that dissolves at the anodes is deposited in purer form on the cathodes (Fig. 17.34). Impurities that are more easily oxidized than copper, such as nickel, dissolve along with the copper but remain in solution; elements that are less easily oxidized, such as silver and gold, do not dissolve but fall away from the anode as a metallic slime. Periodically, the anode slime and the solution are removed and further processed for recovery of the elements they contain.

A related process is **electroplating,** in which electrolysis is used to plate out a thin layer of a metal on another material, often a second metal. In chrome plating, the piece of metal to be plated is placed in a hot bath of sulfuric acid and chromic acid (H_2CrO_4) and is made the cathode in an electrolytic cell. As current passes through the cell, chromium is reduced from the +6 oxidation state in chromic acid to elemental chromium and plates out on the cathode. A decorative chromium layer can be as thin as 2.5×10^{-5} cm (corresponding to 2 g of Cr per square meter of surface). Thicker layers ranging up to 10^{-2} cm are found in hard chromium plate, prized for its resistance to wear and used in automobile trim. Steel can be plated with cadmium to improve its resistance to corrosion in marine environ-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

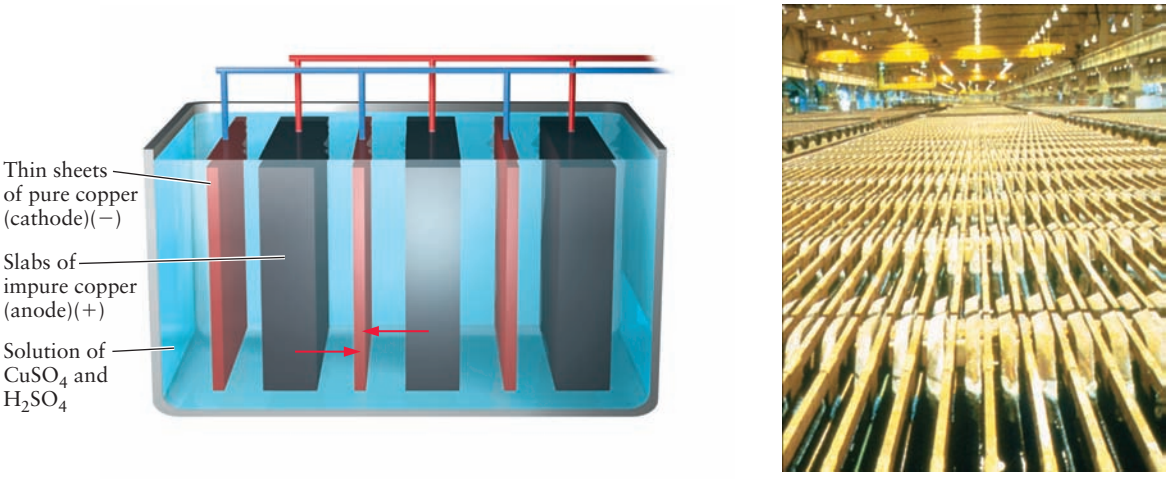

FIGURE 17.34 Electrolytic refining of copper. Many slabs of impure copper (anodes) alternating with thin sheets of pure copper (cathodes) are immersed into a dilute acidic solution of $CuSO_4$. Copper metal oxidized from the impure anodes enters the solution as Cu^{2+} ions that migrate to the cathodes where they plate out as copper metal of higher purity.

ments. Gold and silver are used both for decorative plating and (because they are good conductors of electricity) on electronic devices.

EXAMPLE 17.14

Suppose a layer of chromium 3.0×10^{-3} cm thick is to be plated onto an automobile bumper with a surface area of 2.0×10^{3} cm^2. If a current of 250 A is used, how long must current be passed through the cell to achieve the desired thickness? The density of chromium is 7.2 g cm^{-3}.

Solution

The volume of the Cr is the product of the thickness of the layer and the surface area:

$$\text{volume} = (3.0 \times 10^{-3}\ \text{cm})(2.0 \times 10^{3}\ \text{cm}^2) = 6.0\ \text{cm}^3$$

The mass of chromium is the product of this volume and the density:

$$\text{mass Cr} = (6.0\ \text{cm}^3)(7.2\ \text{g cm}^{-3}) = 43.2\ \text{g}$$

From this, the number of moles of Cr that must be reduced is

$$\frac{43.2\ \text{g}}{52.00\ \text{g mol}^{-1}} = 0.831\ \text{mol Cr}$$

Because Cr is being reduced from oxidation state +6 in H_2CrO_4 to 0 in the elemental form, six electrons are required for each atom of Cr deposited. The number of moles of electrons is then

$$0.831\ \text{mol Cr} \times \left(\frac{6\ \text{mol}\ e^-}{1\ \text{mol Cr}}\right) = 4.98\ \text{mol}\ e^-$$

$$\text{total charge} = (4.98\ \text{mol})(96{,}485\ \text{C mol}^{-1}) = 4.81 \times 10^{5}\ \text{C}$$

The required electrolysis time is the total charge divided by the current (in amperes):

$$\text{time} = \frac{4.81 \times 10^{5}\ \text{C}}{250\ \text{C s}^{-1}} = 1.9 \times 10^{3}\ \text{s} = 32\ \text{min}$$

A DEEPER LOOK

17.9 ELECTROLYSIS OF WATER AND AQUEOUS SOLUTIONS

In Section 17.8 we discussed applications of electrolysis in the extraction and purification of metals from their ore sources. We examine here the electrolysis of water and aqueous solutions. Consider first the electrolysis of water using a pair of inert electrodes such as platinum, for which the half-cell reactions are

$$\begin{aligned} 2\ H_3O^+ + 2\ e^- &\longrightarrow H_2 + 2\ H_2O && \text{(cathode)} \\ 3\ H_2O &\longrightarrow \tfrac{1}{2}\ O_2 + 2\ H_3O^+ + 2\ e^- && \text{(anode)} \\ \hline H_2O &\longrightarrow H_2 + \tfrac{1}{2}\ O_2 \end{aligned}$$

A practical problem immediately arises. The concentration of $H_3O^+(aq)$ and $OH^-(aq)$ ions in pure water at 25°C is only 1.0×10^{-7} M, so the *rate* of electrolysis will be exceedingly small. This practical consideration is put aside for the moment because it does not alter the *thermodynamic* analysis.

The concentration of H_3O^+ in pure water at 25°C is 1.0×10^{-7} M, so we must use the Nernst equation to calculate the reduction potentials for each half-reaction as follows:

$$\begin{aligned} E_{\text{cathode}} &= E^\circ_{\text{cathode}} - \frac{0.0592\ \text{V}}{n_{\text{hc}}}\ \log Q_{\text{hc}} \\ &= 0.00 - \frac{0.0592}{2}\ \log \frac{P_{H_2}}{[H_3O^+]^2} \end{aligned}$$

If $H_2(g)$ is produced at atmospheric pressure, this result simplifies to

$$\begin{aligned} E_{\text{cathode}} &= 0.00 - \frac{0.0592\ \text{V}}{2} \log \frac{1}{(10^{-7})^2} \\ &= -0.414\ \text{V} \end{aligned}$$

The reduction potential for the anode half-reaction

$$\tfrac{1}{2}\ O_2(g) + 4\ H_3O^+(aq) + 4\ e^- \longrightarrow 6\ H_2O(\ell)$$

is calculated using the standard reduction potential for that reaction as tabulated in Appendix E:

$$\begin{aligned} E_{\text{anode}} &= E^\circ_{\text{anode}} - \frac{0.0592\ \text{V}}{2}\ \log \frac{1}{(P_{O_2})^{1/2}[H_3O^+]^2} \\ &= 1.229\ \text{V} - \frac{0.0592\ \text{V}}{2}\ \log \frac{1}{(10^{-7})^2} \\ &= 0.815\ \text{V} \end{aligned}$$

if $P_{O_2} = 1$ atm. The overall cell potential is

$$E_{\text{cell}} = E_{\text{cathode}} - E_{\text{anode}} = -0.414 - 0.815\ \text{V} = -1.229\ \text{V}$$

which means that the decomposition of water to produce hydrogen and oxygen does not occur spontaneously, as we know very well. It can be made to occur by applying a potential that is sufficiently large and positive, called the **decomposition potential** of water, which is 1.229 V. Electrolysis of water can proceed under these

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. conditions to produce hydrogen, which produces bubbles at the cathode, and oxygen, which produces bubbles at the anode (see Figure 1.2).

What happens when we attempt to run electrolysis reactions in aqueous solutions? The products that are produced depend upon the nature of the solutes, their standard reduction potentials, and their concentrations. We could imagine the following reactions occurring in a 0.10 M aqueous solution of NaCl.
Cathode:

$$\mathrm{Na^+(0.1\ M)} + e^- \longrightarrow \mathrm{Na}$$

$$2\ \mathrm{H_3O^+(10^{-7}\ M)} + 2\ e^- \longrightarrow \mathrm{H_2} + 2\ \mathrm{H_2O}$$

Anode:

$$2\ \mathrm{Cl^-} \longrightarrow \mathrm{Cl_2} + 2\ e^-$$

$$6\ \mathrm{H_2O} \longrightarrow \mathrm{O_2} + 4\ \mathrm{H_3O^+(10^{-7}\ M)} + 4\ e^-$$

Let's examine each of these reactions in turn. The reduction potential for the first half-reaction is

$$E(\mathrm{Na^+|Na}) = E°(\mathrm{Na^+|Na}) - \frac{0.0592\ \mathrm{V}}{1}\ \log\ \frac{1}{[\mathrm{Na^+}]}$$

$$= -2.71 - 0.06 = -2.77\ \mathrm{V}$$

which is more negative than the reduction potential for H_3O^+ in pure water: $E^o = -0.414$ V. Hydronium ions are reduced preferentially over sodium ions under these conditions. The reduction potential for the third half-reaction is

$$E(\mathrm{Cl_2|Cl^-}) = E°(\mathrm{Cl_2|Cl^-}) - \frac{0.0592\ \mathrm{V}}{1}\ \log\ \frac{[\mathrm{Cl^-}]}{P_{\mathrm{Cl_2}}^{1/2}}$$

$$= 1.36 + 0.06 = 1.42\ \mathrm{V}$$

which is more positive than the reduction potential for water under these conditions: $E^o = 0.815$ V. Cl_2 is more easily reduced than O_2, which means that the other half of that couple, Cl^-, is less easily oxidized than $O_2(g)$, which is generated at the anode. Therefore, increasing the potential above 1.229 V only *increases* the rate of the electrolysis reaction. It is not possible to generate sodium and chlorine electrolytically in aqueous solutions of NaCl.

Suppose now that 0.10 M NaI is substituted for the 0.10 M NaCl solution. Sodium ions still will not be reduced; however, $E(I_2|I^-)$ is

$$E(\mathrm{I_2|I^-}) = E°(\mathrm{I_2|I^-}) - \frac{0.0592\ \mathrm{V}}{1}\ \log\ [\mathrm{I^-}]$$

$$= 0.535 + 0.059 = 0.594\ \mathrm{V}$$

The iodine reduction potential is more negative than the reduction potential of $O_2(g)$ in water at pH = 7, so the oxidation of 0.10 M I^- occurs in preference to the oxidation of water. The anode reaction is therefore

$$\mathrm{I^-(0.10\ M)} \longrightarrow \tfrac{1}{2}\,\mathrm{I_2}(s) + e^-$$

and the overall cell reaction is

$$\mathrm{H_3O^+(10^{-7}\ M)} + \mathrm{I^-(0.10\ M)} \longrightarrow \tfrac{1}{2}\,\mathrm{H_2}(g) + \tfrac{1}{2}\,\mathrm{I_2}(s) + \mathrm{H_2O}(\ell)$$

The intrinsic cell voltage is

$$\Delta E = E(\text{cathode}) - E(\text{anode}) = -0.414 - 0.594 = -1.008\ \mathrm{V} < 0$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

$H_2(g)$ and $I_2(s)$ will be generated by applying a potential greater than the decomposition potential of the solution, which is 1.008 V. The concentration of I^- begins to decrease as the electrolysis proceeds, making the potential of the $(I_2|I^-)$ couple more positive. When the iodide ion concentration reaches about 2×10^{-5} M, $E(I_2|I^-) = 0.815$ V, the external voltage required to maintain electrolysis would have to be increased to 1.229 V. At this point, water will start to be electrolyzed, and oxygen will be produced at the anode.

Our results for the electrolysis of *neutral* aqueous solutions are summarized as follows:

1. A species can be reduced only if its reduction potential is more positive than −0.414 V.
2. A species can be oxidized only if its reduction potential is more negative than 0.815 V.

In solutions with pH different from 7, these results must be modified, as shown by the following example.

EXAMPLE 17.15

An aqueous 0.10 M solution of $NiCl_2$ is electrolyzed under 1 atm pressure. Determine the products formed at the anode and the cathode and the decomposition potential, if the pH is (a) 7.0; (b) 0.0.

Solution

The reduction of Ni^{2+} at the cathode has the half-cell potential

$$Ni^{2+}(aq) + 2e^- \longrightarrow Ni(s)$$

$$E(Ni^{2+}|Ni) = E°(Ni^{2+}|Ni) - \frac{0.0592\ V}{2} \log \frac{1}{[Ni^{2+}]}$$

$$= -0.23 - 0.03 = -0.26\ V$$

and the oxidation of the Cl^- at the anode has the *reduction* potential

$$\tfrac{1}{2}Cl_2(g) + e^- \longrightarrow Cl^-(aq)$$

$$E(Cl_2|Cl^-) = E°(Cl_2|Cl^-) - \frac{0.0592\ V}{2} \log \frac{[Cl^-]}{P_{Cl_2}^{1/2}}$$

$$= 1.36\ V - (0.0592\ V) \log 0.2 = 1.40\ V$$

(a) In neutral solution the cathode half-reaction is

$$Ni^{2+}(aq) + 2\ e^- \longrightarrow Ni(s)$$

because $E(Ni^{2+}|Ni) = -0.26\ V > -0.414\ V$. The anode half-reaction is

$$3\ H_2O(\ell) \longrightarrow 2\ H_3O^+(10^{-7}\ M) + \tfrac{1}{2}O_2(g) + 2\ e^-$$

because $E(Cl_2|Cl^-) = 1.40\ V > 0.815\ V$ (the reduction potential for this half-reaction). The cell voltage is

$$\Delta E = E(\text{cathode}) - E(\text{anode}) = -0.26 - 0.815\ V = -1.08\ V$$

so the decomposition potential is 1.08 V.

(b) In 1.0 M acid solution (pH = 0.0), the anode half-reaction is still

$$3\ H_2O(\ell) \longrightarrow 2\ H_3O^+(1\ M) + \tfrac{1}{2}O_2(g) + 2\ e^-$$

The reduction potential for this reaction is now $E_{hc} = E°_{hc} = 1.229$ V, which is still less than 1.40 V, the reduction potential for the competing reaction involving chlorine.

The cathode half-reaction now becomes

$$2\,H_3O^+(1\,M) + 2\,e^- \longrightarrow H_2(g) + 2\,H_2O(\ell)$$

because $E(H_3O^+|H_2) = 0.0\ V > -0.26\ V$ for $E(Ni^{2+}|Ni)$. We now have

$$\Delta E = E(\text{cathode}) - E(\text{anode}) = 0.00 - 1.229 = -1.229\ V$$

so the decomposition potential of the solution is now 1.229 V, just as it is for pure water.

Related Problems: 63, 64

CHAPTER SUMMARY

Electrochemical reactions are an important class of oxidation–reduction (redox) reactions that interconvert chemical and electrical energy. The free energy released in a spontaneous chemical reaction can be used to generate electricity, or electrical energy can be provided from an external source to drive chemical reactions that are not normally spontaneous. The key to this flexibility is the separation of the oxidation and reduction parts of the reaction with the electrons being transferred through an external circuit. The cell potential E_{cell} is simply related to the Gibbs free energy for an electrochemical reaction, providing a quantitative measure of the driving force for the reaction. The cell potential goes to zero for reactions at equilibrium, so the standard cell potential E^o_{cell} is a direct measure of the equilibrium constant in electrochemical reactions. Since E is a state function, the equilibrium constant for a particular reaction is the same whether carried out electrochemically or otherwise, so electrochemistry is a powerful way to measure equilibrium constants for reactions that can be difficult to measure in other environments. Standard reduction potentials can be associated with orbital energies and provide a molecular level interpretation of electrochemical reactions and processes. Electrochemical organic synthesis, sensors, and photoelectrochemistry were discussed from this point of view. Electrochemistry is enormously important in many existing technologies such as energy conversion and storage, and large-scale chemical syntheses of commodity chemicals like chlorine. It is also an enabling science for alternative energy sources such as fuel cells for large-scale deployment in transportation and small dedicated power plants, and for the efficient capture and storage of solar energy in batteries, and potentially as chemical energy stored in hydrogen produced by photoelectrochemical water splitting.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 17.1 – Electrochemical Cells

Sketch a typical galvanic cell, identify all of its components, specifically the anode and the cathode, write out the oxidation and reduction reactions explicitly, and use the standard shorthand notation to represent the cell (Problems 1–2).

- There are many possible choices. The sketch in Figure 17.2 could be modified to illustrate any number of cells by substituting different metals and electrolytes in each half-cell. The galvanic cell represented by the notation $Zn|Zn^{2+}||Cu^{2+}|Cu$ would have a Zn electrode immersed in a solution of $Zn(NO_3)_2$ in the left-hand beaker and a Cu electrode immersed in a solution of $Zn(NO_3)_2$ in the right-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

hand beaker. Cu would be the cathode and Zn would be the anode in this cell, with the reactions being

$$Zn(s) \longrightarrow Zn^{2+} + 2\ e^-$$

$$Cu^{2+} + 2\ e^- \longrightarrow Cu(s)$$

Use Faraday's laws to calculate the quantities of substances produced or consumed at the electrodes of electrochemical cells in relation to the total charge passing through the circuit (Problems 3–10).

- The number of moles of a substance that are oxidized or reduced in an electrochemical reaction is proportional to the number of moles of electrons passed through the cell. One mole of electrons is 96,485 C, and it is called the Faraday constant, *F*.

Section 17.2 – Cell Potentials and the Gibbs Free Energy

Explain the relationship between the change in the Gibbs free energy and the electrical work done by the system for a galvanic cell (Problems 11–12).

- The electrical work is always $w_{elec} = \Delta G$, which for a galvanic cell is a negative quantity; work is done by the system, and it is paid for by the decrease in the Gibbs free energy of the system. The maximum work is done when the cell operates reversibly $w_{elec,max} = \Delta G_{rev}$. The change in the Gibbs free energy under standard conditions is calculated from the standard cell potential $\Delta G^\circ = -nFE^\circ$.

Represent cell reactions as combinations of half-reactions, and calculate standard cell potentials from the standard reduction potentials of the half-reactions (Problems 13–16).

- Identify the oxidation and reduction half-reactions, and calculate the standard cell potential from the standard reduction potentials using $E^\circ_{cell} = E^\circ_{cathode} - E^\circ_{anode}$.

Find standard reduction potentials for half-reactions not listed in Appendix E by combining the tabulated half-reactions and their standard reduction potentials (Problems 23–24).

- Write the half-reaction whose potential is not known in terms of the half-reactions whose potentials are tabulated. Identify the anode and cathode half-reactions, and calculate the standard cell potential from the standard reduction potentials using $E^\circ_{cell} = E^\circ_{cathode} - E^\circ_{anode}$.

Use reduction potential diagrams to determine strengths of oxidizing and reducing agents and stability toward disproportionation (Problems 17–26).

- Strong oxidizing agents are those that are easily reduced, whereas strong reducing agents are those that are easily oxidized. They are listed near the top and bottom of the table in Appendix E, respectively.
- The tendency for a given species to disproportionate can be determined by a reduction potential diagram that arranges a series of species with the most oxidized form on the left and the most reduced form on the right. Disproportionation will occur when the reduction potential for the reaction that connects a species to one on its right is more positive than the reduction potential that connects it to one on its left.

Section 17.3 – Molecular Interpretation of Electrochemical Processes

Relate standard reduction potentials to orbital energy levels and predict the direction of spontaneous change by considering both the electrostatic driving force and the occupation of energy levels.

- The electrostatic driving force is given by $E_{cell} = E_{cathode} - E_{anode} > 0$ for a spontaneous process. The more stable state, from a molecular point of view, is the one in which electrons occupy the orbitals of lowest energy.

Section 17.4 – Concentration Effects and the Nernst Equation

Apply the Nernst equation to calculate cell potentials for cells in which the reactants and products are not in their standard states, and to calculate equilibrium constants for chemical reactions from cell potentials (Problems 27–38).

$$E_{cell} = E^{o}_{cell} - \frac{RT}{nF} \ln Q \text{ and } \log_{10} K = \frac{nF}{RT} E^{o}_{cell}$$

Describe the principles that underlie the use of electrochemical cells as pH meters (Problems 39–40).

- The $Pt|H_2|H^+$ cell potential depends upon the concentration of $H^+(aq)$ in solution. A pH meter measures the half-cell potential of a solution of unknown pH against a reference that is calibrated against the SHE, with the unknown pH being calculated using $\text{pH} = \dfrac{E - E_{ref}}{(0.0592\ \text{V})}$.

Calculate solubility product constants K_{sp} from cell potentials (Problems 41,42).

- K_{sp} is calculated from cell potentials using the Nernst equation, using the same equation presented earlier for calculating equilibrium constants.

Section 17.5 – Molecular Electrochemistry

Discuss electrochemical processes from a molecular point of view, considering electron transfer processes between electrodes and redox couples as well as between redox couples, and be able to describe the salient features of the examples chosen (Problems 43–50).

- Electrochemical organic synthesis achieves great selectivity by using potential to control the thermodynamic driving forces and kinetics of electrochemical reactions.
- Enzyme-catalyzed reactions coupled to electrochemical cells provide extremely sensitive and selective sensors. Mediators efficiently transport redox equivalents between the enzyme and the electrode.
- Light absorbed by semiconductors produces electron-hole pairs that can be used to carry out oxidation–reduction reactions. Dye-sensitized TiO_2 has been shown to be a promising candidate for generating hydrogen from water using sunlight.

Section 17.6 – Batteries and Fuel Cells

Discuss the electrochemistry of a primary battery and contrast it with that of a secondary battery and a fuel cell (Problems 51–58).

- Primary batteries cannot be recharged, due to one or more irreversible steps during the discharge reaction, the formation of a gaseous product, or corrosion of one of its components. Reactions in secondary cells can be reversed by applying voltages opposite in sign and greater in magnitude than the galvanic cell potential.

Section 17.7 – Corrosion and Corrosion Prevention

Discuss the electrochemical corrosion of metals and describe measures that may be used to minimize it (Problems 59–62).

- Electrochemical corrosion of metals refers to the oxidation of the metal and the subsequent dissolution of the ions, resulting in the disintegration of materials. Metals may be protected by painting; by passivating layers such as the native oxides that form on aluminum or the thin layer of protective chromium oxide that forms on stainless steel; or by attaching sacrificial anodes to the material that are preferentially oxidized.

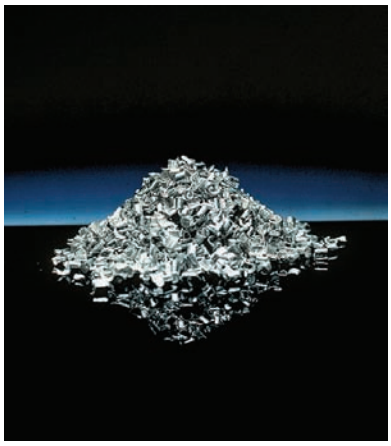
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Section 17.8 – Electrometallurgy

Describe the Hall–Héroult process for the production of aluminum and the methods used to recover magnesium from seawater (Problems 63–64).
Calculate theoretical yields for redox reactions, and the current and time required to produce specified quantities of products in electrometallurgy (Problems 65–68).



- Al_2O_3 is dissolved in molten cryolite, Na_3AlF_6, and reduced electrolytically to produce molten aluminum. Magnesium is produced from seawater in a multistep process. The mineral dolomite is calcined to drive off CO_2, producing CaO·MgO, which reacts with Mg^{2+} ions to produce magnesium hydroxide. The hydroxide reacts with HCl to produce the chloride, which is reduced electrolytically to produce the metal.
- Use Faraday's laws to relate current to metal deposited in electrorefining and electroplating operations (Problems 69–70).

Section 17.9 – A Deeper Look . . . Electrolysis of Water and Aqueous Solutions

Predict the products liberated at the anode and cathode of an electrolysis cell with a given aqueous electrolyte composition (Problems 63–64).

- Oxidation and reduction reactions in aqueous solution are limited to a potential window that is set by the oxidation and reduction of water at pH = 7. Applied potentials more positive than 0.814 V will oxidize $OH^-(aq)$ to O_2 and potentials more negative than −0.414 V will reduce $H^+(aq)$ to H_2.

CUMULATIVE EXERCISE

© Cengage Learning/Charles D. Winters

A pile of manganese metal.

Manganese—A Versatile Reagent and Essential Mineral

Manganese is the twelfth-most-abundant element on the earth's surface. Its most important ore source is pyrolusite (MnO_2). The preparation and uses of manganese and its compounds (which range up to +7 in oxidation state) are intimately bound up with electrochemistry.

(a) Elemental manganese in a state of high purity can be prepared by electrolyzing aqueous solutions of Mn^{2+}. At which electrode (anode or cathode) does the Mn appear? Electrolysis is also used to make MnO_2 in high purity from Mn^{2+} solutions. At which electrode does the MnO_2 appear?

(b) The Winkler method is an analytical procedure for determining the amount of oxygen dissolved in water. In the first step, $Mn(OH)_2(s)$ is oxidized by gaseous oxygen to $Mn(OH)_3(s)$ in basic aqueous solution. Write the oxidation and reduction half-equations for this step, and write the balanced overall equation. Then use Appendix E to calculate the standard voltage that would be measured if this reaction were carried out in an electrochemical cell.

(c) Calculate the equilibrium constant at 25°C for the reaction in part (b).

(d) In the second step of the Winkler method, the $Mn(OH)_3$ is acidified to give Mn^{3+}, and iodide ion is added. Will Mn^{3+} spontaneously oxidize I^-? Write a balanced equation for its reaction with I^-, and use data from Appendix E to calculate its equilibrium constant. Titration of the I_2 produced completes the use of the Winkler method.

(e) Manganese(IV) is an even stronger oxidizing agent than manganese(III). It oxidizes zinc to Zn^{2+} in the dry cell. Such a battery has a cell voltage of 1.5 V. Calculate the electrical work done by this battery in 1.00 hour if it produces a steady current of 0.70 A.

(f) Calculate the mass of zinc reacting in the process described in part (e).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(g) The reduction potential of permanganate ion (+7 oxidation state) in acidic aqueous solution is given by

$$MnO_4^-(aq) + 8\ H_3O^+(aq) + 5\ e^- \longrightarrow Mn^{2+}(aq) + 12\ H_2O(\ell) \qquad E^\circ = 1.491\ V$$

whereas that of the analogous fifth-period species, pertechnetate ion, is

$$TcO_4^-(aq) + 8\ H_3O^+(aq) + 5\ e^- \longrightarrow Tc^{2+}(aq) + 12\ H_2O(\ell) \qquad E^\circ = 0.500\ V$$

Which is the stronger oxidizing agent, permanganate ion or pertechnetate ion?

(h) A galvanic cell is made from two half-cells. In the first, a platinum electrode is immersed in a solution at pH 2.00 that is 0.100 M in both MnO_4^- and Mn^{2+}. In the second, a zinc electrode is immersed in a 0.0100 M solution of $Zn(NO_3)_2$. Calculate the cell voltage that will be measured.

Answers

(a) Mn appears at the cathode and MnO_2 at the anode.

(b)

$$\begin{aligned} Mn(OH)_2(s) + OH^-(aq) &\longrightarrow Mn(OH)_3(s) + e^- \qquad \text{(oxidation)} \\ O_2(g) + 2\ H_2O(\ell) + 4\ e^- &\longrightarrow 4\ OH^-(aq) \qquad \text{(reduction)} \\ \hline 4\ Mn(OH)_2(s) + O_2(g) + 2\ H_2O(\ell) &\longrightarrow 4\ Mn(OH)_3(s) \end{aligned}$$

$$\Delta E^\circ = 0.401 - (-0.40) = 0.80\ V$$

(c) $K = 1 \times 10^{54}$

(d) Mn^{3+} will spontaneously oxidize I^-.

$$2\ Mn^{3+}(aq) + 2\ I^-(aq) \longrightarrow 2\ Mn^{2+}(aq) + I_2(s) \qquad K = 9 \times 10^{32}$$

(e) 3.8×10^3 J

(f) 0.85 g Zn is oxidized.

(g) Permanganate ion

(h) 2.12 V

PROBLEMS

Electrochemical Cells

1. Diagram the following galvanic cell, indicating the direction of flow of electrons in the external circuit and the motion of ions in the salt bridge.

$$Pt(s)|Cr^{2+}(aq), Cr^{3+}(aq)||Cu^{2+}(aq)|Cu(s)$$

Write a balanced equation for the overall reaction in this cell.

2. Diagram the following galvanic cell, indicating the direction of flow of electrons in the external circuit and the motion of ions in the salt bridge.

$$Ni(s)|Ni^{2+}(aq)||HCI(aq)|H_2(g)|Pt(s)$$

Write a balanced equation for the overall reaction in this cell.

3. A quantity of electricity equal to 6.95×10^4 C passes through an electrolytic cell that contains a solution of $Sn^{4+}(aq)$ ions. Compute the maximum chemical amount, in moles, of Sn(*s*) that can be deposited at the cathode.

4. A quantity of electricity equal to 9.263×10^4 C passes through a galvanic cell that has an Ni(*s*) anode. Compute the maximum chemical amount, in moles, of $Ni^{2+}(aq)$ that can be released into solution.

5. A galvanic cell is constructed that has a zinc anode immersed in a $Zn(NO_3)_2$ solution and a platinum cathode immersed in an NaCl solution equilibrated with $Cl_2(g)$ at 1 atm and 25°C. A salt bridge connects the two half-cells.
   (a) Write a balanced equation for the cell reaction.
   (b) A steady current of 0.800 A is observed to flow for a period of 25.0 minutes. How much charge passes through the circuit during this time? How many moles of electrons is this charge equivalent to?
   (c) Calculate the change in mass of the zinc electrode.
   (d) Calculate the volume of gaseous chlorine generated or consumed as a result of the reaction.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

6. A galvanic cell consists of a cadmium cathode immersed in a $CdSO_4$ solution and a zinc anode immersed in a $ZnSO_4$ solution. A salt bridge connects the two half-cells.
   (a) Write a balanced equation for the cell reaction.
   (b) A current of 1.45 A is observed to flow for a period of 2.60 hours. How much charge passes through the circuit during this time? How many moles of electrons is this charge equivalent to?
   (c) Calculate the change in mass of the zinc electrode.
   (d) Calculate the change in mass of the cadmium electrode.
7. An acidic solution containing copper ions is electrolyzed, producing gaseous oxygen (from water) at the anode and copper at the cathode. For every 16.0 g of oxygen generated, 63.5 g of copper plates out. What is the oxidation state of the copper in the solution?
8. Michael Faraday reported that passing electricity through one solution liberated 1 mass of hydrogen at the cathode and 8 masses of oxygen at the anode. The same quantity of electricity liberated 36 masses of chlorine at the anode and 58 masses of tin at the cathode from a second solution. What were the oxidation states of hydrogen, oxygen, chlorine, and tin in these solutions?
9. Liquid potassium chloride, $KCl(\ell)$, is decomposed in an electrolytic cell to form potassium and chlorine. Liquid KCl consists of K^+ and Cl^- ions.
   (a) Write balanced equations for the half-cell reactions at the anode and at the cathode, and for the overall cell reaction.
   (b) If a current of 2.00 A is passed through the cell for a period of 5.00 hours, calculate the mass of metal deposited and of gas liberated.
10. In the Hall–Héroult process for the electrolytic production of aluminum, Al^{3+} ions from Al_2O_3 dissolved in molten cryolite (Na_3AlF_6) are reduced to $Al(l)$ while carbon (graphite) is oxidized to CO_2 by reaction with oxide ions.
   (a) Write balanced equations for the half-reactions at the anode and at the cathode, and for the overall cell reaction.
   (b) If a current of 50,000 A is passed through the cell for a period of 24 hours, what mass of aluminum will be recovered?

Cell Potentials and the Gibbs Free Energy

11. A $Ni|Ni^{2+}||Ag^+|Ag$ galvanic cell is constructed in which the standard cell potential is 1.03 V. Calculate the free energy change at 25°C when 1.00 g of silver plates out, if all concentrations remain at their standard value of 1 M throughout the process. What is the maximum electrical work done by the cell on its surroundings during this experiment?
12. A $Zn|Zn^{2+}||Co^{2+}|Co$ galvanic cell is constructed in which the standard cell potential is 0.48 V. Calculate the free energy change at 25°C per gram of zinc lost at the anode, if all concentrations remain at their standard value of 1 M throughout the process. What is the maximum electrical work done by the cell on its surroundings during this experiment?
13. A galvanic cell is constructed in which a $Br_2|Br^+$ half-cell is connected to a $Co^{2+}|Co$ half-cell.
   (a) By referring to Appendix E, write balanced chemical equations for the half-reactions at the anode and the cathode and for the overall cell reaction.
   (b) Calculate the cell potential, assuming that all reactants and products are in their standard states.
14. A galvanic cell is constructed in which a $Pt|Fe^{2+}\ Fe^{3+}$ half-cell is connected to a $Cd^{2+}|Cd$ half-cell.
   (a) Referring to Appendix E, write balanced chemical equations for the half-reactions at the anode and the cathode and for the overall cell reaction.
   (b) Calculate the cell potential, assuming that all reactants and products are in their standard states.
15. In a galvanic cell, one half-cell consists of a zinc strip dipped into a 1.00 M solution of $Zn(NO_3)_2$. In the second half-cell, solid indium adsorbed on graphite is in contact with a 1.00 M solution of $In(NO_3)_3$. Indium is observed to plate out as the galvanic cell operates, and the initial cell potential is measured to be 0.425 V at 25°C.
   (a) Write balanced equations for the half-reactions at the anode and the cathode.
   (b) Calculate the standard reduction potential of an $In^{3+}|In$ half-cell. Consult Appendix E for the reduction potential of the $Zn^{2+}|Zn$ electrode.
16. In a galvanic cell, one half-cell consists of gaseous chlorine bubbled over a platinum electrode at a pressure of 1.00 atm into a 1.00 M solution of NaCl. The second half-cell has a strip of solid gallium immersed in a 1.00 M $Ga(NO_3)_3$ solution. The initial cell potential is measured to be 1.918 V at 25°C, and as the cell operates, the concentration of chloride ion is observed to increase.
   (a) Write balanced equations for the half-reactions at the anode and the cathode.
   (b) Calculate the standard reduction potential of a $Ga^{3+}|Ga$ half-cell. Consult Appendix E for the reduction potential of the $Cl_2|Cl^-$ electrode.
17. Would you expect powdered solid aluminum to act as an oxidizing agent or as a reducing agent?
18. Would you expect potassium perchlorate, KClO4(*aq*), in a concentrated acidic solution to act as an oxidizing agent or as a reducing agent?
19. Bromine is sometimes used in place of chlorine as a disinfectant in swimming pools. If the effectiveness of a chemical as a disinfectant depends solely on its strength as an oxidizing agent, do you expect bromine to be better or worse than chlorine as a disinfectant, at a given concentration?
20. Many bleaches, including chlorine and its oxides, oxidize dye compounds in cloth. Predict which of the following will be the strongest bleach at a given concentration and pH 0: $NaClO_3(aq)$, $NaClO(aq)$, $Cl_2(aq)$. How does the strongest chlorine-containing bleach compare in strength with ozone, $O_3(g)$?
21. Suppose you have the following reagents available at pH 0, atmospheric pressure, and 1 M concentration:

$$Co(s),\ Ag^+(aq),\ Cl^-(aq),\ Cr(s),\ BrO_3^-(aq),\ I_2(s)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) Which is the strongest oxidizing agent?
(b) Which is the strongest reducing agent?
(c) Which reagent will reduce $Pb^{2+}(aq)$ while leaving $Cd^{2+}(aq)$ unreacted?

22. Suppose you have the following reagents available at pH 0, atmospheric pressure, and 1 M concentration:

$$Sc(s),\ Hg_2^{2+}(aq),\ Cr_2O_7^{2-}(aq),\ H_2O_2(aq),\ Sn^{2+}(aq),\ Ni(s)$$

(a) Which is the strongest oxidizing agent?
(b) Which is the strongest reducing agent?
(c) Which reagent will oxidize $Fe(s)$ while leaving $Cu(s)$ unreacted?

23. (a) Use the data from Appendix E to calculate the half-cell potential E^o for the half-reaction

$$Mn^{3+}(aq) + 3\ e^- \longrightarrow MN(s)$$

(b) Consider the disproportionation reaction

$$3\ Mn^{2+}(aq) \rightleftharpoons Mn(s) + 2\ Mn^{3+}(aq)$$

Will Mn^{2+} disproportionate in aqueous solution?

24. The following standard reduction potentials have been measured in aqueous solution at 25°C:

$$Tl^{3+} + e^- \longrightarrow Tl^{2+} \qquad E^o = -0.37\ V$$

$$Tl^{3+} + 2\ e^- \longrightarrow Tl^{+} \qquad E^o = 1.25\ V$$

(a) Calculate the half-cell potential for the half-reaction

$$Tl^{2+} + e^- \longrightarrow Tl^{+}$$

(b) Consider the disproportionation reaction

$$2\ Tl^{2+}(aq) \rightleftharpoons Tl^{3+}(aq) + Tl^{+}(aq)$$

Will Tl^{2+} disproportionate in aqueous solution?

25. The following reduction potentials are measured at pH 0:

$$BrO_3^- + 6\ H_3O^+ + 5\ e^- \longrightarrow \frac{1}{2}\,Br_2(\ell) + 9\ H_2O \qquad E^o = 1.52\ V$$

$$Br_2(\ell) + 2\ e^- \longrightarrow 2\ Br^- \qquad E^o = 1.065\ V$$

(a) Will bromine disproportionate spontaneously in acidic solution?
(b) Which is the stronger reducing agent at pH 0: $Br_2(\ell)$ or Br_2?

26. The following reduction potentials are measured at pH 14:

$$ClO^- + H_2O + 2\ e^- \longrightarrow Cl^- + 2\ OH^- \qquad E^o = 0.90\ V$$

$$ClO_2^- + H_2O + 2\ e^- \longrightarrow ClO^- + 2\ OH^- \qquad E^o = 0.59\ V$$

(a) Will ClO^- disproportionate spontaneously in basic solution?
(b) Which is the stronger reducing agent at pH 14: ClO^- or Cl^-?

Concentration Effects and the Nernst Equation

27. A galvanic cell is constructed that carries out the reaction

$$Pb^{2+}(aq) + 2\ Cr^{2+}(aq) \longrightarrow Pb(s) + 2\ Cr^{3+}(aq)$$

If the initial concentration of $Pb^{2+}(aq)$ is 0.15 M, that of $Cr^{2+}(aq)$ is 0.20 M, and that of $Cr^{3+}(aq)$ is 0.0030 M, calculate the initial voltage generated by the cell at 25°C.

28. A galvanic cell is constructed that carries out the reaction

$$2\ Ag(s) + Cl_2(g) \longrightarrow 2\ Ag^+(aq) + 2\ Cl^-(aq)$$

If the partial pressure of $Cl_2(g)$ is 1.00 atm, the initial concentration of $Ag^+(aq)$ is 0.25 M, and that of $Cl^-(aq)$ is 0.016 M, calculate the initial voltage generated by the cell at 25°C.

29. Calculate the reduction potential for a $Pt\,|\,Cr^{3+}, Cr^{2+}$ half-cell in which $[Cr^{3+}]$ is 0.15 M and $[Cr^{2+}]$ is 0.0019 M.

30. Calculate the reduction potential for an $I_2(s)\,|\,I^-$ half-cell in which $[I^-]$ is 1.5×10^{-6} M.

31. An $I_2(s)\,|\,I^-$ (1.00 M) half-cell is connected to an $H_3O^+\,|\,H_2$ (1 atm) half-cell in which the concentration of the hydronium ion is unknown. The measured cell potential is 0.841 V, and the $I_2\,|\,I^-$ half-cell is the cathode. What is the pH in the $H_3O^+\,|\,H_2$ half-cell?

32. A $Cu^{2+}(1.00\ M)\,|\,Cu$ half-cell is connected to a $Br_2(\ell)\,|\,Br^-$ half-cell in which the concentration of bromide ion is unknown. The measured cell potential is 0.963 V, and the $Cu^{2+}\,|\,Cu$ half-cell is the anode. What is the bromide ion concentration in the $Br_2(\ell)\,|\,Br^-$ half-cell?

33. The following reaction occurs in an electrochemical cell:

$$3\ HClO_2(aq) + 2\ Cr^{3+}(aq) + 12\ H_2O(\ell) \longrightarrow 3\ HClO(aq) + Cr_2O_7^{2-}(aq) + 8\ H_3O^+(aq)$$

(a) Calculate E^o for this cell.
(b) At pH 0, with $[Cr_2O_7^{2-}] = 0.80$ M $[HClO_2] = 0.15$ M, and [HClO] = 0.20 M, the cell potential is found to be 0.15 V. Calculate the concentration of $Cr^{3+}(aq)$ in the cell.

34. A galvanic cell is constructed in which the overall reaction is

$$Cr_2O_7^{2-}(aq) + 14\ H_2O^+(aq) + 6\ I^-(aq) \longrightarrow 2\ Cr^{3+}(aq) + 3\ I_2(s) + 21\ H_2O(\ell)$$

(a) Calculate E^o for this cell.
(b) At pH 0, with $[Cr_2O_7^{2-}] = 1.5$ M and $[I^-] = 0.40$ M, the cell potential is found to equal 0.87 V. Calculate the concentration of $Cr^{3+}(aq)$ in the cell.

35. By using the half-cell potentials in Appendix E, calculate the equilibrium constant at 25°C for the reaction in problem 33. Dichromate ion $(Cr_2O_7^{2-})$ is orange, and Cr^{3+} is light green in aqueous solution. If 2.00 L of 1.00 M $HClO_2$ solution is added to 2.00 L of 0.50 M $Cr(NO_3)_3$ solution, what color will the resulting solution have?

36. By using the half-cell potentials in Appendix E, calculate the equilibrium constant at 25°C for the reaction

$$6\ Hg^{2+}(aq) + 2\ Au(s) \rightleftharpoons 3\ Hg_2^{2+}(aq) + 2\ Au^{3+}(aq)$$

If 1.00 L of a 1.00 M $Au(NO_3)_3$ solution is added to 1.00 L of a 1.00 M $Hg_2(NO_3)_2$ solution, calculate the concentrations of Hg^{2+}, Hg_2^{2+}, and Au^{3+} at equilibrium.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

37. The following standard reduction potentials have been determined for the aqueous chemistry of indium:

$$In^{3+}(aq) + 2\,e^- \longrightarrow In^+(aq) \qquad E^o = -0.40\ V$$

$$In^+(aq) + e^- \longrightarrow In(s) \qquad E^o = -0.21\ V$$

Calculate the equilibrium constant (K) for the disproportionation of $In^+(aq)$ at 25°C.

$$3\,In^+(aq) \rightleftharpoons 2\,In(s) + In^{3+}(aq)$$

38. Use data from Appendix E to compute the equilibrium constant for the reaction

$$Hg^{2+}(aq) + Hg(\ell) \rightleftharpoons Hg_2^{2+}(aq)$$

39. A galvanic cell consists of a $Pt\,|H_3O^+(1.00\ M)\,|H_2(g)$ cathode connected to a $Pt\,|H_3O^+(aq)\,|H_2(g)$ anode in which the concentration of H_3O^+ is unknown but is kept constant by the action of a buffer consisting of a weak acid, HA(0.10 M), mixed with its conjugate base, A^-(0.10 M). The measured cell potential is $E_{cell} = 0.150$ V at 25°C, with a hydrogen pressure of 1.00 atm at both electrodes. Calculate the pH in the buffer solution, and from it determine the K_a of the weak acid.

40. In a galvanic cell, the cathode consists of a $Ag^+(1.00\ M)\,|Ag$ half-cell. The anode is a platinum wire, with hydrogen bubbling over it at 1.00-atm pressure, which is immersed in a buffer solution containing benzoic acid and sodium benzoate. The concentration of benzoic acid (C_6H_5COOH) is 0.10 M, and that of benzoate ion ($C_6H_5COO^-$) is 0.050 M. The overall cell reaction is then

$$Ag^+(aq) + \frac{1}{2}H_2(g) + H_2O(\ell) \longrightarrow Ag(s) + H_3O^+(aq)$$

and the measured cell potential is 1.030 V. Calculate the pH in the buffer solution and determine the K_a of benzoic acid.

41. A galvanic cell is constructed in which the overall reaction is

$$Br_2(\ell) + H_2O(g) + 2\,H_2O(\ell) \longrightarrow 2\,Br^-(aq) + 2\,H_3O^+(aq)$$

(a) Calculate E^o for this cell.
(b) Silver ions are added until AgBr precipitates at the cathode and $[Ag^+]$ reaches 0.060 M. The cell potential is then measured to be 1.710 V at pH = 0 and = 1.0 atm. Calculate $[Br^-]$ under these conditions.
(c) Calculate the solubility product constant K_{sp} for AgBr.

42. A galvanic cell is constructed in which the overall reaction is

$$Pb(s) + 2\,H_3O^+(aq) \longrightarrow Pb^{2+}(aq) + H_2(g) + 2\,H_2O(\ell)$$

(a) Calculate E^{os} for this cell.
(b) Chloride ions are added until $PbCl_2$ precipitates at the anode and $[Cl^-]$ reaches 0.15 M. The cell potential is then measured to be 0.22 V at pH = 0 and P_{H_2} = 1.0 atm. Calculate $[Pb^{2+}]$ under these conditions.
(c) Calculate the solubility product constant K_{sp} of $PbCl_2$.

Molecular Electrochemistry

43. Sketch and interpret the cyclic voltammogram you expect for the $[Ru(NH_3)_6]^{3+}/[Ru(NH_3)_6]^{2+}$ redox couple measured with a Ag/AgCl reference electrode. The standard reduction potential for this system is −0.215 V measured with respect to SCE.

44. Ferrocene is an organometallic complex that contains iron sandwiched between two five-membered cyclopentadiene rings (C_5H_5). Ferrocene methanol, a derivative, is another convenient reference redox couple used in electrochemistry. Sketch and interpret the cyclic voltammogram for the ferrocene methanol couple (Fc^+/Fc) measured with respect to SHE; the standard redox potential is 0.64 V.

45. What is the wavelength and color of light emitted in an ECL experiment in which the redox potential associated with the HOMO is 1.5 V and that associated with the LUMO is −0.9 V? The experiment is conducted in a nonaqueous solution.

46. Suppose that you were asked to synthesize a molecule for use in ECL that emits light at 520 nm and has a potential associated with the HOMO located at 0.5 V, for compatibility with other requirements in a particular analytical application. What is the redox potential associated with the LUMO?

47. Would CdS be a suitable semiconductor for direct photoelectrochemical water splitting? Why or why not? The conduction band lies at about −1.25 V vs NHE and the valence band lies at about 0.12 V vs NHE.

48. GaP has a bandgap of 2.3 eV with a conduction band redox potential located at −1.3 V vs SHE. Would this material be suitable for direct photoelectrochemical water splitting? Why or why not?

49. Strontium titanate ($SrTiO_3$) is another wide bandgap semiconductor that has been investigated for use in dye-sensitized solar cells. Depending on morphology and pH the conduction band of $SrTiO_3$ lies around −0.2 V vs. SHE. What energies for the HOMO and LUMO of a sensitizing dye would you specify for electron injection into the conduction band of strontium titanate and for water oxidation by the radical cation formed by photoexcitation?

50. A Grätzel cell is to be designed using strontium titanate as the semiconductor and the iodide/triode mediator discussed in the *Connection to Energy:* Solar Energy Conversion. Where should the energy levels of the sensitizer lie for maximum solar-to-electrical conversion efficiency?

Batteries and Fuel Cells

51. Calculate the potential E^o of a lead–acid cell if all reactants and products are in their standard states. What will be the voltage if six such cells are connected in a series?

52. Calculate the standard potential of the zinc–mercuric oxide cell shown in Figure 17.22. (*Hint:* The easiest way to proceed is to calculate ΔG° for the corresponding overall reaction, and then find E^o from it.) Take $\Delta_f^o\ [Zn(OH)_2(s)] = -553.5\ kJ\ mol^{-1}$.

53. (a) What quantity of charge (in coulombs) is a fully charged 12-V lead–acid storage battery theoretically capable of furnishing if the spongy lead available for reaction at the anodes weighs 10 kg and there is excess PbO_2?
(b) What is the theoretical maximum amount of work (in joules) that can be obtained from this battery?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

54. (a) What quantity of charge (in coulombs) is a fully charged 1.34-V zinc–mercuric oxide watch battery theoretically capable of furnishing if the mass of HgO in the battery is 0.50 g?
    (b) What is the theoretical maximum amount of work (in joules) that can be obtained from this battery?

55. The concentration of the electrolyte, sulfuric acid, in a lead–acid storage battery diminishes as the battery is discharged. Is a discharged battery recharged by replacing the dilute H_2SO_4 with fresh, concentrated H_2SO_4? Explain.

56. One cold winter morning the temperature is well below 0°F. In trying to start your car, you run the battery down completely. Several hours later, you return to replace your fouled spark plugs and find that the liquid in the battery has now frozen even though the air temperature is actually a bit higher than it was in the morning. Explain how this can happen.

57. Consider the fuel cell that accomplishes the overall reaction

$$H_2(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O(\ell)$$

If the fuel cell operates with 60% efficiency, calculate the amount of electrical work generated per gram of water produced. The gas pressures are constant at 1 atm, and the temperature is 25°C.

58. Consider the fuel cell that accomplishes the overall reaction

$$CO(g) + \frac{1}{2}O_2(g) \longrightarrow CO_2(g)$$

Calculate the maximum electrical work that could be obtained from the conversion of 1.00 mol of $CO(g)$ to $CO_2(g)$ in such a fuel cell operated with 100% efficiency at 25°C and with the pressure of each gas equal to 1 atm.

Corrosion and Corrosion Prevention

59. Two half-reactions proposed for the corrosion of iron in the absence of oxygen are

$$Fe(s) \longrightarrow Fe^{2+}(aq) + 2\ e^-$$

$$2\ H_2O(\ell) + 2\ e^- \longrightarrow 2\ OH^-(aq) + H_2(g)$$

Calculate the standard cell potential generated by a galvanic cell running this pair of half-reactions. Is the overall reaction spontaneous under standard conditions? As the pH falls from 14, will the reaction become spontaneous?

60. In the presence of oxygen, the cathode half-reaction written in the preceding problem is replaced by

$$\frac{1}{2}O_2(g) + 2\ H_3O^+(aq) + 2\ e^- \longrightarrow 3\ H_2O(\ell)$$

but the anode half-reaction is unchanged. Calculate the standard cell potential for *this* pair of reactions operating as a galvanic cell. Is the overall reaction spontaneous under standard conditions? As the water becomes more acidic, does the driving force for the rusting of iron increase or decrease?

61. Could sodium be used as a sacrificial anode to protect the iron hull of a ship?

62. If it is shown that titanium can be used as a sacrificial anode to protect iron, what conclusion can be drawn about the standard reduction potential of its half-reaction?

$$Ti^{3+}(aq) + 3\ e^- \longrightarrow Ti(s)$$

Electrometallurgy

63. In the Downs process, molten sodium chloride is electrolyzed to produce sodium. A valuable byproduct is chlorine. Write equations representing the processes taking place at the anode and at the cathode in the Downs process.

64. The first element to be prepared by electrolysis was potassium. In 1807, Humphry Davy, then 29 years old, passed an electric current through molten potassium hydroxide (KOH), obtaining liquid potassium at one electrode and water and oxygen at the other. Write equations to represent the processes taking place at the anode and at the cathode.

65. A current of 55,000 A is passed through a series of 100 Hall–Héroult cells for 24 hours. Calculate the maximum theoretical mass of aluminum that can be recovered.

66. A current of 75,000 A is passed through an electrolysis cell containing molten $MgCl_2$ for 7.0 days. Calculate the maximum theoretical mass of magnesium that can be recovered.

67. An important use for magnesium is to make titanium. In the Kroll process, magnesium reduces titanium(IV) chloride to elemental titanium in a sealed vessel at 800°C. Write a balanced chemical equation for this reaction. What mass of magnesium is needed, in theory, to produce 100 kg of titanium from titanium(IV) chloride?

68. Calcium is used to reduce vanadium(V) oxide to elemental vanadium in a sealed steel vessel. Vanadium is used in vanadium steel alloys for jet engines, high-quality knives, and tools. Write a balanced chemical equation for this process. What mass of calcium is needed, in theory, to produce 20.0 kg of vanadium from vanadium(V) oxide?

69. Galvanized steel consists of steel with a thin coating of zinc to reduce corrosion. The zinc can be deposited electrolytically, by making the steel object the cathode and a block of zinc the anode in an electrochemical cell containing a dissolved zinc salt. Suppose a steel garbage can is to be galvanized and requires that a total mass of 7.32 g of zinc be coated to the required thickness. How long should a current of 8.50 A be passed through the cell to achieve this?

70. In the electroplating of a silver spoon, the spoon acts as the cathode and a piece of pure silver as the anode. Both dip into a solution of silver cyanide (AgCN). Suppose that a current of 1.5 A is passed through such a cell for 22 minutes and that the spoon has a surface area of 16 cm^2. Calculate the average thickness of the silver layer deposited on the spoon, taking the density of silver to be 10.5 g cm^{-3}.

A Deeper Look . . . Electrolysis of Water and Aqueous Solutions

71. An electrolytic cell consists of a pair of inert metallic electrodes in a solution buffered to pH = 5.0 and containing nickel sulfate ($NiSO_4$) at a concentration of 1.00 M. A current of 2.00 A is passed through the cell for 10.0 hours.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) What product is formed at the cathode?
(b) What is the mass of this product?
(c) If the pH is changed to pH = 1.0, what product will form at the cathode?

72. A 0.100 M neutral aqueous $CaCl_2$ solution is electrolyzed using platinum electrodes. A current of 1.50 A passes through the solution for 50.0 hours.
(a) Write the half-reactions occurring at the anode and at the cathode.
(b) What is the decomposition potential?
(c) Calculate the mass, in grams, of the product formed at the cathode.

ADDITIONAL PROBLEMS

73. The drain cleaner Drano consists of aluminum turnings mixed with sodium hydroxide. When it is added to water, the sodium hydroxide dissolves and releases heat. The aluminum reacts with water to generate bubbles of hydrogen and aqueous ions. Write a balanced net ionic equation for this reaction.

74. Sulfur-containing compounds in the air tarnish silver, giving black Ag_2S. A practical method of cleaning tarnished silverware is to place the tarnished item in electrical contact with a piece of zinc and dip both into water containing a small amount of salt. Write balanced half-equations to represent what takes place.

75. A current passed through inert electrodes immersed in an aqueous solution of sodium chloride produces chlorate ion, $ClO_3^-(aq)$, at the anode and gaseous hydrogen at the cathode. Given this fact, write a balanced equation for the chemical reaction if gaseous hydrogen and aqueous sodium chlorate are mixed and allowed to react spontaneously until they reach equilibrium.

76. A galvanic cell is constructed by linking a $Co^{2+}|Co(s)$ half-cell to an $Ag^+|Ag(s)$ half-cell through a salt bridge and then connecting the cobalt and silver electrodes through an external circuit. When the circuit is closed, the cell potential is measured to be 1.08 V, and silver is seen to plate out while cobalt dissolves.
(a) Write the half-reactions that occur at the anode and at the cathode and the balanced overall cell reaction.
(b) The cobalt electrode is weighed after 150 minutes of operation and is found to have decreased in mass by 0.36 g. By what amount has the silver electrode increased in mass?
(c) What is the average current drawn from the cell during this period?

77. The galvanic cell $Zn(s)|Zn^{2+}(aq)||Ni^{2+}(aq)|Ni(s)$ is constructed using a completely immersed zinc electrode that weighs 32.68 g and a nickel electrode immersed in 575 mL of 1.00 M $Ni^{2+}(aq)$ solution. A steady current of 0.0715 A is drawn from the cell as the electrons move from the zinc electrode to the nickel electrode.
(a) Which reactant is the limiting reactant in this cell?
(b) How long does it take for the cell to be completely discharged?
(c) How much mass has the nickel electrode gained when the cell is completely discharged?
(d) What is the concentration of the $Ni^{2+}(aq)$ when the cell is completely discharged?

78. A newly discovered bacterium can reduce selenate ion, $SeO_4^{2-}(aq)$, to elemental selenium, Se(*s*), in reservoirs. This is significant because the soluble selenate ion is potentially toxic, but elemental selenium is insoluble and harmless. Assume that water is oxidized to oxygen as the selenate ion is reduced. Compute the mass of oxygen produced if all the selenate in a 1012-L reservoir contaminated with 100 mg L^{-1} of selenate ion is reduced to selenium.

79. Thomas Edison invented an electric meter that was nothing more than a simple coulometer, a device to measure the amount of electricity passing through a circuit. In this meter, a small, fixed fraction of the total current supplied to a household was passed through an electrolytic cell, plating out zinc at the cathode. Each month the cathode could then be removed and weighed to determine the amount of electricity used. If 0.25% of a household's electricity passed through such a coulometer and the cathode increased in mass by 1.83 g in a month, how many coulombs of electricity were used during that month?

80. The chief chemist of the Brite-Metal Electroplating Co. is required to certify that the rinse solutions that are discharged from the company's tin-plating process into the municipal sewer system contain no more than 10 ppm (parts per million) by mass of Sn^{2+}. The chemist devises the following analytical procedure to determine the concentration. At regular intervals, a 100-mL (100-g) sample is withdrawn from the waste stream and acidified to pH = 1.0. A starch solution and 10 mL of 0.10 M potassium iodide are added, and a 25.0-mA current is passed through the solution between platinum electrodes. Iodine appears as a product of electrolysis at the anode when the oxidation of Sn^{2+} to Sn^{4+} is practically complete and signals its presence with the deep blue color of a complex formed with starch. What is the maximum duration of electrolysis to the appearance of the blue color that ensures that the concentration of Sn^{2+} does not exceed 10 ppm?

81. Estimate the cost of the electrical energy needed to produce 1.5×10^{10} kg (a year's supply for the world) of aluminum from $Al_2O_3(s)$ if electrical energy costs 10 cents per kilowatt-hour (1 kWh = 3.6 MJ = 3.6×10^6 J) and if the cell potential is = V.

82. Titanium can be produced by electrolytic reduction from an anhydrous molten salt electrolyte that contains titanium(IV) chloride and a spectator salt that furnishes ions to make the electrolyte conduct electricity. The standard enthalpy of formation of $TiCl_4(l)$ is -750 kJ mol^{-1}, and the standard entropies of $TiCl_4(l)$, Ti(*s*), and $Cl_2(g)$ are 253, 30, and 223 J K^{-1} mol^{-1}, respectively. What minimum applied voltage will be necessary at 100°C?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

83. A half-cell has a graphite electrode immersed in an acidic solution (pH 0) of Mn^{2+} (concentration 1.00 M) in contact with solid MnO_2. A second half-cell has an acidic solution (pH 0) of H_2O_2 (concentration 1.00 M) in contact with a platinum electrode past which gaseous oxygen at a pressure of 1.00 atm is bubbled. The two half-cells are connected to form a galvanic cell.
(a) Referring to Appendix E, write balanced chemical equations for the half-reactions at the anode and the cathode and for the overall cell reaction.
(b) Calculate the cell potential.

84. By considering these half-reactions and their standard reduction potentials,

$$Pt^{2+} + 2\,e^- \longrightarrow Pt \qquad E^\circ = 1.2\ V$$

$$NO_3^- + 4\,H_3O + 3\,e^- \longrightarrow NO + 6\,H_2O \qquad E^\circ = 0.96\ V$$

$$PtCl_4^{2-} + 2\,e^- \longrightarrow Pt + 4\,Cl^- \qquad E^\circ = 0.73\ V$$

account for the fact that platinum will dissolve in a mixture of hydrochloric acid and nitric acid (*aqua regia*) but will not dissolve in either acid alone.

85. (a) One method to reduce the concentration of unwanted $Fe^{3+}(aq)$ in a solution of $Fe^{2+}(aq)$ is to drop a piece of metallic iron into the storage container. Write the reaction that removes the Fe^{3+}, and compute its standard cell potential.
(b) Referring to problem 23, suggest a way to remove unwanted $Mn^{3+}(aq)$ from solutions of $Mn^{2+}(aq)$.

86. (a) Based only on the standard reduction potentials for the $Cu^{2+}|Cu^+$ and $I_2(s)|I^-$ the half-reactions, would you expect $Cu^{2+}(aq)$ to be reduced to $Cu^+(aq)$ by $I^-(aq)$?
(b) The formation of solid CuI plays a role in the interaction between $Cu^{2+}(aq)$ and $I^-(aq)$.

$$Cu^{2+}(aq) + I^-(aq) + e^- \rightleftharpoons CuI(s) \qquad E^\circ = 0.86\ V$$

Taking into account this added information, do you expect Cu^{2+} to be reduced by iodide ion?

87. In some old European churches, the stained-glass windows have so darkened from corrosion and age that hardly any light comes through. Microprobe analysis showed that tiny cracks and defects on the glass surface were enriched in insoluble Mn(III) and Mn(IV) compounds. From Appendix E, suggest a reducing agent and conditions that might successfully convert these compounds to soluble Mn(II) without simultaneously reducing Fe(III) (which gives the glass its colors) to Fe(II). Take MnO_2 as representative of the insoluble Mn(III) and Mn(IV) compounds.

88. (a) Calculate the half-cell potential for the reaction

$$O_2(g) + 4\,H_3O^+(aq) + 4\,e^- \longrightarrow 6\,H_2O(\ell)$$

at pH 7 with the oxygen pressure at 1 atm.
(b) Explain why aeration of solutions of I^- leads to their decomposition. Write a balanced equation for the redox reaction that occurs.
(c) Will the same problem arise with solutions containing Br^- or Cl^-? Explain.
(d) Will decomposition be favored or opposed by increasing acidity?

89. An engineer needs to prepare a galvanic cell that uses the reaction

$$2\,Ag^+(aq) + Zn(s) \longrightarrow Zn^{2+}(aq) + 2\,Ag(s)$$

and generates an initial voltage of 1.50 V. She has 0.010 M $AgNO_3(aq)$ and 0.100 M $Zn(NO_3)_2(aq)$ solutions, as well as electrodes of metallic copper and silver, wires, containers, water, and a KNO_3 salt bridge. Sketch the cell. Clearly indicate the concentrations of all solutions.

90. Consider a galvanic cell for which the anode reaction is

$$Pb(s) \longrightarrow Pb^{2+}(1.0 \times 10^{-2}\ M) + 2\,e^-$$

and the cathode reaction is

$$VO^{2+}(0.10\ M) + 2\,H_3O^+(0.10\ M) + e^- \longrightarrow V^{3+}(1.0 \times 10^{-5}\ M) + 3\,H_2O(\ell)$$

The measured cell potential is 0.640 V.
(a) Calculate E° for the $VO^{2+}|V^{3+}$ half-reaction, using $E^\circ(Pb^{2+}|Pb)$ from Appendix E.
(b) Calculate the equilibrium constant (K) at 25°C for the reaction

$$Pb(s) + 2\,VO^{2+}(aq) + 4\,H_3O^+(aq) \rightleftharpoons Pb^{2+}(aq) + 2\,V^{3+}(aq) + 6\,H_2O(\ell)$$

91. Suppose we construct a pressure cell in which the gas pressures differ in the two half-cells. Suppose such a cell consists of a $Cl_2(0.010\ atm)|Cl^-(1\ M)$ half-cell connected to a $Cl_2(0.50\ atm)|Cl^-(1\ M)$ half-cell. Determine which half-cell will be the anode, write the overall equation for the reaction, and calculate the cell potential.

92. A student decides to measure the solubility of lead sulfate in water and sets up the electrochemical cell

$$Pb|PbSO_4|SO_4^{2-}(aq, 0.0500\ M)||Cl^-(aq, 1.00\ M)|AgCl|Ag$$

At 25°C the student finds the cell potential to be 0.546 V, and from Appendix E the student finds

$$AgCl(s) + e \rightleftharpoons Ag(s) + Cl^-(aq) \qquad E^\circ = 0.222\ V$$

What does he find for the K_{sp} of $PbSO_4$?

93. A wire is fastened across the terminals of the Leclanché cell in Figure 17.21. Indicate the direction of electron flow in the wire.

94. Overcharging a lead–acid storage battery can generate hydrogen. Write a balanced equation to represent the reaction taking place.

95. An ambitious chemist discovers an alloy electrode that is capable of catalytically converting ethanol reversibly to carbon dioxide at 25°C according to the half-reaction

$$C_2H_5OH(\ell) + 15\,H_2O(\ell) \longrightarrow 2\,CO_2(g) + 12\,H_3O^+(aq) + 12\,e^-$$

Believing that this discovery is financially important, the chemist patents its composition and designs a fuel cell that may be represented as

$$Alloy|C_2H_5OH(\ell)|CO_2(g) + H_3O^+(1\ M)||H_3O^+(1\ M)|O_2|Ni$$

(a) Write the half-reaction occurring at the cathode.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(b) Using data from Appendix D, calculate $E°$ for the cell at 25°C.
(c) What is the $E°$ value for the ethanol half-cell?

96. Iron or steel is often covered by a thin layer of a second metal to prevent rusting: Tin cans consist of steel covered with tin, and galvanized iron is made by coating iron with a layer of zinc. If the protective layer is broken, however, iron will rust more readily in a tin can than in galvanized iron. Explain this observation by comparing the half-cell potentials of iron, tin, and zinc.

97. An electrolysis cell contains a solution of 0.10 M $NiSO_4$. The anode and cathode are both strips of Pt foil. Another electrolysis cell contains the same solution, but the electrodes are strips of Ni foil. In each case a current of 0.10 A flows through the cell for 10 hours.
(a) Write a balanced equation for the chemical reaction that occurs at the anode in each cell.
(b) Calculate the mass, in grams, of the product formed at the anode in each cell. (The product may be a gas, a solid, or an ionic species in solution.)

98. A potential difference of 2.0 V is impressed across a pair of inert electrodes (e.g., platinum) that are immersed in a 0.050 M aqueous KBr solution. What are the products that form at the anode and the cathode?

99. An aqueous solution is simultaneously 0.10 M in $SnCl_2$ and in $CoCl_2$.
(a) If the solution is electrolyzed, which metal will appear first?
(b) At what decomposition potential will that metal first appear?
(c) As the electrolysis proceeds, the concentration of the metal being reduced will drop and the potential will change. How complete a separation of the metals using electrolysis is theoretically possible? In other words, at the point where the second metal begins to form, what fraction of the first metal is left in solution?

100. A 55.5-kg slab of crude copper from a smelter has a copper content of 98.3%. Estimate the time required to purify it electrochemically if it is used as the anode in a cell that has acidic copper(II) sulfate as its electrolyte and a current of 2.00×10^3 A is passed through the cell.

101. Sheet iron can be galvanized by passing a direct current through a cell containing a solution of zinc sulfate between a graphite anode and the iron sheet. Zinc plates out on the iron. The process can be made continuous if the iron sheet is a coil that unwinds as it passes through the electrolysis cell and coils up again after it emerges from a rinse bath. Calculate the cost of the electricity required to deposit a 0.250-mm-thick layer of zinc on both sides of an iron sheet that is 1.00 m wide and 100 m long, if a current of 25 A at a voltage of 3.5 V is used and the energy efficiency of the process is 90%. The cost of electricity is 10 cents per kilowatt–hour (1 kWh = 3.6 MJ). Consult Appendix F for data on zinc.

CUMULATIVE PROBLEMS

102. A 1.0 M solution of NaOH is electrolyzed, generating $O_2(g)$ at the anode. A current of 0.15 A is passed through the cell for 75 minutes. Calculate the volume of (wet) oxygen generated in this period if the temperature is held at 25°C and the total pressure is 0.985 atm. (*Hint:* Use the vapor pressure of water at this temperature from Table 10.3.)

103. Use standard entropies from Appendix D to predict whether the standard potential of the $Cu|Cu^{2+}\|Ag^+|Ag$ cell (diagrammed in Figure 17.2) will increase or decrease if the temperature is raised above 25°C.

104. About 50,000 kJ of electrical energy is required to produce 1.0 kg of Al from its $Al(OH)^3$ ore. The major energy cost in recycling aluminum cans is the melting of the aluminum. The enthalpy of fusion of Al(*s*) is 10.7 kJ mol^{-1}. Compare the energy cost for making new aluminum with that for recycling.

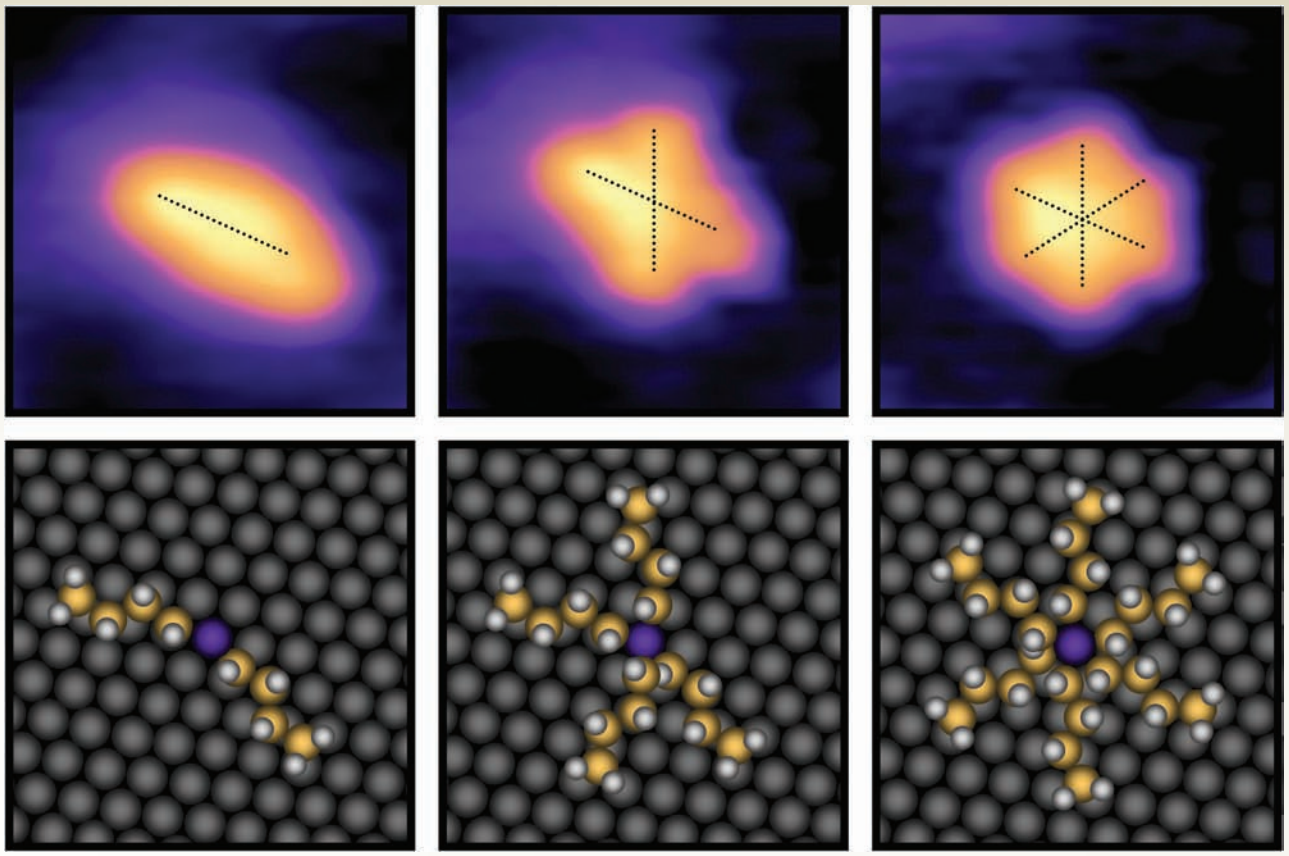
105. (a) Use the following half-reactions and their reduction potentials to calculate the K_{sp} of AgBr:

$$Ag^+ + e^- \longrightarrow Ag(s) \qquad E^o = 0.7996 \text{ V}$$

$$AgBr(s) + e^- \longrightarrow Ag(s) + Br^- \qquad E^o = 0.0713 \text{ V}$$

(b) Estimate the solubility of AgBr in 0.10 M NaBr(*aq*).

106. Amounts of iodine dissolved in aqueous solution, $I_2(aq)$, can be determined by titration with thiosulfate ion ($S_2O_3^{2-}$). The thiosulfate ion is oxidized to $S_4O_6^{2-}$ while the iodine is reduced to iodide ion. Starch is used as an indicator because it has a strong blue color in the presence of dissolved iodine.
(a) Write a balanced equation for this reaction.
(b) If 56.40 mL of 0.100 M $S_2O_3^{2-}$ solution is used to reach the endpoint of a titration of an unknown amount of iodine, calculate the number of moles of iodine originally present.
(c) Combine the appropriate half-cell potentials from Appendix E with thermodynamic data from Appendix D for the equilibrium



$$I_2(s) \rightleftharpoons I_2(aq)$$

to calculate the equilibrium constant at 25°C for the reaction in part (a).

RATES OF CHEMICAL AND PHYSICAL PROCESSES

J. Phys. Chem. C, 2009, 113(25), pp 10913–10920

Scanning tunneling microscope images of dibutyl sulfide adsorbed on a single crystal gold surface, measured at 7 K, 13 K, and 25 K (top row, left to right), with corresponding ball-and-stick models shown in the bottom row. The molecule occupies a single unique site at 7 K, then samples the two lowest energy, nearly equivalent sites at 13 K, and finally rotates freely at 25 K. These "molecular rotors" are being studied to understand how more complex "molecular machines" operate in biological processes and potential applications in nanotechnology are also being explored. This series of images was chosen to illustrate the role of temperature in activating molecular motions and to anticipate the central role it plays in controlling the rates of chemical reactions.

Thermodynamics explains *why* chemical reactions occur; minimizing the Gibbs free energy is the driving force toward chemical equilibrium. Thermodynamics provides deep insight into the nature of chemical equilibrium, but it gives no answer to the crucial question of how rapidly that equilibrium is achieved.

Chemical kinetics explains *how* reactions occur by studying their rates and mechanisms. Chemical kinetics explains how the speeds of different chemical reactions vary from explosive rapidity to glacial sluggishness and how slow reactions can be accelerated by materials called catalysts. Chemical kinetics has enormous practical importance because it provides the basis for optimizing conditions to carry out chemical reactions at reasonable speed, under proper control.

The central goal in chemical kinetics is to find the relationship between the rate of a reaction and the amount of reactants present. Once this connection is established, the influence of external conditions—principally the temperature—can be explored.

Nuclear chemistry represents a particularly simple limiting form of kinetics in which unstable nuclei decay with a constant probability during any time interval. Its richness arises from the multiplicity of decay paths that are possible, which arise from the mass-energy relationships that determine nuclear stability.

The interactions between molecules and electromagnetic radiation form the basis of molecular spectroscopy, which provides a number of methods with which to deduce molecular structure and follow the dynamics of physical processes and chemical reactions. The absorption of light can also induce a number of chemical reactions that are very different from those activated by thermal energy. Selected examples drawn from atmospheric photochemistry and from photosynthesis are discussed.

UNIT CHAPTERS

CHAPTER 18
Chemical Kinetics

CHAPTER 19
Nuclear Chemistry

CHAPTER 20
Molecular Spectroscopy and Photochemistry

UNIT GOALS

- To relate the rate of a chemical reaction to the instantaneous concentration(s) of reactants by determining the rate law and the rate constant for the reaction
- To describe the influence of temperature on the reaction rate by measuring the activation energy for the reaction
- To explain the mechanism of a complex reaction by identifying the separate elementary reaction steps through which it proceeds
- To explain the role of catalysts in manipulating reaction rates
- To develop an elementary description of the rates of nuclear reactions, emphasizing the half-life of radioactive species
- To survey the applications and consequences of nuclear reactions in medicine, biology, energy production, and the environment
- To introduce and discuss methods and applications of molecular spectroscopy
- To relate the initiation of photochemical reactions to the wavelength of light, and survey consequences of photochemical reactions in the atmosphere as well as those associated with photosynthesis

Powdered chalk (mostly calcium carbonate $CaCO_3$) reacts rapidly with dilute hydrochloric acid because it has a large total surface area. A stick of chalk has a much smaller surface area, so it reacts much more slowly.

Why do some chemical reactions proceed with lightning speed when others require days, months, or even years to produce detectable amounts of products? How do catalysts increase the rates of chemical reactions? Why do small changes in temperature often have such large effects on the cooking rate of food? How does a study of the rate of a chemical reaction inform us about the way in which molecules combine to form products? All of these questions involve studies of reaction rates, which is the subject of chemical kinetics.

Chemical kinetics is a complex subject, the details of which are not currently as well understood as in chemical thermodynamics. For many reactions the equilibrium constants are known accurately, but the rates and detailed reaction pathways remain poorly understood. This is particularly true of reactions in which many spe-

cies participate in the overall process connecting reactants to products. One good example is the reaction

$$5\ Fe^{2+}(aq) + MnO_4^-(aq) + 8\ H_3O^+(aq) \longrightarrow 5\ Fe^{3+}(aq) + Mn^{2+}(aq) + 12\ H_2O(\ell)$$

We can measure the equilibrium constant for this reaction easily from the voltage of a galvanic cell, and then calculate from it the equilibrium concentrations that will result from arbitrary initial conditions. It is considerably harder to determine the exact pathway by which the reaction goes from reactants to products. This path certainly does *not* involve the simultaneous collision of five Fe^{2+} ions and one MnO_4^- ion with eight H_3O^+ ions, because such a collision would be exceedingly rare. Instead, the path proceeds through a series of elementary steps involving two or at most three ions, such as

$$Fe^{2+}(aq) + MnO_4^-(aq) \longrightarrow Fe^{3+}(aq) + MnO_4^{2-}(aq)$$

$$MnO_4^{2-}(aq) + H_3O^+(aq) \longrightarrow HMnO_4^-(aq) + H_2O(\ell)$$

$$HMnO_4^-(aq) + Fe^{2+}(aq) \longrightarrow HMnO_4^{2-}(aq) + Fe^{3+}(aq)$$

Other postulated steps take the process to its final products. Some of these steps are slow, and others fast; taken together they constitute the **reaction mechanism.**

The primary goal of chemical kinetics is to deduce the mechanism of a reaction from experimental studies of its rate. For this, we have to measure how the rate depends on the concentrations of the reacting species. This chapter lays out the methods and concepts for measuring and interpreting reaction rates and for identifying the mechanism.

18.1 RATES OF CHEMICAL REACTIONS

The speed of a reaction depends on many factors. Concentrations of reacting species certainly play a major role in speeding up or slowing down a particular reaction (Fig. 18.1). As we see in Section 18.5, many reaction rates are extremely sensitive to temperature. This means that careful control of temperature is critical for quantitative measurements in chemical kinetics. Finally, the rate often depends crucially on the physical forms of the reactants, as shown in the chapter opening pho-

FIGURE 18.2 Steel wool burning in oxygen.

tograph. An iron nail oxidizes only very slowly in dry air to iron oxide, but steel wool burns spectacularly in oxygen (Fig. 18.2). Because the quantitative study of heterogeneous reactions—those involving two or more phases, such as a solid and a gas—is difficult, we begin with homogeneous reactions, which take place entirely within the gas phase or solution. In Section 18.8 we turn briefly to some important aspects of heterogeneous reactions.

Measuring Reaction Rates

A kinetics experiment measures the rate of change of the concentration of a substance participating in a chemical reaction. How can we experimentally monitor a changing concentration? If the reaction is slow enough, we can let it run for a measured time and then abruptly "quench" (effectively stop) it by rapidly cooling the reaction mixture sufficiently. At that low temperature the composition of the reaction mixture remains constant, so we have time to analyze the mixture for some particular reactant or product. This procedure is not useful for rapid reactions, especially those involving gas mixtures, because they are difficult to cool quickly. An alternative is to probe the concentrations by the absorption of light. Chapter 20 shows that different molecules absorb at different wavelengths. If a wavelength is absorbed by only one particular reactant or product, measuring the amount of light absorbed by the reaction mixture at that wavelength determines the concentration of the absorbing species. A series of such measurements at different times reveals the rate of change of the concentration. Often, a flash of light can also be used to initiate a very fast reaction, whose rate is then tracked by measuring absorption at a particular wavelength.

The average rate of a reaction is analogous to the average speed of a car. If the average position of a car is recorded at two different times, then

$$\text{average speed} = \frac{\text{distance traveled}}{\text{time elapsed}} = \frac{\text{change in location}}{\text{change in time}}$$

In the same way, the **average reaction rate** is obtained by dividing the change in concentration of a reactant or product by the time interval over which that change occurs:

$$\text{average reaction rate} = \frac{\text{change in concentration}}{\text{change in time}}$$

If concentration is measured in mol L^{-1} and time in seconds, then the rate of a reaction has units of mol L^{-1} s^{-1}.

Consider a specific example. In the gas-phase reaction

$$NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g)$$

NO_2 and CO are consumed as NO and CO_2 are produced. If a probe can measure the NO concentration, the average rate of reaction can be estimated from the ratio of the change in NO concentration $\Delta[NO]$ to the time interval Δt:

$$\text{average rate} = \frac{\Delta[NO]}{\Delta t} = \frac{[NO]_f - [NO]_i}{t_f - t_i}$$

This estimate depends on the time interval Δt that is selected, because the rate at which NO is produced changes with time. Average rates for this reaction can be calculated for various time periods (see Fig. 18.3), the average rate during the first 50 s being given by

$$\text{average rate} = \frac{\Delta[NO]}{\Delta t} = \frac{(0.0160 - 0)\ \text{mol L}^{-1}}{(50 - 0)\ \text{s}} = 3.2 \times 10^{-4}\ \text{mol L}^{-1}\ \text{s}^{-1}$$

During the second 50 s, the average rate is 1.6×10^{-4} mol L^{-1} s^{-1}, and during the third 50 s it is 9.6×10^{-5} mol L^{-1} s^{-1}. Clearly, this reaction slows as it progresses,

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and its average rate indeed depends on the time interval chosen. Figure 18.3 shows a graphical method for determining average rates. The average rate is the slope of the straight line connecting the concentrations at the initial and final points of a time interval.

The **instantaneous rate** of a reaction is obtained by considering smaller and smaller time increments Δt (with correspondingly smaller values of Δ[NO]). As Δt approaches 0, the rate becomes the slope of the line tangent to the curve at time t (see Fig. 18.3). This slope is written as the derivative of [NO] with respect to time:

$$\text{instantaneous rate} = \text{limit}_{\Delta t \longrightarrow 0} \frac{[\text{NO}]_{t+\Delta t} - [\text{NO}]_t}{\Delta t} = \frac{d[\text{NO}]}{dt}$$

Throughout the rest of this book, we refer to the instantaneous rate simply as the *rate*. The instantaneous rate of a reaction at the moment that it begins (at $t = 0$) is the **initial rate** of that reaction.

The rate of this sample reaction could just as well have been measured by monitoring changes in the concentration of CO_2, NO_2, or CO instead of NO. Because every molecule of NO produced is accompanied by one molecule of CO_2, the rate of increase of CO_2 concentration is the same as that of NO. The concentrations of the two reactants, NO_2 and CO, *decrease* at the same rate that the concentrations of the products increase, because the coefficients in the balanced equation are also both equal to 1. This is summarized as

$$\text{rate} = -\frac{d[\text{NO}_2]}{dt} = -\frac{d[\text{CO}]}{dt} = \frac{d[\text{NO}]}{dt} = \frac{d[\text{CO}_2]}{dt}$$

Another gas-phase reaction is

$$2\ \text{NO}_2(g) + \text{F}_2(g) \longrightarrow 2\ \text{NO}_2\text{F}(g)$$

This equation states that two molecules of NO_2 disappear and two molecules of NO_2F appear for each molecule of F_2 that reacts. Thus, the NO_2 concentration

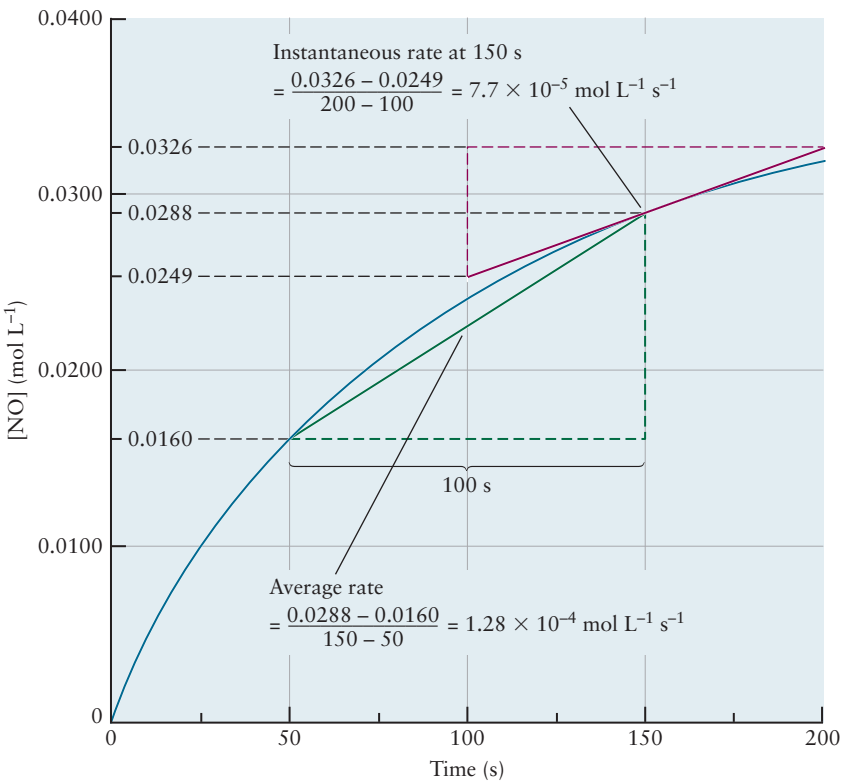

FIGURE 18.3 A graph of the concentration of NO against time in the reaction $NO_2 + CO \longrightarrow NO + CO_2$. The average rate during the time interval from 50 to 150 seconds is obtained by dividing the change in NO concentration by the duration of the interval (green box). Note that the average rate (green line) underestimates the true production rate over the time interval. The instantaneous rate 150 seconds after the start of the reaction is found by calculating the slope of the line tangent to the curve at that point (red box).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

changes twice as fast as the F_2 concentration; the NO_2F concentration also changes twice as fast and has the opposite sign. We write the rate in this case as

$$\text{rate} = -\frac{1}{2}\frac{d[NO_2]}{dt} = -\frac{d[F_2]}{dt} = \frac{1}{2}\frac{d[NO_2F]}{dt}$$

The rate of change of concentration of each species is divided by its coefficient in the balanced chemical equation. Rates of change of reactants appear with negative signs and those of products with positive signs. For the general reaction

$$aA + bB \longrightarrow cC + dD$$

the rate is

$$\text{rate} = -\frac{1}{a}\frac{d[A]}{dt} = -\frac{1}{b}\frac{d[B]}{dt} = \frac{1}{c}\frac{d[C]}{dt} = \frac{1}{d}\frac{d[D]}{dt} \qquad [18.1]$$

These relations hold true provided there are no transient intermediate species or, if there are intermediates, their concentrations are independent of time for most of the reaction period.

18.2 RATE LAWS

In discussing chemical equilibrium we stressed that both forward and reverse reactions can occur; once products are formed, they can react back to give the original reactants. The net rate is the difference:

$$\text{net rate} = \text{forward rate} - \text{reverse rate}$$

Strictly speaking, measurements of concentration give the net rate rather than simply the forward rate. Near the beginning of a reaction that starts from pure reactants the concentrations of reactants are far higher than those of products, and the reverse rate can be neglected. In addition, many reactions go to "completion" ($K \gg 1$). This means they have a measurable rate only in the forward direction, or else the experiment can be arranged so that the products are removed as they are formed. This section focuses on forward rates exclusively.

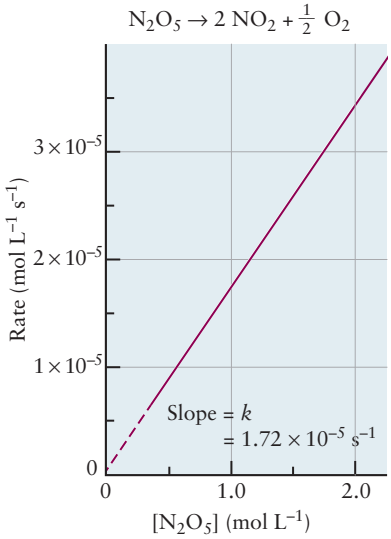

FIGURE 18.4 The rate of decomposition of $N_2O_5(g)$ at 25°C is proportional to its concentration. The slope of this line is equal to the rate constant k for the reaction.

Order of a Reaction

The forward rate of a chemical reaction depends on the concentrations of the reactants. As an example, consider the decomposition of gaseous dinitrogen pentaoxide (N_2O_5). This compound is a white solid that is stable below 0°C but decomposes when vaporized:

$$N_2O_5(g) \longrightarrow 2\ NO_2(g) + \tfrac{1}{2}\ O_2(g)$$

The rate of the reaction depends on the concentration of $N_2O_5(g)$. Figure 18.4 shows the graph of rate versus concentration to be a straight line that can be extrapolated to pass through the origin. So, the rate can be written

$$\text{rate} = k[N_2O_5]$$

This relation between the rate of a reaction and concentration is called an **empirical rate expression** or **rate law,** and the proportionality constant k is called the **rate constant** for the reaction. Like an equilibrium constant, a rate constant is independent of concentration but depends on temperature, as we describe in Section 18.5.

For many (but not all) reactions with a single reactant, the rate is proportional to the concentration of that reactant raised to a power. That is, the rate expression for

$$a\text{A} \longrightarrow \text{products}$$

frequently has the form

$$\text{rate} = k[\text{A}]^n$$

It is important to note that the power n in the rate expression has no direct relation to the coefficient a in the balanced chemical equation. This number has to be determined experimentally for each rate law. For the decomposition of ethane at high temperatures and low pressures,

$$C_2H_6(g) \longrightarrow 2\ CH_3(g)$$

the rate expression has the form

$$\text{rate} = k[C_2H_6]^2$$

Therefore, $n = 2$ even though the coefficient in the chemical equation is 1.

The power to which the concentration is raised is called the **order** of the reaction with respect to that reactant. Thus, the decomposition of N_2O_5 is **first order,** whereas that of C_2H_6 is **second order.** Some processes are **zeroth order** over a range of concentrations. Because $[A]^0 = 1$, such reactions have rates that are independent of concentration:

$$\text{rate} = k \qquad \text{(for zeroth-order kinetics)}$$

The order of a reaction does not have to be an integer; fractional powers are sometimes found. At 450 K, the decomposition of acetaldehyde (CH_3CHO) is described by the rate expression

$$\text{rate} = k[CH_3CHO]^{3/2}$$

These examples demonstrate that reaction order is an experimentally determined property that cannot be predicted from the form of the chemical equation.

The following example illustrates how the order of a reaction can be deduced from experimental data.

EXAMPLE 18.1

At elevated temperatures, HI reacts according to the chemical equation

$$2\ HI(g) \longrightarrow H_2(g) + I_2(g)$$

At 443°C, the rate of the reaction increases with concentration of HI as follows:

[HI] (mol L^{-1})	0.0050	0.010	0.020
Rate (mol L^{-1} s^{-1})	7.5×10^{-4}	3.0×10^{-3}	1.2×10^{-2}

(a) Determine the order of the reaction and write the rate expression.

(b) Calculate the rate constant, and give its units.

(c) Calculate the reaction rate for a 0.0020 M concentration of HI.

Solution

(a) The rate expressions at two different concentrations $[HI]_1$ and $[HI]_2$ are

$$\text{rate}_1 = k([HI]_1)^n$$

$$\text{rate}_2 = k([HI]_2)^n$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

After dividing the second equation by the first, the rate constant k drops out, leaving the reaction order n as the only unknown quantity.

$$\frac{\text{rate}_2}{\text{rate}_1} = \left(\frac{[\text{HI}]_2}{[\text{HI}]_1}\right)^n$$

We can now substitute any two sets of data into this equation and solve for n. Taking the first two sets with $[\text{HI}]_1 = 0.0050$ M and $[\text{HI}]_2 = 0.010$ M gives

$$\frac{3.0 \times 10^{-3}}{7.5 \times 10^{-4}} = \left(\frac{0.010}{0.0050}\right)^n$$

which simplifies to

$$4 = (2)^n$$

By inspection, $n = 2$, so the reaction is second order in HI. When the solution of the equation is less obvious, we can take the logarithms of both sides, giving (in this case)

$$\log_{10} 4 = n \log_{10} 2$$

$$n = \frac{\log_{10} 4}{\log_{10} 2} = \frac{0.602}{0.301} = 2$$

The rate expression has the form

$$\text{rate} = k[\text{HI}]^2$$

(**b**) The rate constant k is calculated by inserting any of the sets of data into the rate expression. Taking the first set gives

$$7.5 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1} = k(0.0050 \text{ mol L}^{-1})^2$$

Solving for k gives

$$k = 30 \text{ L mol}^{-1} \text{ s}^{-1}$$

(**c**) Finally, the rate is calculated for [HI] = 0.0020 M:

$$\text{rate} = k[\text{HI}]^2 = (30 \text{ L mol}^{-1} \text{ s}^{-1})(0.0020 \text{ mol L}^{-1})^2$$

$$= 1.2 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1}$$

So far, each example reaction rate has depended only on a single concentration. In reality, many rates depend on the concentrations of two or more different chemical species, and the rate expression is written in a form such as

$$\text{rate} = -\frac{1}{a}\frac{d[\text{A}]}{dt} = k[\text{A}]^m[\text{B}]^n$$

Again the exponents m and n do not derive from the coefficients in the balanced equation for the reaction; they must be determined experimentally and are usually integers or half-integers.

The exponents $m, n, \ldots$ give the order of the reaction, just as in the simpler case where only one concentration appeared in the rate expression. The preceding reaction is said to be mth order in A, meaning that a change in the concentration of A by a certain factor leads to a change in the rate by that factor raised to the mth power. The reaction is nth order in B, and the **overall reaction order** is $m + n$. For the reaction

$$H_2PO_2^-(aq) + OH^-(aq) \longrightarrow HPO_3^{2-}(aq) + H_2(g)$$

the experimentally determined rate expression is

$$\text{rate} = k[H_2PO_2^-][OH^-]^2$$

so the reaction is said to be first order in $H_2PO_2^-(aq)$ and second order in $OH^-(aq)$, with an overall reaction order of 3. The units of k depend on the reaction order. If

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

all concentrations are expressed in mol L^{-1} and if $p = m + n + \cdots$ is the overall reaction order, then k has units of mol$^{-(p-1)}$ L^{p-1} s^{-1}.

EXAMPLE 18.2

Use the preceding rate expression to determine the effect of the following changes on the rate of decomposition of $H_2PO_2^-(aq)$:

(a) Tripling the concentration of $H_2PO_2^-(aq)$ at constant pH

(b) Changing the pH from 13 to 14 at a constant concentration of $H_2PO_2^-(aq)$

Solution

(a) Because the reaction is first order in $H_2PO_2^-(aq)$, tripling this concentration will triple the reaction rate.

(b) A change in pH from 13 to 14 corresponds to an increase in the $OH^-(aq)$ concentration by a factor of 10. Because the reaction is second order in $OH^-(aq)$ (that is, this term is squared in the rate expression), this will increase the reaction rate by a factor of 10^2, or 100.

Related Problems: 5, 6

Rate expressions that depend on more than one concentration are more difficult to obtain experimentally than those that depend just on one. One method is to find the instantaneous initial rates of reaction for several values of one of the concentrations, holding the other initial concentrations fixed from one run to the next. The experiment can then be repeated, changing one of the other concentrations. The following example illustrates this procedure.

EXAMPLE 18.3

The reaction of $NO(g)$ with $O_2(g)$ gives $NO_2(g)$:

$$2\ NO(g) + O_2(g) \longrightarrow 2\ NO_2(g)$$

From the dependence of the initial rate $(-\frac{1}{2}\,d[NO]/dt)$ on the initial concentrations of NO and O_2, determine the rate expression and the value of the rate constant.

[NO] (mol L^{-1})	[O_2] (mol L^{-1})	Initial Rate (mol L^{-1} s^{-1})
1.0×10^{-4}	1.0×10^{-4}	2.8×10^{-6}
1.0×10^{-4}	3.0×10^{-4}	8.4×10^{-6}
2.0×10^{-4}	3.0×10^{-4}	3.4×10^{-5}

Solution

When $[O_2]$ is multiplied by 3 (with [NO] constant), the rate is also multiplied by 3 (from 2.8×10^{-6} to 8.4×10^{-6}), so the reaction is first order in O_2. When [NO] is multiplied by 2 (with $[O_2]$ constant), the rate is multiplied by

$$\frac{3.4 \times 10^{-5}}{8.4 \times 10^{-6}} \approx 4 = 2^2$$

so the reaction is second order in NO. Thus, the form of the rate expression is

$$\text{rate} = k[O_2][NO]^2$$

To evaluate k, we insert any set of data into the equation. From the first set,

$$2.8 \times 10^{-6}\ \text{mol}\ L^{-1}\ s^{-1} = k(1.0 \times 10^{-4}\ \text{mol}\ L^{-1})(1.0 \times 10^{-4}\ \text{mol}\ L^{-1})^2$$

$$k = 2.8 \times 10^{6}\ L^2\ \text{mol}^{-2}\ s^{-1}$$

Integrated Rate Laws

Measuring an initial rate involves determining small changes in concentration $\Delta[A]$ that occur during a short time interval Δt. Sometimes it can be difficult to obtain sufficiently precise experimental data for these small changes. An alternative is to use an **integrated rate law,** which expresses the concentration of a species directly as a function of the time. For any simple rate expression, a corresponding integrated rate law can be obtained.

First-Order Reactions

Consider again the reaction

$$N_2O_5(g) \longrightarrow 2\ NO_2(g) + \tfrac{1}{2}\ O_2(g)$$

whose rate law has been determined experimentally to be

$$\text{rate} = -\frac{d[N_2O_5]}{dt} = k[N_2O_5]$$

This is a first-order reaction. If we let $[N_2O_5] = c$, a function of time, we have

$$\frac{dc}{dt} = -kc$$

We seek a function whose slope at every time is proportional to the value of the function itself. This function can be found through the use of calculus. Separating the variables (with concentration c on the left and time t on the right) gives

$$\frac{1}{c}\,dc = -k\,dt$$

Integrating from an initial concentration c_0 at time $t = 0$ to a concentration c at time t (see Appendix C, Section C.5) gives

$$\int_{c_0}^{c} \frac{1}{c}\,dc = -k\int_0^t dt$$

$$\ln c - \ln c_0 = -kt$$

$$\ln (c/c_0) = -kt$$

$$c = c_0\ e^{-kt} \qquad [18.2]$$

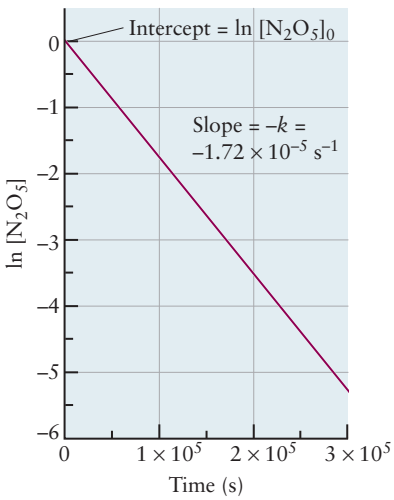

FIGURE 18.5 In a first-order reaction such as the decomposition of N_2O_5, a graph of the natural logarithm of the concentration against time is a straight line, whose negative slope gives the rate constant for the reaction.

The concentration falls off exponentially with time. For a first-order reaction, a plot of ln c against t is a straight line with slope $-k$ (Fig. 18.5).

A useful concept in discussions of first-order reactions is the **half-life** $t_{1/2}$ which is defined as the time it takes for the original concentration c_0 to be reduced to half its value, $c_0/2$. Setting $c = c_0/2$ gives

$$\ln\left(\frac{c}{c_0}\right) = \ln\left(\frac{c_0/2}{c_0}\right) = -\ln 2 = -kt_{1/2}$$

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.6931}{k} \qquad [18.3]$$

If k has units of s^{-1}, $(\ln 2)/k$ is the half-life in seconds. During each half-life, the concentration of A falls to half its value again (Fig. 18.6).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

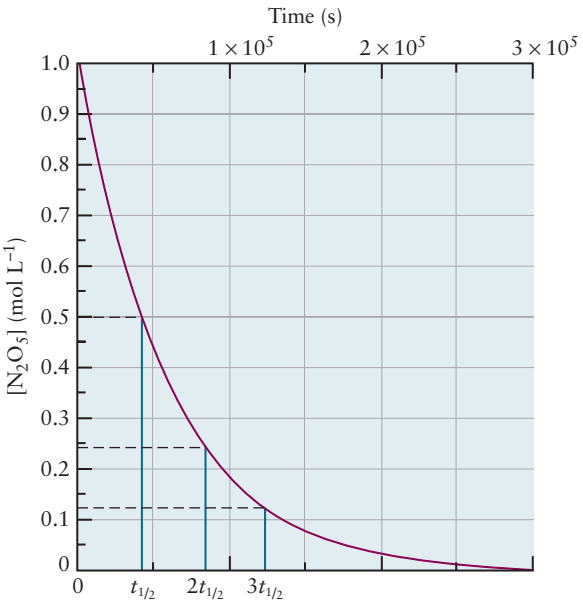

FIGURE 18.6 The same data as in Figure 18.5 are graphed in a concentration-versus-time picture. The half-life $t_{1/2}$ is the time it takes for the concentration to be reduced to half its initial value. In two half-lives, the concentration falls to one quarter of its initial value.

EXAMPLE 18.4

(a) What is the rate constant k for the first-order decomposition of $N_2O_5(g)$ at 25°C if the half-life of $N_2O_5(g)$ at that temperature is 4.03×10^4 s?

(b) What percentage of the N_2O_5 molecules will *not* have reacted after one day?

Solution

(a)
$$t_{1/2} = \frac{\ln 2}{k} = 4.03 \times 10^4 \text{ s}$$

Solving for the rate constant k gives

$$k = \frac{\ln 2}{t_{1/2}} = \frac{0.6931}{4.03 \times 10^4 \text{ s}} = 1.72 \times 10^{-5} \text{ s}^{-1}$$

(b) From the integrated rate law for a first-order reaction,

$$\frac{c}{c_0} = e^{-kt}$$

Putting in the value for k and setting t to 1 day $= 8.64 \times 10^4$ s gives

$$\frac{c}{c_0} = \exp\left[-(1.72 \times 10^{-5} \text{ s}^{-1})(8.64 \times 10^4 \text{ s})\right]$$

$$= e^{-1.49} = 0.226$$

Therefore, 22.6% of the molecules will not yet have reacted after one day.

Related Problems: 11, 12

Second-Order Reactions

Integrated rate laws can be obtained for reactions of other orders. The observed rate of the reaction

$$2\ NO_2(g) \longrightarrow 2\ NO(g) + O_2(g)$$

is second order in $[NO_2]$:

$$\text{rate} = -\frac{1}{2}\frac{d[NO_2]}{dt} = k[NO_2]^2$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

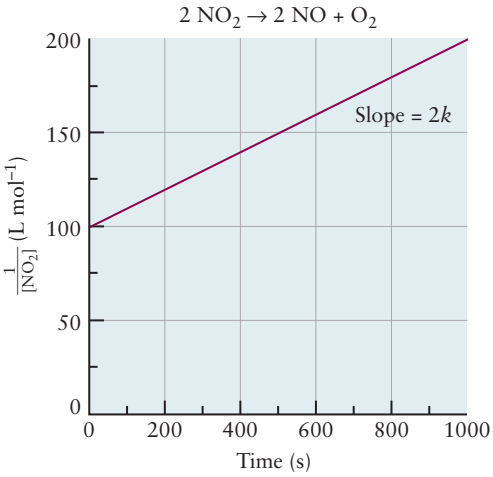

FIGURE 18.7 For a second-order reaction such as $2\ NO_2 \longrightarrow 2\ NO + O_2$, a graph of the reciprocal of the concentration against time is a straight line with slope $2k$.

Writing $[NO_2] = c$ and multiplying both sides of the equation by -1 gives

$$\frac{dc}{dt} = -2kc^2$$

$$\frac{1}{c^2}\,dc = -2k\,dt$$

Integrating this from the initial concentration c_0 at time 0 to c at time t gives

$$\int_{c_0}^{c} \frac{1}{c^2}\,dc = -2k\int_0^t dt$$

$$-\frac{1}{c} + \frac{1}{c_0} = -2kt$$

$$\frac{1}{c} = \frac{1}{c_0} + 2kt \qquad [18.4]$$

For such a second-order reaction, a plot of $1/c$ against t is linear (Fig. 18.7). The factor 2 multiplying kt in this expression arises from the stoichiometric coefficient 2 for NO_2 in the balanced equation for the specific example reaction. For other second-order reactions with different stoichiometric coefficients for the reactant (see the thermal decomposition of ethane described on page 840), we must modify the integrated rate law accordingly.

The concept of half-life has little use for second-order reactions. Setting $[NO_2]$ equal to $[NO_2]_0/2$ in the preceding equation and solving for t gives

$$\frac{2}{[NO_2]} = 2kt_{1/2} + \frac{1}{[NO_2]_0}$$

$$t_{1/2} = \frac{1}{2k[NO_2]_0}$$

For second-order reactions, the half-life is not a constant; it depends on the initial concentration.

EXAMPLE 18.5

The dimerization of tetrafluoroethylene (C_2F_4) to octafluorocyclobutane (C_4F_8) is second order in the reactant C_2F_4, and at 450 K its rate constant is $k = 0.0448\ L\ mol^{-1}\ s^{-1}$. If the initial concentration of C_2F_4 is $0.100\ mol\ L^{-1}$, what will its concentration be after 205 s?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution
For this second-order reaction,

$$\frac{1}{c} - \frac{1}{c_0} = 2kt$$

Solving for the concentration c after a time $t = 205$ s gives

$$\frac{1}{c} = (2)(0.0448 \text{ L mol}^{-1} \text{ s}^{-1})(205 \text{ s}) + \frac{1}{0.100 \text{ mol L}^{-1}} = 28.4 \text{ L mol}^{-1}$$

$$c = 3.53 \times 10^{-2} \text{ mol L}^{-1}$$

Related Problems: 15, 16

Empirical rate laws are established in two ways: by measuring the dependence of initial rates on the concentrations of each reactant and by plotting the concentration as a function of time, as illustrated earlier. It is often the case that rate laws cannot be definitively established by one concentration–time plot alone and is helpful to plot the data in several ways to choose the best fit, as shown in Figure 18.8. You may use this approach in one of your undergraduate laboratories. Determining the order of a reaction in more complicated cases requires sophisticated data analysis using specialized computer codes designed for chemical kinetics.

18.3 REACTION MECHANISMS

Many reactions do not occur in a single step, but rather proceed through a sequence of steps to arrive at the products. Each step is called an **elementary reaction** and occurs through the collisions of atoms, ions, or molecules, as discussed in Section 8.6. The rate expression for an overall reaction cannot be derived from the stoichiometry of the balanced equation, and must be determined experimentally. But the rate of an elementary reaction *is* directly proportional to the product of the concentrations of the reacting species, each raised to a power equal to its coefficient in the balanced elementary equation.

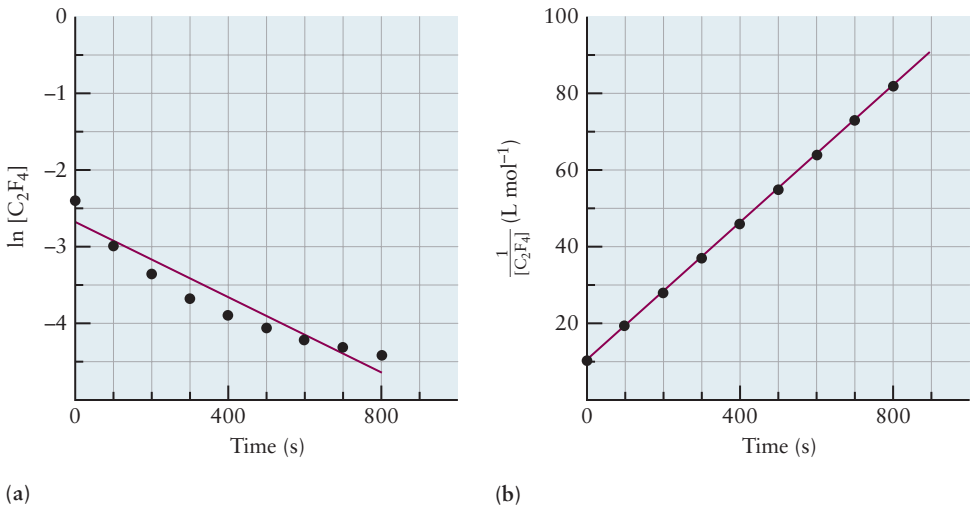

FIGURE 18.8 For the reaction in Example 18.5, (a) plotting the logarithm of the concentration of C_2F_4 against time tests for first-order kinetics and (b) plotting the reciprocal of the concentration of C_2F_4 against time tests for second-order kinetics. It is clear that the assumption of first-order kinetics does not fit the data as well; no straight line will pass through the data.

Elementary Reactions

A **unimolecular** elementary reaction involves only a single reactant molecule. An example is the dissociation of energized N_2O_5 molecules in the gas phase:

$$N_2O_5^*(g) \longrightarrow NO_2(g) + NO_3(g)$$

The asterisk indicates that the N_2O_5 molecules have far more than ground state energy. This step is unimolecular and has the rate expression

$$\text{rate} = k[N_2O_5^*]$$

An important class of unimolecular reactions is the decay of radioactive nuclei, considered in Chapter 19.

The most common type of elementary reaction involves the collision of two atoms, ions, or molecules and is called **bimolecular.** An example is the reaction

$$NO(g) + O_3(g) \longrightarrow NO_2(g) + O_2(g)$$

The frequency at which a given NO molecule collides with ozone molecules is proportional to the concentration of ozone: If there are twice as many ozone molecules per unit volume, each NO molecule will undergo twice as many collisions as it moves through space, and ozone will react twice as rapidly. The rate of collisions of *all* the NO molecules in the container is proportional to the concentration of NO as well, so the rate law of a bimolecular reaction like this one has the form

$$\text{rate} = k[NO][O_3]$$

A **termolecular** reaction step involves the simultaneous collision of three molecules, which is a much less likely event. An example is the recombination of iodine atoms in the gas phase to form iodine molecules. So much energy is released in forming the I—I bond that the molecule would simply fly apart as soon as it was formed if the event were a binary collision. A third atom or molecule is necessary to take away some of the excess energy. If iodine recombination takes place in the presence of a sufficiently high concentration of an inert gas such as argon, termolecular reactions

$$I(g) + I(g) + Ar(g) \longrightarrow I_2(g) + Ar(g)$$

occur in which the argon atom leaves with more kinetic energy than it had initially. The rate law for this termolecular reaction is

$$\text{rate} = k[I]^2[Ar]$$

Elementary reactions involving collisions of four or more molecules are not observed, and even termolecular collisions are rare if other pathways are possible.

Elementary reactions in liquid solvents involve encounters of solute species with one another. If the solution is ideal, the rates of these processes are proportional to the product of the concentrations of the solute species involved. Solvent molecules are always present and may affect the reaction, even though they do not appear in the rate expression because the solvent concentration cannot be varied appreciably. A reaction such as the recombination of iodine atoms occurs readily in a liquid. It appears to be second order with rate law

$$\text{rate} = k[I]^2$$

only because the third bodies involved are solvent molecules, with constant concentrations. In the same way, a reaction between a solvent molecule and a solute molecule appears to be unimolecular, and only the concentration of solute molecules enters the rate expression for that step.

Reaction Mechanisms

A **reaction mechanism** is a detailed sequence of elementary reactions, with their rates, that are combined to yield the overall reaction. It is often possible to write several reaction mechanisms, each of which is consistent with a given overall reaction. One of the goals of chemical kinetics is to use the observed rate of a reaction to choose among various conceivable reaction mechanisms.

The gas-phase reaction of nitrogen dioxide with carbon monoxide provides a good example of a reaction mechanism. The generally accepted mechanism at low temperatures has two steps, both bimolecular:

$$NO_2(g) + NO_2(g) \longrightarrow NO_3(g) + NO(g) \qquad \text{(slow)}$$

$$NO_3(g) + CO(g) \longrightarrow NO_2(g) + CO_2(g) \qquad \text{(fast)}$$

For any reaction mechanism, combining the steps must give the overall reaction. When each elementary step occurs the same number of times in the course of the reaction, the chemical equations can simply be added. (If one step occurs twice as often as the others, it must be multiplied by 2 before the elementary reactions are added.) In this case, we add the two chemical equations to give

$$2\ NO_2(g) + NO_3(g) + CO(g) \longrightarrow NO_3(g) + NO(g) + NO_2(g) + CO_2(g)$$

Canceling out the NO_3 and one molecule of NO_2 from each side leads to

$$NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g)$$

A **reaction intermediate** (here, NO_3) is a chemical species that is formed and consumed in the reaction but does not appear in the overall balanced chemical equation. One of the major challenges in chemical kinetics is to identify intermediates, which are often so short-lived that they are difficult to detect directly.

EXAMPLE 18.6

Consider the following reaction mechanism:

$$Cl_2(g) \longrightarrow 2\ Cl(g)$$

$$Cl(g) + CHCl_3(g) \longrightarrow HCl(g) + CCl_3(g)$$

$$CCl_3(g) + Cl(g) \longrightarrow CCl_4(g)$$

(a) What is the molecularity of each elementary step?

(b) Write the overall equation for the reaction.

(c) Identify the reaction intermediate(s).

Solution

(a) The first step is unimolecular, and the other two are bimolecular.

(b) Adding the three steps gives

$$Cl_2(g) + 2\ Cl(g) + CHCl_3(g) + CCl_3(g) \longrightarrow 2\ Cl(g) + HCl(g) + CCl_3(g) + CCl_4(g)$$

The two species that appear in equal amounts on both sides cancel out to leave

$$Cl_2(g) + CHCl_3(g) \longrightarrow HCl(g) + CCl_4(g)$$

(c) The two reaction intermediates are Cl and CCl_3.

Kinetics and Chemical Equilibrium

There is a direct connection between the rates for the elementary steps in a chemical reaction mechanism and the overall equilibrium constant K. To see this connection, consider the reaction

$$2\ NO(g) + 2\ H_2(g) \rightleftharpoons N_2(g) + 2\ H_2O(g)$$

This reaction is believed to occur in a three-step process involving N_2O_2 and N_2O as intermediates:

$$NO(g) + NO(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} N_2O_2(g)$$

$$N_2O_2(g) + H_2(g) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} N_2O(g) + H_2O(g)$$

$$N_2O(g) + H_2(g) \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} N_2(g) + H_2O(g)$$

These elementary reactions are shown as equilibria, so the reverse reactions (from products to reactants) are included here as well; k_1, k_2, and k_3 are the rate constants for the forward elementary steps, and k_{-1}, k_{-2}, and k_{-3} are the rate constants for the corresponding reverse reactions.

We now invoke the principle of **detailed balance,** which states that at equilibrium the rate of *each* elementary process is balanced by (equal to) the rate of its reverse process. For the preceding mechanism we conclude that

$$k_1[NO]_{eq}^2 = k_{-1}[N_2O_2]_{eq}$$

$$k_2[N_2O_2]_{eq}[H_2]_{eq} = k_{-2}[N_2O]_{eq}[H_2O]_{eq}$$

$$k_3[N_2O]_{eq}[H_2]_{eq} = k_{-3}[N_2]_{eq}[H_2O]_{eq}$$

The equilibrium constants[1] K_1, K_2, and K_3 for the elementary reactions are equal to the ratio of the forward and reverse reaction rate constants:

$$K_1 = \frac{[N_2O_2]_{eq}}{[NO]_{eq}^2} = \frac{k_1}{k_{-1}}$$

$$K_2 = \frac{[N_2O]_{eq}[H_2O]_{eq}}{[N_2O_2]_{eq}[H_2]_{eq}} = \frac{k_2}{k_{-2}}$$

$$K_3 = \frac{[N_2]_{eq}[H_2O]_{eq}}{[N_2O]_{eq}[H_2]_{eq}} = \frac{k_3}{k_{-3}}$$

The steps of the mechanism are now added together to obtain the overall reaction. Recall from Section 14.4 that when reactions are added, their equilibrium constants are multiplied. Therefore, the overall equilibrium constant K is

$$K = K_1K_2K_3 = \frac{k_1k_2k_3}{k_{-1}k_{-2}k_{-3}} = \frac{[N_2O_2]_{eq}[N_2O]_{eq}[H_2O]_{eq}[N_2]_{eq}[H_2O]_{eq}}{[NO]_{eq}^2[N_2O_2]_{eq}[H_2]_{eq}[N_2O]_{eq}[H_2]_{eq}}$$

$$= \frac{[H_2O]_{eq}^2[N_2]_{eq}}{[NO]_{eq}^2[H_2]_{eq}^2}$$

[1]Thermodynamic equilibrium constants are dimensionless because they are expressed in terms of activities rather than partial pressure or concentration. The convention in chemical kinetics is to use concentrations rather than activities, even for gaseous species. Therefore, the equilibrium constants K_1, K_2, and K_3 introduced here are the empirical equilibrium constants K_c described briefly in Section 14.2. These constants are not dimensionless and must be multiplied by the concentration of the reference state, $c_{ref} = RT/P_{ref}$, raised to the appropriate power to be made equal to the thermodynamic equilibrium constant. Nevertheless, to maintain consistency with the conventions of chemical kinetics, such constants as K_1, K_2, and K_3 are referred to as equilibrium constants in this section and are written without the subscript c.

The concentrations of the intermediates N_2O_2 and N_2O cancel out, giving the usual expression of the mass-action law.

This result can be generalized to any reaction mechanism. The product of the forward rate constants for the elementary reactions divided by the product of the reverse rate constants is always equal to the equilibrium constant of the overall reaction. If there are several possible mechanisms for a given reaction (which might involve intermediates other than N_2O_2 and N_2O), their forward and reverse rate constants will all be consistent in this way with the equilibrium constant of the overall reaction.

18.4 REACTION MECHANISMS AND RATE

In many reaction mechanisms, one step is significantly slower than all the others; this step is called the **rate-determining step.** Because an overall reaction can occur only as fast as its slowest step, that step is crucial in determining the rate of the reaction. This is analogous to the flow of automobile traffic on a highway which has a slowdown at some point. The rate at which cars can complete a trip down the full length of the highway (in cars per minute) is approximately equal to the rate at which they pass through the bottleneck.

If the rate-determining step is the first one, the analysis is particularly simple. An example is the reaction

$$2\ NO_2(g) + F_2(g) \longrightarrow 2\ NO_2F(g)$$

for which the experimental rate law is

$$\text{rate} = k_{obs}[NO_2][F_2]$$

A possible mechanism for the reaction is

$$NO_2(g) + F_2(g) \xrightarrow{k_1} NO_2F(g) + F(g) \qquad \text{(slow)}$$

$$NO_2(g) + F(g) \xrightarrow{k_2} NO_2F(g) \qquad \text{(fast)}$$

The first step is slow and determines the rate, $k_1[NO_2][F_2]$, in agreement with the observed rate expression. The subsequent fast step does not affect the reaction rate because fluorine atoms react with NO_2 almost as soon as they are produced.

Mechanisms in which the rate-determining step occurs after one or more fast steps are often signaled by a reaction order greater than 2, by a nonintegral reaction order, or by an inverse concentration dependence on one of the species taking part in the reaction. An example is the reaction

$$2\ NO(g) + O_2(g) \longrightarrow 2\ NO_2(g)$$

for which the experimental rate law is

$$\text{rate} = k_{obs}[NO]^2[O_2]$$

One possible mechanism would be a single-step termolecular reaction of two NO molecules with one O_2 molecule. This would be consistent with the form of the rate expression, but termolecular collisions are rare, and if there is an alternative pathway it is usually followed.

One such alternative is the two-step mechanism

$$NO(g) + NO(g) \underset{}{\overset{k_1}{\rightleftharpoons}} N_2O_2(g) \qquad \text{(fast equilibrium)}$$

$$N_2O_2(g) + O_2(g) \xrightarrow{k_2} 2\ NO_2(g) \qquad \text{(slow)}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Because the slow step determines the overall rate, we can write

$$\text{rate} = k_2[N_2O_2][O_2]$$

The concentration of a reactive intermediate such as N_2O_2 cannot be varied at will. Because the N_2O_2 reacts only slowly with O_2, the reverse reaction (to 2 NO) is possible and must be taken into account. In fact, it is reasonable to assume that all of the elementary reactions that occur *before* the rate-determining step are in equilibrium, with the forward and reverse reactions occurring at the same rate. In this case, we have

$$\frac{[N_2O_2]}{[NO]^2} = \frac{k_1}{k_{-1}} = K_1$$

$$[N_2O_2] = K_1[NO]^2$$

$$\text{rate} = k_2K_1[NO]^2[O_2]$$

This result is consistent with the observed reaction order, with $k_2K_1 = k_{obs}$.

EXAMPLE 18.7

In basic aqueous solution the reaction

$$I^- + OCl^- \longrightarrow Cl^- + OI^-$$

follows a rate law that is consistent with the following mechanism:

$$OCl^-(aq) + H_2O(\ell) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} HOCl(aq) + OH^-(aq) \qquad \text{(fast equilibrium)}$$

$$I^-(aq) + HOCl(aq) \xrightarrow{k_2} HOI(aq) + Cl^-(aq) \qquad \text{(slow)}$$

$$OH^-(aq) + HOI(aq) \xrightarrow{k_3} H_2O(\ell) + OI^-(aq) \qquad \text{(fast)}$$

What rate law is predicted by this mechanism?

Solution

The rate is determined by the slowest elementary step, the second one:

$$\text{rate} = k_2[I^-][HOCl]$$

But, the HOCl is in equilibrium with OCl^- and OH^- due to the first step:

$$\frac{[HOCl][OH^-]}{[OCl^-]} = K_1 = \frac{k_1}{k_{-1}}$$

Solving this for [HOCl] and inserting it into the previous expression gives the prediction

$$\text{rate} = k_2K_1\frac{[I^-][OCl^-]}{[OH^-]}$$

which is, in fact, the experimentally observed rate law.

Related Problems: 25, 26, 27, 28, 29, 30

The rate law of the foregoing example depends on the inverse of the concentration of OH^- ion. Such a form is often a clue that a rapid equilibrium occurs in the first steps of a reaction, preceding the rate-determining step. Fractional orders of reaction provide a similar clue, as in the reaction of H_2 with Br_2 to form HBr,

$$H_2 + Br_2 \longrightarrow 2\ HBr$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

for which the initial reaction rate (before very much HBr builds up) is

$$\text{rate} = k_{\text{obs}}[H_2][Br_2]^{1/2}$$

How can such a fractional power appear? One reaction mechanism that predicts this rate law is

$$Br_2 + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Br + Br + M \qquad \text{(fast equilibrium)}$$

$$Br + H_2 \xrightarrow{k_2} HBr + H \qquad \text{(slow)}$$

$$H + Br_2 \xrightarrow{k_3} HBr + Br \qquad \text{(fast)}$$

Here M stands for a second molecule that does not react but that supplies the energy to break up the bromine molecules. For such a mechanism the reaction rate is determined by the slow step:

$$\text{rate} = k_2[Br][H_2]$$

However, [Br] is fixed by the establishment of equilibrium in the first reaction,

$$\frac{[Br]^2}{[Br_2]} = K_1 = \frac{k_1}{k_{-1}}$$

so

$$[Br] = K_1^{1/2}[Br_2]^{1/2}$$

The rate expression predicted by this mechanism is thus

$$\text{rate} = k_2K_1^{1/2}[H_2][Br_2]^{1/2}$$

This is in accord with the observed fractional power in the rate law. On the other hand, the simple bimolecular mechanism

$$H_2 + Br_2 \xrightarrow{k_1} 2\ HBr \qquad \text{(slow)}$$

predicts a rate law:

$$\text{rate} = k_1[H_2][Br_2]$$

This disagrees with the observed rate law, so it can be ruled out as the major contributor to the measured rate.

This discussion shows that deducing a rate law from a proposed mechanism is relatively straightforward, but doing the reverse is much harder. In fact, several competing mechanisms often give rise to the same rate law, and only some independent type of measurement can distinguish between them. A proposed reaction mechanism cannot be proven to be correct if its predictions agree with an experimental rate law, but it can be proven wrong if its predictions disagree with the experimental results.

A classic example is the reaction

$$H_2 + I_2 \longrightarrow 2\ HI$$

for which the observed rate law is

$$\text{rate} = k_{\text{obs}}[H_2][I_2]$$

(Contrast this with the rate law already given for the analogous reaction of H_2 with Br_2.) This is one of the earliest and most extensively studied reactions in chemical kinetics, and until 1967 it was widely believed to occur as a one-step elementary

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

reaction. At that time J. H. Sullivan investigated the effect of illuminating the reacting sample with light, which splits some of the I_2 molecules into iodine atoms. If the mechanism we proposed for H_2 and Br_2 is correct here as well, the effect of the light on the reaction should be small because it leads only to a small decrease in the I_2 concentration.

Instead, Sullivan observed a dramatic *increase* in the rate of reaction under illumination, which could be explained only by the participation of iodine *atoms* in the reaction mechanism. One such mechanism is

$$I_2 + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} I + I + M \qquad \text{(fast equilibrium)}$$

$$H_2 + I + I \xrightarrow{k_2} 2\,HI \qquad \text{(slow)}$$

for which the rate law is

$$\text{rate} = k_2[H_2][I]^2 = k_2K_1[H_2][I_2]$$

This mechanism gives the same rate law that is observed experimentally, and it is consistent with the effect of light on the reaction. The other reaction mechanism also appears to contribute significantly to the overall rate.

This example illustrates the hazards of trying to determine reaction mechanisms from rate laws: several mechanisms can fit any given empirical rate law, and it is always possible that a new piece of information suggesting a different mechanism will be found. A number of experimental methods have been developed to investigate reaction mechanisms. Isotopic labelling has been used for nearly a century to trace the fates of individual atoms as they are converted from reactants into products. Time-resolved spectroscopic methods developed over the past 20 years or so have allowed us to identify transient intermediates present in extremely low concentrations with lifetimes as short as 10 femtoseconds (10^{-14} s), providing great insight into the mechanisms of chemical reactions occurring in environments that include low-density gases (atmospheric chemistry and the chemistry of interstellar space), solutions, the solid state (including geochemistry), and the biology of life processes.

The Steady-State Approximation

In some reaction mechanisms there is no single step that is much slower than the others, so the methods discussed so far cannot predict the rate law. In such cases we use the **steady-state approximation,** which states that the concentrations of reactive intermediates remain nearly constant through most of the reaction.

To illustrate this approximation, let's examine the mechanism proposed by F. A. Lindemann for the dissociation of molecules in the gas phase. A molecule such as N_2O_5 undergoes collisions with neighboring molecules M, where M can stand for another N_2O_5 molecule or for an inert gas such as argon. Through such collisions the N_2O_5 molecule can become excited (or activated) to a state indicated by $N_2O_5^*$:

$$N_2O_5(g) + M(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} N_2O_5^*(g) + M(g)$$

The reverse process, with rate constant k_{-1}, is also indicated because the activated molecule can be deactivated by collisions with other molecules. The second step is the unimolecular decomposition of $N_2O_5^*$:

$$N_2O_5^*(g) \xrightarrow{k_2} NO_3(g) + NO_2(g)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Subsequent reaction steps to form O_2 and NO_2 from NO_3 occur rapidly and do not affect the measured rate:

$$NO_3(g) + NO_2(g) \xrightarrow{k_3} NO(g) + NO_2(g) + O_2(g) \qquad \text{(fast)}$$

$$NO_3(g) + NO(g) \xrightarrow{k_4} 2\ NO_2(g) \qquad \text{(fast)}$$

The $N_2O_5^*$ is a reactive intermediate; it is produced at a rate $k_1[N_2O_5][M]$ from collisions of N_2O_5 molecules with other molecules and is lost at a rate $k_{-1}[N_2O_5^*][M]$ due to deactivation and at a rate $k_{-2}[N_2O_5^*][M]$ due to dissociation. The net rate of change of $[N_2O_5^*]$ is then

$$\frac{d[N_2O_5^*]}{dt} = k_1[N_2O_5][M] - k_{-1}[N_2O_5^*][M] - k_2[N_2O_5^*]$$

At the beginning of the reaction, $[N_2O_5^*] = 0$, but this concentration builds up after a short time to a small value. The steady-state approximation consists of the assumption that after this short time the rates of production and loss of $N_2O_5^*$ become equal, and

$$\frac{d[N_2O_5^*]}{dt} = 0$$

The steady-state concentration of $[N_2O_5^*]$ persists practically unchanged throughout most of the course of the reaction.

Setting the net rate of change of the $N_2O_5^*$ concentration to 0 gives

$$\frac{d[N_2O_5^*]}{dt} = 0 = k_1[N_2O_5][M] - k_{-1}[N_2O_5^*][M] - k_2[N_2O_5^*]$$

Solving for $[N_2O_5^*]$ gives

$$[N_2O_5^*](k_2 + k_{-1}[M]) = k_1[N_2O_5][M]$$

$$[N_2O_5^*] = \frac{k_1[N_2O_5][\mathbf{M}]}{k_2 + k_{-1}[M]}$$

The rate of the overall reaction $N_2O_5 \longrightarrow 2\ NO_2 + \frac{1}{2}\ O_2$ is

$$\text{rate} = \frac{1}{2}\frac{d[NO_2]}{dt} = k_2[N_2O_5^*] = \frac{k_1k_2[N_2O_5][M]}{k_2 + k_{-1}[M]}$$

This expression has two limiting cases:

1. *Low pressure* When [M] is small enough, $k_2 \gg k_{-1}[M]$ and we can use the approximation

$$\text{rate} = k_1[N_2O_5][M] \qquad \text{(second order)}$$

This same result would be found by assuming the first step to be rate-determining.

2. *High pressure* When [M] is large enough, $k_{-1}[M] \gg k_2$ and we can use the approximation

$$\text{rate} = \left(\frac{k_1}{k_{-1}}\right) k_2[N_2O_5] = K_1k_1[N_2O_5] \qquad \text{(first order)}$$

This same result would be found by assuming the second step to be rate-determining.

The steady-state approximation is a more general approach than those considered earlier and produces identical results under the limiting conditions defined

above. The steady-state approximation is invoked in many areas of chemical kinetics, an example of which is the kinetics of enzyme-catalyzed reactions discussed in Section 18.8.

Chain Reactions

A **chain reaction** proceeds through a series of elementary steps, some of which are repeated many times. Chain reactions have three stages: (1) **initiation,** in which two or more reactive intermediates are generated; (2) **propagation,** in which products are formed but reactive intermediates are continuously regenerated; and (3) **termination,** in which two intermediates combine to give a stable product.

An example of a chain reaction is the reaction of methane with fluorine to give CH_3F and HF:

$$CH_4(g) + F_2(g) \longrightarrow CH_3F(g) + HF(g)$$

Although in principle this reaction could occur through a one-step bimolecular process, that route turns out to be too slow to contribute significantly under normal reaction conditions. Instead, the mechanism involves a chain reaction of the following type:

$$CH_4(g) + F_2(g) \longrightarrow CH_3(g) + HF(g) + F(g) \quad \text{(initiation)}$$

$$CH_3(g) + F_2(g) \longrightarrow CH_3F(g) + F(g) \quad \text{(propagation)}$$

$$CH_4(g) + F(g) \longrightarrow CH_3(g) + HF(g) \quad \text{(propagation)}$$

$$CH_3(g) + F(g) + M(g) \longrightarrow CH_3F(g) + M(g) \quad \text{(termination)}$$

In the initiation step, two reactive intermediates (CH_3 and F) are produced. During the propagation steps, these intermediates are not used up while reactants (CH_4 and F_2) are being converted to products (CH_3F and HF). The propagation steps can be repeated again and again, until eventually two reactive intermediates come together in a termination step. As we see in Chapter 23, chain reactions are important in building up long-chain molecules called polymers.

The chain reaction just considered proceeds at a constant rate, because each propagation step both uses up and produces a reactive intermediate. The concentrations of the reactive intermediates remain approximately constant and are determined by the rates of chain initiation and termination. Another type of chain reaction is possible in which the number of reactive intermediates increases during one or more propagation steps. This is called a **branching chain reaction.** An example is the reaction of oxygen with hydrogen. The mechanism is complex and can be initiated in various ways, leading to the formation of several reactive intermediates such as O, H, and OH. Some propagation steps are of the type already seen for CH_4 and F_2, such as

$$OH(g) + H_2(g) \longrightarrow H_2O(g) + H(g)$$

in which one reactive intermediate (OH) is used up and one (H) is produced. Other propagation steps are branching:

$$H(g) + O_2(g) \longrightarrow OH(g) + O(g)$$

$$O(g) + H_2(g) \longrightarrow OH(g) + H(g)$$

In these steps, each reactive intermediate used up causes the generation of two others. This leads to rapid growth in the number of reactive species, speeding the rate further and possibly causing an explosion. Branching chain reactions are critical in the fission of uranium (see Chapter 19).

18.5 EFFECT OF TEMPERATURE ON REACTION RATES

The first four sections of this chapter describe the experimental determination of rate laws and their relation to assumed mechanisms for chemical reactions. Now we have to find out what determines the actual magnitudes of rate constants (either for elementary reactions or for overall rates of multistep reactions), and how temperature affects reaction rates. To consider these matters, it is necessary to connect molecular collision rates to the rates of chemical reactions. We limit the discussion to gas-phase reactions, for which the kinetic theory of Chapter 9 is applicable.

Gas-Phase Reaction Rate Constants

In Section 9.7, we applied the kinetic theory of gases to estimate the frequency of collisions between a particular molecule and other molecules in a gas. In Example 9.12, we calculated this frequency to be $4.1 \times 10^9\ s^{-1}$ under room conditions for a typical small molecule such as oxygen. If every collision led to reaction, the reaction would be practically complete in about 10^{-9} s. Some reactions do proceed at rates almost this high. An example is the bimolecular reaction between two CH_3 radicals to give ethane, C_2H_6,

$$2\ CH_3 \longrightarrow C_2H_6$$

for which the observed rate constant is $1 \times 10^{10}\ L\ mol^{-1}\ s^{-1}$. For initial pressure of CH_3 near 1 atm at 25°C, the concentration initially is about 0.04 M. The second-order integrated rate law from Section 18.2 predicts that the concentration would drop to 0.02 M after a period of 10^{-9} s. But, reaction rates that are much lower—by factors of 10^{12} or more—are common. The naive idea that "to collide is to react" clearly must be modified if we are to understand these lower rates.

We find a clue in the observed temperature dependence of reaction rate constants. The rates of many reactions increase extremely rapidly as temperature increases; typically a 10°C rise in temperature may double the rate. In 1889 Svante Arrhenius suggested that rate constants vary exponentially with inverse temperature,

$$k = Ae^{-E_a/RT} \qquad [18.5]$$

where E_a is a constant with dimensions of energy and A is a constant with the same dimensions as k. Taking the natural logarithm of this equation gives

$$\ln k = \ln A - \frac{E_a}{RT} \qquad [18.6]$$

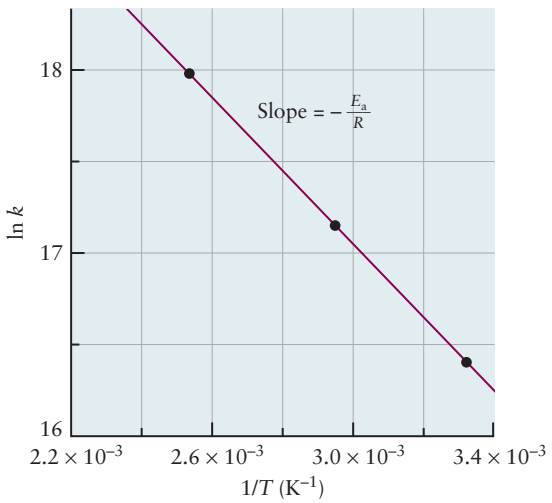

FIGURE 18.9 An Arrhenius plot of ln k against $1/T$ for the reaction of benzene vapor with oxygen atoms. An extrapolation to $1/T = 0$ gives the constant ln A from the intercept of this line.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

So a plot of ln k against $1/T$ should be a straight line with slope $-E_a/R$ and intercept ln A. Many rate constants do show just this kind of temperature dependence (Fig. 18.9).

EXAMPLE 18.8

The decomposition of hydroxylamine (NH_2OH) in the presence of oxygen follows the rate law

$$-\frac{d[NH_2OH]}{dt} = k_{obs}[NH_2OH][O_2]$$

where k_{obs} is 0.237×10^{-4} L mol^{-1} s^{-1} at 0°C and 2.64×10^{-4} L mol^{-1} s^{-1} at 25°C. Calculate E_a and the factor A for this reaction.

Solution

Let us write the Arrhenius equation at two different temperatures T_1 and T_2:

$$\ln k_1 = \ln A - \frac{E_a}{RT_1} \quad \text{and} \quad \ln k_2 = \ln A - \frac{E_a}{RT_2}$$

If the first equation is subtracted from the second, the term ln A cancels out, leaving

$$\ln k_2 - \ln k_1 = \ln \frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

which can be solved for E_a. In the present case, $T_1 = 273$ K and $T_2 = 298$ K; therefore,

$$\ln \frac{2.64 \times 10^{-4}}{0.237 \times 10^{-4}} = \frac{-E_a}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}}\left(\frac{1}{298 \text{ K}} - \frac{1}{273 \text{ K}}\right)$$

$$2.410 = \frac{E_a}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}} \ (3.07 \times 10^{-4} \text{ K}^{-1})$$

$$E_a = 6.52 \times 10^4 \text{ J mol}^{-1} = 65.2 \text{ kJ mol}^{-1}$$

Now that E_a is known, the constant A can be calculated by using data at either temperature. At 273 K,

$$\ln A = \ln k_1 + \frac{E_a}{RT}$$

$$= \ln(0.237 \times 10^{-4}) + \frac{6.52 \times 10^4 \text{ J mol}^{-1}}{(8.315 \text{ J K}^{-1} \text{ mol}^{-1})(273 \text{ K})}$$

$$= -10.65 + 28.73 = 18.08$$

$$A = e^{18.08} = 7.1 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-}$$

We could determine E_a and A more accurately from measurements at a series of temperatures and a least-squares fit to a plot such as that in Figure 18.9.

Related Problems: 35, 36

Arrhenius believed that for molecules to react upon collision they must become "activated," so the parameter E_a came to be known as the **activation energy.** His ideas were refined by later scientists. In 1915 A. Marcelin pointed out that, while molecules make many collisions, not all collisions are reactive. Only those collisions for which the collision energy (i.e., the relative translational kinetic energy of the colliding molecules) exceeds some critical energy result in reaction. Thus, Marcelin gave a dynamic interpretation for the activation energy inferred from reaction rates.

The strong temperature dependence of rate constants, described by the Arrhenius law, is explained by the Maxwell–Boltzmann distribution of molecular

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

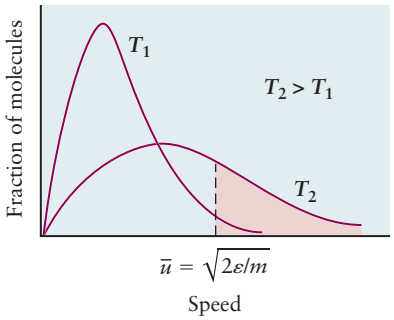

FIGURE 18.10 The Maxwell–Boltzmann distribution of molecular kinetic energies, ε, plotted as a function of the average speed $\bar{u}$, showing the effect of temperature on the fraction of molecules having large enough kinetic energies to react. This figure shows only translational energy; internal vibrational and rotational energy also promote reactions.

energies (Fig. 18.10). If E_a is the critical relative collision energy required for a pair of molecules to react, only a small fraction of the molecules will have at least this much energy at sufficiently low temperature. This fraction corresponds to the area under the Maxwell–Boltzmann distribution curve between E_a and ∞. As the temperature increases, the distribution function spreads out to include higher energies. The fraction of molecules having more than the critical energy E_a increases exponentially as $\exp(-E_a/RT)$, in agreement with Arrhenius's law and experiment. The reaction rate is then proportional to $\exp(-E_a/RT)$. So, both the strong temperature dependence and the order of magnitude of the experimental rate constants are explained by the kinetic theory of gases.

The Reaction Coordinate and the Activated Complex

Why should there be a critical collision energy E_a for reaction to occur between two molecules? To understand this, let's consider the physical analogy of marbles rolling on a hilly surface. As a marble rolls up a hill, its potential energy increases and its kinetic energy decreases; it slows down as it climbs the hill. If it can reach the top of the hill, it will fall down the other side, whereupon its kinetic energy will increase and its potential energy will decrease. Not every marble will make it over the hill. If its initial speed, and therefore kinetic energy, is too small, a marble will roll only part way up and then fall back down. Only those marbles with initial kinetic energy higher than some critical threshold will pass over the hill.

We can use this physical model to describe molecular collisions and reactions. As two reactant molecules, atoms, or ions approach each other along a **reaction path,** their potential energy increases as the bonds within them distort. At some maximum potential energy the collision partners become connected in an unstable entity called the **activated complex** or **transition state.** The activated complex is the cross-over stage where the smooth ascent in potential energy as the reactants come together becomes a smooth descent as the product molecules separate. As in the case of the marbles, not all pairs of colliding bodies react. Only those pairs with sufficient kinetic energy can stretch bonds and rearrange atoms enough to become the transition state through which reactants become products. If the barrier to reach the transition state is too high, almost all colliding pairs of reactant molecules separate from each other without reacting. The height of the barrier is close to the measured activation energy for the reaction.

Figure 18.11 shows a graph of the potential energy versus position along the reaction path for the reaction

$$NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g)$$

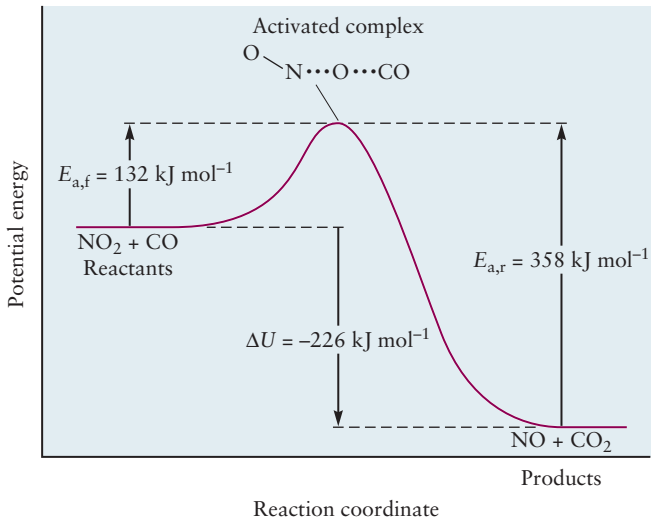

FIGURE 18.11 The energy profile along the reaction coordinate for the reaction $NO_2 + CO \longrightarrow NO + CO_2$. This direct reaction dominates the kinetics at high temperatures (above about 500 K).

Two activation energies are shown in Figure 18.11: $E_{a,f}$ is the activation energy for the forward reaction, and $E_{a,r}$ is that for the reverse reaction, in which NO takes an oxygen atom from CO_2 to form NO_2 and CO. The difference between the two is ΔU, the change in internal energy of the chemical reaction:

$$\Delta U = E_{a,f} - E_{a,r}$$

Whereas ΔU is a thermodynamic quantity that can be obtained from calorimetric measurements, $E_{a,f}$ and $E_{a,r}$ must be found from the temperature dependence of the rate constants for the forward and reverse reactions. In this reaction the forward and reverse activation energies are 132 and 358 kJ mol^{-1}, respectively, and ΔU from thermodynamics is -226 kJ mol^{-1}.

The activation energy for an elementary reaction is always positive—although in some cases it can be quite small—because there is always some energy barrier to surmount. Rates of elementary reactions therefore increase with increasing temperature. This is not necessarily true for rates of overall reactions consisting of more than one elementary reaction. These sometimes have "negative activation energies," which means that the overall reaction rate is slower at higher temperature. How can this be? Let's examine a specific example: the reaction of NO with oxygen

$$2\ NO(g) + O_2(g) \longrightarrow 2\ NO_2(g)$$

has the observed rate law

$$\text{rate} = k_{obs}[NO]^2[O_2]$$

where k_{obs} *decreases* with increasing temperature. In Section 18.4 we accounted for this rate expression with a two-step mechanism. The first step is a rapid equilibrium (with equilibrium constant K_1) between two NO molecules and their dimer, N_2O_2. The second step is the slow reaction (with rate constant k_2) of N_2O_2 with O_2 to form products. The overall rate constant is therefore the product of k_2 and K_1. Whereas k_2 is the rate constant for an elementary reaction, and so increases with increasing temperature, K_1 is an *equilibrium* constant and may decrease as temperature increases. Provided the reaction is sufficiently exothermic (as it is in this case), K_1 will decrease so rapidly with increasing temperature that the product k_2K_1 will decrease as well. This combination of effects explains the observation of "negative activation energies" in some overall chemical reactions.

18.6 MOLECULAR THEORIES OF ELEMENTARY REACTIONS

The kinetic theory of gases, introduced in Section 9.5, is the starting point for the development of microscopic theories of reaction rates, a field of study that is called **reaction dynamics.** We introduce you to several different theories and experimental approaches to the study of reaction dynamics in this section to provide you with insight into the nature of chemical reactions at the molecular level. These include collision theory, built upon the kinetic theory of gases; transition state theory, which is based in statistical mechanics; and the experimental technique that uses molecular beams to probe the details of reactive collisions between single pairs of molecules.

Collision Theory

Collision theory provides a method for calculating rate constants for bimolecular reactions based upon the properties of the reacting molecules that influence the probabilities of reactive encounters; these include size, kinetic energy, and relative

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

orientation. Let's begin by recalling the calculation of Z_1, the rate of collisions between a particular A molecule and the other A molecules in a gas (Section 9.7). The equation just before Equation 9.26 gives

$$Z_1 = \sqrt{2}\pi d^2 \bar{u}\left(\frac{N_A}{V}\right) = 4\sigma_c\sqrt{\frac{k_B T}{\pi m}}\left(\frac{N_A}{V}\right) \qquad [18.7]$$

In Equation 18.7, the **collision cross section** $\sigma_c = \pi d^2$ is the geometric cross section of a sphere that represents the "size" of a molecule. Recall that the factor of $\sqrt{2}$ arises because we consider only the relative motions of the molecules. We incorporate this factor in all of the definitions and equations that follow so that the quantities u, v, and ε represent relative speeds, velocities, and energies, respectively. Collision rates defined by Equation 18.7 are often called **hard sphere** collision rates; to touch is to collide. They can be quite large for gases at 1 atm and 298 K; Z_1 for N_2 is about $5 \times 10^9\ s^{-1}$ (Example 9.12).

We can generalize this result to the case of a single A molecule colliding with a collection of B molecules by defining $d = \frac{1}{2}(d_A + d_B)$ as the sum of the molecular radii (see Fig. 18.12), and substituting $\mu = m_A m_B/(m_A + m_B)$, the reduced mass for m in Equation 18.7. The reduced mass is always used when describing the relative motions of two particles (see footnote on p. 195). The total collision rate (sometimes called the collision frequency) *per unit volume* in a mixture containing both A and B molecules is calculated by multiplying the single molecule collision rate by the number of A molecules and dividing by the volume to get

$$Z_{AB} = \sigma_c\sqrt{\frac{8k_B T}{\pi\mu}}\left(\frac{N_A}{V}\right)\left(\frac{N_B}{V}\right)$$

Our goal is to arrive at an expression for the bimolecular rate constant k_{AB} given by Equation 18.14 (see later). Students may skip the following derivation and focus on the result and interpretation. Key steps in the derivation include:

1. Associating the rate constant with a reactive cross section and the average relative speed by comparing the left hand side of the preceding equation with the macroscopic second order rate constant expression rate = $k_r(N_A/V)(N_B/V)$ to get $k_r = \sigma_r \bar{u}$.
2. Defining an energy-dependent **reactive cross section** $\sigma_r(\varepsilon)$ to account for the fact that only those collisions that meet a specific energy criterion will lead to reaction. Reactive cross sections are generally smaller than hard sphere cross sections because not every collision is effective for reaction.
3. Asserting that there is an energy threshold that determines whether a particular collision leads to reaction or not; those collisions with relative energies above this threshold are reactive and those with relative energies below this threshold are not. We find the threshold energy and determine the functional dependence

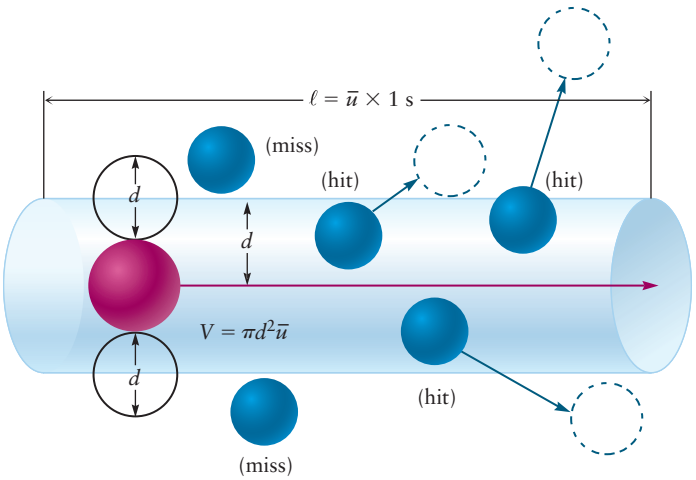

FIGURE 18.12 Molecule A (red) sweeps out a cylinder of volume ($\pi d^2 \bar{u}$ per second, where $d = 1/2(d_A + d_B)$. It will collide with all of the B molecules (blue) whose centers lie within the cylinder.

of $\sigma_r(\varepsilon)$ on ε by analyzing the component of the relative kinetic energy directed along the line of centers.

4. Recognizing that there is a distribution of relative kinetic energies given by the Maxwell–Boltzmann distribution $f(\varepsilon)$ and integrating the energy-dependent reaction probability over all possible relative kinetic energies weighted by that distribution.

We begin with the biomolecular rate equation introduced above and indicate our intention to integrate over the energy-dependent factors as follows.

$$\text{rate}(\varepsilon) = k_r\left(\frac{N_A}{V}\right)\left(\frac{N_B}{V}\right) = \sigma_r(\varepsilon)\bar{u}\left(\frac{N_A}{V}\right)\left(\frac{N_B}{V}\right) = \sigma_r(\varepsilon)\left(\frac{2\varepsilon}{\mu}\right)^{1/2}\left(\frac{N_A}{V}\right)\left(\frac{N_B}{V}\right) \quad [18.8]$$

$$\text{total rate} = \left(\int_0^\infty \sigma_r(\varepsilon)\left(\frac{2\varepsilon}{\mu}\right)^{1/2} f(\varepsilon)\, d\varepsilon\right)\left(\frac{N_A}{V}\right)\left(\frac{N_B}{V}\right)$$

from which we see that the rate constant is given by

$$k_r = \int_0^\infty \sigma_r(\varepsilon)\left(\frac{2\varepsilon}{\mu}\right)^{1/2} f(\varepsilon)d\varepsilon \quad [18.9]$$

The next step is to relate $f(\varepsilon)d\varepsilon$ to $f(u)du$, where $f(u)$ is the Maxwell–Boltzmann distribution function of Equation 9.17.

$$f(u) = 4\pi\left(\frac{m}{2\pi k_B T}\right)^{3/2} u^2 \exp(-mu^2/2k_B T) \quad [18.10]$$

We make the following substitutions into Equation 18.10

$$\varepsilon = \tfrac{1}{2}\mu u^2,\ u^2 = \left(\frac{2\varepsilon}{\mu}\right),\ du = d\varepsilon/(2\mu\varepsilon)^{1/2}$$

which allows us to relate $f(\mu)du$, and $f(\varepsilon)d\varepsilon$ as follows.

$$f(u)du = 4\pi\left(\frac{\mu}{2\pi k_B T}\right)^{3/2}\frac{2\varepsilon}{\mu}\exp(-\varepsilon/k_B T)\frac{d\varepsilon}{(2\mu\varepsilon)^{1/2}}$$

$$= 2\pi\left(\frac{1}{\pi k_B T}\right)^{3/2}\varepsilon^{1/2}\exp(-\varepsilon/k_B T)d\varepsilon = f(\varepsilon)d\varepsilon$$

Substituting this result into the integral in Equation 18.9 gives

$$k_r = 2\pi\left(\frac{1}{\pi k_B T}\right)^{3/2}\int_0^\infty \sigma_r(\varepsilon)\left(\frac{2\varepsilon}{\mu}\right)^{1/2}\varepsilon^{1/2}\exp(-\varepsilon/k_B T)\ d\varepsilon$$

$$= \left(\frac{8}{\pi\mu k_B T}\right)^{1/2}\left(\frac{1}{k_B T}\right)\int_0^\infty \varepsilon\sigma_r(\varepsilon)\exp(-\varepsilon/k_B T)\ d\varepsilon \quad [18.11]$$

We develop a model to determine the functional dependence of σ_r on ε by asserting that only the relative velocity directed along the line of centers is effective in activating a reaction. Figure 18.13 shows the molecules A and B represented as hard spheres separated by the distance d. The velocity of A *relative* to B is given by the vector v_A. We draw a line parallel to v_A that goes through the center of B; the distance b between the two parallel lines is called the **impact parameter**. We find the component of the velocity directed along the line of centers, v_{AB}, using the geometric construction illustrated in Figure 18.13. $v_{AB} = v_A\cos\theta$ and $\cos\theta$ can be related to the impact parameter b and the distance d as follows. Let d be the hypotenuse of a right triangle with a vertical side of height b. Then $\sin\theta = b/d$

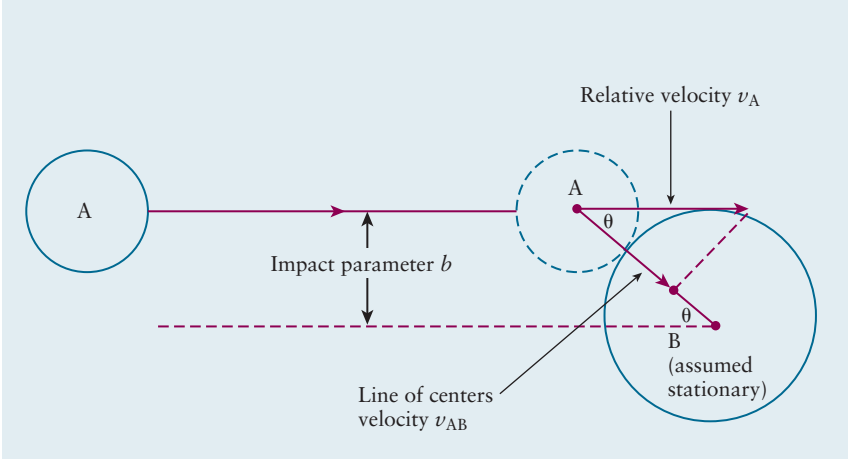

FIGURE 18.13 Molecule A is moving towards molecule B with a relative velocity given by the velocity vector v_A shown. The distance between the parallel lines is called the impact parameter *b*.

and we use the trigonometric identity $\sin^2 + \cos^2 = 1$ to get $\cos\theta = [(d^2 - b^2)/d^2]^{1/2}$. Substituting this result to solve for v_{AB} gives

$$v_{AB} = v_A \cos\theta = v_A[d^2 - b^2)/d^2]^{1/2}$$

from which we get

$$\varepsilon_{AB} = \varepsilon[d^2 - b^2)/d^2] \qquad [18.12]$$

by squaring both sides of the previous expression and multiplying by μ.

Let's consider what happens as we vary the impact parameter. Head-on collisions, for which $b = 0$, must certainly be most likely to lead to reaction. The reaction probability falls off with increasing b until the probability goes to zero; no products are formed. Let's define b_o as the largest value of b that results in reaction and investigate the connection between the impact parameter and the relative energy by rearranging Equation 18.12 to get

$$b_o^2 = \left(1 - \frac{\varepsilon_a}{\varepsilon}\right) d^2$$

in which ε_a is the energy associated with b_o. ε_a is the specific energy that corresponds to the largest impact parameter that leads to reaction. Smaller values of ε_a do not lead to reaction. We multiply both sides of the equation by π and identify $\sigma_r(\varepsilon) = \pi b_o^2$ and $\sigma_c = \pi d^2$ to get

$$\sigma_r(\varepsilon) = \sigma_c \left(1 - \frac{\varepsilon_a}{\varepsilon}\right) \qquad [18.13]$$

Let's examine the behavior of $\sigma_r(\varepsilon)$ as a function of ε. The reactive cross section $\sigma_r(\varepsilon)$, calculated using Equation 18.13, is negative for all values of $\varepsilon < \varepsilon_a$; these solutions are incompatible with the physical interpretation of the cross section as an area and must be rejected. $\sigma_r(\varepsilon) = 0$ when $\varepsilon = \varepsilon_a$ and becomes positive when $\varepsilon > \varepsilon_a$, so we identify ε_a as the threshold energy. $\sigma_r(\varepsilon)$ is small near the threshold energy, increases with increasing ε and finally saturates at $\sigma_r(\varepsilon) = \sigma_c$, the hard sphere cross section, when ε becomes much larger than ε_a, as shown in Figure 18.14.

We interpret this behavior as follows. The cross section is very small at low energy because the energy delivered along the line of centers is small. The reactive, or effective, cross section, interpreted as an area, increases with increasing ε because more energy is being made available along the line of centers. The reactive cross section saturates at the hard sphere value, which means that every collision leads to reaction.

We are now in a position to derive an expression for the rate constant by substituting Equation 18.13 into the integral in Equation 18.11 and integrating to get

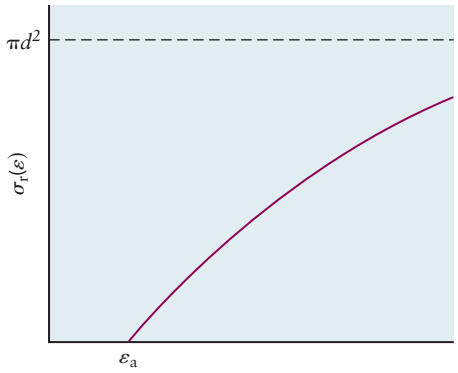

FIGURE 18.14 Dependence of the reactive cross section $\sigma_r(\varepsilon)$ on the relative translational energy ε.

$$\int_0^\infty \varepsilon\sigma_r(\varepsilon)\exp(-\varepsilon/k_BT)\,d\varepsilon = \sigma_c\int_0^\infty \varepsilon\left(1-\frac{\varepsilon_a}{\varepsilon}\right)\exp(-\varepsilon/k_BT)\,d\varepsilon$$
$$= (k_BT)\,\sigma_c\,\exp(-\varepsilon_a/k_BT)$$

We arrive at our final goal by substituting this result into Equation 18.11, giving

$$k_r = \left(\frac{8}{\pi\mu k_BT}\right)^{1/2}\left(\frac{1}{k_BT}\right)(k_BT)^2\,\sigma_c\,\exp(-\varepsilon_a/k_BT)$$
$$= \sigma_c\left(\frac{8k_BT}{\pi\mu}\right)^{1/2}\exp(-\varepsilon_a/k_BT) \qquad [18.14]$$

which expresses the temperature-dependent rate constant in terms of molecular parameters. The rate constant depends upon the rate of collisions (which depends upon both the collision cross section and the mean relative speed), and the probability that a particular collision has sufficient energy directed along the line of centers to cause reaction. Comparing this expression with the empirical Arrhenius equation provides a physical rationale for the form of the Arrhenius equation and an interpretation for each of its factors. ε_a is a threshold energy, below which no reaction occurs. As temperature increases, the relative energy of the colliding molecules increases, more collisions overcome the energy threshold, and the reaction rate increases. Identifying the Arrhenius pre-exponential factor A with the first two factors in Equation 18.14 suggests that it can be interpreted as a collision rate. It also shows that a more realistic form of the Arrhenius equation should have a temperature-dependent pre-exponential factor that reflects the $\sqrt{T}$ dependence of molecular speeds on temperature. This rather weak temperature dependence is generally overwhelmed by the much stronger temperature dependence of the exponential factor, but it is observed experimentally and must be accounted for in accurate kinetic studies.

How well does this simple theory agree with experiment? We obtain experimental activation energies and pre-exponential factors by fitting gas-phase elementary reaction rate data to the Arrhenius form. The value of A can be compared with theory, once we estimate the molecular diameter to determine the hard sphere cross section. For the elementary reaction

$$2\text{NOCl}(g) \longrightarrow 2\text{ NO}(g) + \text{Cl}_2(g)$$

the measured rate constant is 0.16 times the calculated rate constant. This result indicates that not all collisions lead to reaction, even if the molecules have sufficient relative kinetic energy. What other effect have we overlooked? The relative orientations of the colliding molecules should certainly play a role in determining whether a particular collision results in a reaction. It seems obvious from the models shown

in Figure 18.15 that the most favorable orientation is the one in which the chlorine ends of the two NOCl molecules collide head on. We improve on the predictions of collision theory by multiplying by a **steric factor** P (0.16 for this reaction) to account for the fact that only a fraction of the collisions occur with the proper orientation to lead to reaction. The steric factor is an empirical correction that has to be identified by comparing results of the simple theory with experimental data. It can be predicted in more advanced theories, but only for especially simple reactions.

Steric factors for a number of bimolecular reactions are given in Table 18.1; they are simply the ratios of the measured rate constants to those predicted using the hard-sphere collision rates for each reaction. These data show some interesting features. P generally decreases down the series as the molecules become progressively more complex. There are a larger number of possible relative orientations for more complex molecules, which means that a smaller fraction of those relative orientations will be optimal. The unusually large cross section for the reaction $K + Br_2 \longrightarrow KBr + Br$ is quite interesting; it appears that the molecules react *before* they collide, because the cross section is *larger* than the hard-sphere cross section. This result is explained by the harpoon mechanism mentioned in Section 3.8. The highly electronegative Br atoms in Br_2 pull an electron away from K, which has a very low ionization energy. The strong Coulomb attraction between the ions pulls them together to initiate the reaction. The electron is the harpoon, being fired from the potassium atom to draw in the bromine molecule.

Transition State Theory

The goal of transition state theory (also called activated complex theory) is to provide an approach to the calculation of rate constants from molecular properties that is more sophisticated than collision theory but not intractable. A full discussion of the theory is beyond the scope of this textbook, but an outline of the general approach used and the thermodynamic viewpoint developed provides additional

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

insight into the molecular details of chemical reaction dynamics. Interpreting thermodynamic driving forces in terms of molecular structure and motion has greatly enhanced our understanding of the rates and mechanisms of chemical reactions of interest in chemistry and biology. We illustrate this point of view in our discussion of the mechanisms of enzyme catalysis in Section 18.8.

Transition state theory postulates the existence of an **activated complex,** as shown in Figure 18.11, for example, which is the configuration of atoms at the highest point on the potential energy function that describes the passage from reactants to products. The terms *transition state* and *activated complex* are often used interchangeably but we find it helpful to refer to the geometric configuration of the atoms as the activated complex and the location of that configuration on a potential energy diagram as the transition state. The activated complex is assumed to exist as if it were in equilibrium with the reactants and the theory focuses on calculating the rate at which the activated complex passes through the transition state to form products. The equilibrium constant is calculated using the methods of statistical thermodynamics in which all of the motions of the molecules are considered separately and explicitly, particularly the rotational and vibrational motions. Motion though the transition state is imagined to proceed along one set of displacements associated with a particular molecular vibration. The simplest situation to imagine is the reaction A + BC → products, in which the relevant mode is one in which the A—B and B—C bonds vibrate out of phase with respect to one another (an antisymmetric stretch, see Section 20.4). We imagine the frequency of that mode decreasing as the reaction proceeds with the vibrational energy stored in the A—B bond being transformed into the translational kinetic energy of the separated products. Reaction rates predicted using transition state theory are often expressed by the Eyring formula:

$$k_r = \kappa \frac{k_B T}{h} K^\dagger$$

in which κ(the transmission coefficient) measures the probability that the system will proceed through the transition state and $k_B T/h$ is the rate at which the activated complex dissociates to form products. $k_B T/h$ is of the order $5 \times 10^{12}\ s^{-1}$ at 300 K, which is a useful number to remember when estimating reaction rates using transition state theory.

The thermodynamic formulation of transition state theory is more useful than the method just described because it is very difficult to calculate equilibrium constants involving activated complexes. We substitute $\exp(-\Delta G^\dagger/RT)$ for $K^\dagger$ in the preceding expression to get

$$\begin{aligned} k_r &= \kappa \frac{k_B T}{h} \exp(-\Delta G^\dagger/RT) \\ &= \kappa \frac{k_B T}{h} \exp(-\Delta H^\dagger/RT) \exp(\Delta S^\dagger/R) \end{aligned}$$

which we compare to the Arrhenius equation

$$k_r = A \exp(-E_a/RT)$$

Transition state theory provides some additional insight into the factors that govern activation. The Arrhenius activation energy E_a may now be expressed as the sum of two separate contributions, ΔH, an activation enthalpy, and ΔS, an activation entropy, and we associate $\kappa(k_B T/h)$ with the pre-exponential factor A. Although it is possible in principle, and sometimes in practice, to calculate enthalpies and entropies of activation, the real utility of this approach is that it provides us with a conceptual framework from which to analyze the driving forces for particular chemical reactions from a molecular point of view. This approach is extremely useful in helping to understand patterns of reactivity in complex systems like enzymes, for example, and it has been adopted widely for that purpose, as we illustrate briefly in Section 18.8.

Isotope Effects in Chemical Kinetics

Isotopes are widely used as tracers in kinetics to help determine reaction mechanisms, as discussed in Section 18.4. Isotopic substitution of the lighter elements in molecules also leads to rather dramatic effects on the rates of chemical reactions that have important ramifications in a number of fields of science. Some plants, for example, preferentially utilize $^{12}CO_2$ in photosynthesis, and the ratio of the various carbon isotopes measured in materials derived from plants can be used to identify their sources. As discussed in more detail in Section 20.6, the ratio of $^{12}CO_2$ to the heavier isotopes in atmospheric CO_2 identifies fossil fuels as the source of the recent increases in the concentrations of this greenhouse gas. Kinetic isotope effects have a purely quantum mechanical origin. They arise because the zero-point energy of the heavier isotopes is less than the zero-point energy of the lighter isotopes, producing an increase in activation energies and a decrease in reaction rates.

The physical origin of kinetic isotope effects is most easily understood by examining a potential energy diagram like that shown in Figure 18.16. The largest effects observed occur for the high-frequency stretching motions of X—H bonds, where X is typically one of the main group elements important in organic chemistry, like carbon, nitrogen, and oxygen. We have drawn this diagram in a slightly different way than those in earlier figures to emphasize the fact that both the reactants and the products have potential energy diagrams, like those introduced in Chapter 3, that describe their bond lengths, dissociation energies, and vibrational frequencies (see Section 20.3). Kinetic isotope effects are considered **primary** when the isotope involved is one of the atoms in a bond and **secondary** when it is in an adjacent bond; the former are generally much larger than the latter, which are nevertheless useful in mechanistic studies. We typically calculate the *maximum* primary kinetic isotope effect by assuming that the zero-point energy of the relevant vibration in the activated complex is identical for both isotopes and it is only the difference in the zero-point energies in the reactants that matters. Let's use the C—H stretching vibration as an example and calculate the kinetic isotope effect that results from deuterium substitution using the Arrhenius equation. We label the rate constants and activation energies associated with the C—H bond and the C—D bond as $k_H(T)$, $E_{a,H}$ and $k_D(T)$, $E_{a,D}$, respectively, identifying the energy difference between the minimum of the potential energy well for the reactants and the maximum in the potential energy curve for the activated complex simply as E. The activation energies are then given by $E_{a,H} = E - \frac{1}{2}h\nu_{CH}$ and $E_{a,D} = E - \frac{1}{2}h\nu_{CD}$. Substituting these values into the Arrhenius equation and taking the ratios of the rate constants gives

$$\frac{k_H(T)}{k_D(T)} = \frac{A\exp(-E_{a,H}/RT)}{A\exp(-E_{a,D}/RT)} = \frac{\exp[(-E + \frac{1}{2}h\nu_{CH})/RT]}{\exp[(-E + \frac{1}{2}h\nu_{CD})/RT]}$$

$$= \exp[\tfrac{1}{2}(h\nu_{CH} - h\nu_{CD})]/RT$$

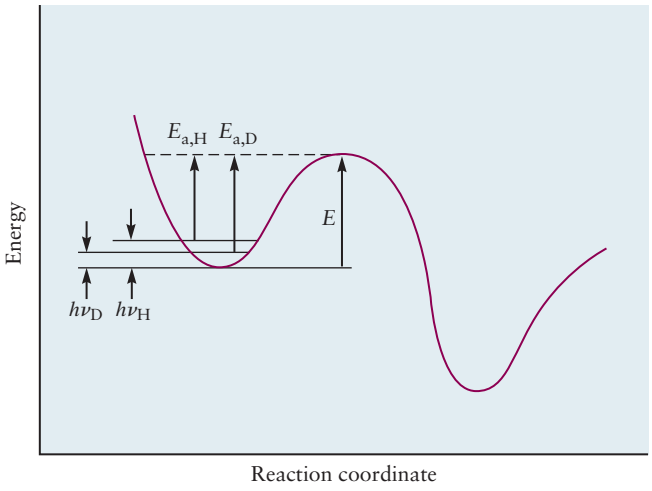

FIGURE 18.16 Energy profiles along a C—H bond reaction coordinate showing the origin of the primary kinetic isotope effect. The zero-point vibrational energy of the C—D bond is less than the zero-point vibrational energy of the C—H bond, which leads to an increase in the activation energy E_a for reactions that involve breaking C—D bonds.

We can calculate the reduction in rate expected when deuterium is substituted for hydrogen in a C—H bond using vibrational frequencies measured by infrared spectroscopy (see Section 20.3) and converting them into vibrational energies using $E = h\nu$. Typical energies for C—H stretching vibrations are about 36 kJ mol^{-1} and those for C—D vibrations are about 25 kJ mol^{-1}, respectively, giving a ratio $k(D)/k(H) = 0.12$ at 300 K.

Measuring the effect of deuterium substitution on the rates of organic reactions provides insight into reaction mechanisms. Experimental kinetic isotope effects in the range 5 to 10 near room temperature or above strongly imply C—H bond breaking at the labeled carbon atom. Secondary kinetic isotope effects involving C—H bond breaking are smaller, but measurable (around 1.5) and point to the role of the increased reduced mass of a functional group adjacent to the carbon atom undergoing reaction.

Molecular Beams

The kinetics experiments described thus far are all carried out by varying the macroscopic properties of the system, such as reactant concentrations and temperature. This approach necessarily averages over the details of individual reactive encounters that depend on particular molecular details such as the distribution of energy among the various modes of the reactants (see Section 12.8) and their relative orientations when they collide with one another. Studying reactions in crossed molecular beams provides a powerful alternative that allows us to investigate the details of chemical reactions at the molecular level. A crossed molecular beam apparatus comprises an ultrahigh vacuum chamber, collimated sources of molecules with well-defined kinetic energies, internal energies, and orientations in space that intersect and react, and one or more detectors that identify the reaction products and characterize their energy distributions as a function of position in three dimensions (see Fig. 18.17).

This apparatus allows the reactant molecules to be prepared in highly selective states. A velocity selector located between the beam source and the collision region (see Fig. 9.13) introduces only those molecules whose velocities fall within a small range. This method allows for much greater control over relative energies than can be achieved simply by controlling the temperature in a macroscopic kinetics experiment. Electric and magnetic fields or laser radiation can be applied to select reactants according to how rapidly they rotate and vibrate. The velocity of products can be measured, their angular distribution relative to the directions of the initial beams can be determined, and their vibration and rotation energies can be determined. All this information allows a much more detailed examination of the way in which molecules collide and react. For example, if the activated complex rotates

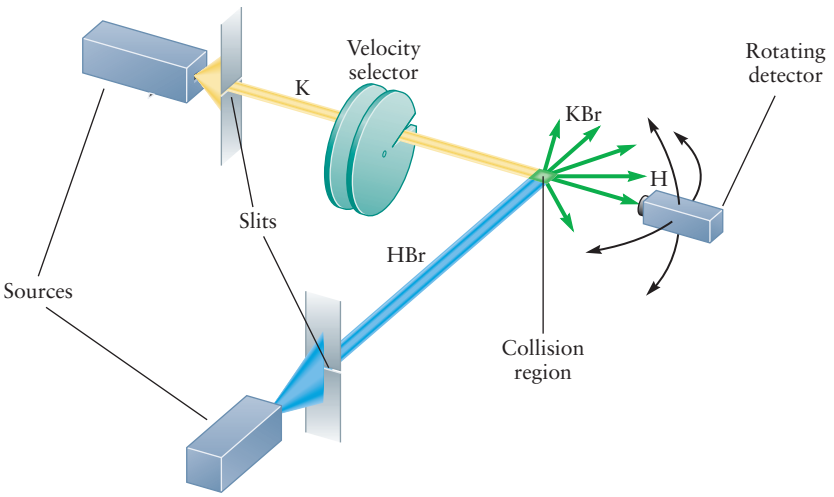

FIGURE 18.17 Diagram of a crossed molecular beam experiment. The reaction being studied is K + HBr → KBr + H. The curved arrows on the right side of the figure represent rotation of the detector in the vertical and horizontal planes.

many times before it finally breaks up into products, the angular distribution of products should be uniform. But if it breaks up before it has a chance to rotate, the angular distribution of products should be very nonuniform and should depend on the directions of the original beams. This type of measurement gives information on the lifetime of an activated complex.

Molecular beams are limited to reactions that are carried out in a vacuum, where well-defined beams of reactant molecules can be prepared. This limits their application to gas-phase reactions and to reactions of gaseous molecules with solid surfaces. Molecular beam methods cannot be used to study kinetics in liquid solvents. The detailed information they provide for gas–gas and gas–surface reactions allows precise testing of models and theories for the dynamics of these classes of reactions.

18.7 REACTIONS IN SOLUTION

Reactions in solution are much more complicated to describe than their gas-phase counterparts because the transport mechanism in solutions is much different. Molecules in the gas phase travel in straight lines between collisions, whereas solute molecules in solution are continually being bounced around by collisions with solvent molecules that lead to transport by diffusion. Collisions between reactants in solution occur much less frequently than for those in the gas phase, but the reactants may be bound together by a "cage" of solvent molecules for sufficiently long periods that they can acquire enough energy through collisions with the solvent to react. We can use the steady-state approximation to help understand the process.

Consider the two-step sequence

$$\mathrm{A} + \mathrm{B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{AB}$$

$$\mathrm{AB} \xrightarrow{k_2} \text{products}$$

We invoke the steady-state approximation to calculate the concentration of the intermediate AB, from which we can calculate the rate of the overall reaction as follows.

$$\text{rate} = k_2[\mathrm{AB}]$$

$$\frac{d[\mathrm{AB}]}{dt} = k_1[\mathrm{A}][\mathrm{B}] - k_{-1}[\mathrm{AB}] - k_2[\mathrm{AB}] = 0$$

$$[\mathrm{AB}] = \frac{k_1[\mathrm{A}][\mathrm{B}]}{k_{-1} + k_2}$$

$$\text{rate} = k_2[\mathrm{AB}] = \frac{k_1 k_2[\mathrm{A}][\mathrm{B}]}{k_{-1} + k_2}$$

Let's investigate the limits $k_2 >> k_{-1}$ and $k_2 < k_{-1}$, respectively. The overall rate in the former case is given by

$$\text{rate} = k_1[\mathrm{A}][\mathrm{B}]$$

and if k_1 is limited by the rate at which the reactants encounter one another by diffusion we call the reaction **diffusion-controlled** with a rate constant conventionally called k_d. If the rate constant for the second step is slower than that of the first step and equilibrium is established in the first step, then the rate expression becomes

$$\text{rate} = k_2 K_1$$

where K_1 is the equilibrium constant for the first reaction in the series. A slow second step implies a large activation energy, so reactions of this type are often called **activation-energy-controlled.**

A simple model for diffusion-controlled reactions was constructed by M. V. Smoluchowski in 1916, shortly after Einstein presented his model of Brownian motion. The idea is that molecules diffuse toward one another with mean-square displacements given by the formula

$$\overline{(\Delta r)^2} = 6Dt$$

where D is the diffusion constant in units $m^2\ s^{-1}$. Typical values for diffusion constants of small molecules in solution are of the order of $10^{-9}\ m^2\ s^{-1}$, which means that a small molecule will travel about 10 μm in a second, in contrast to molecular speeds in gases that are the order of a few hundred meters per second near room temperature. Smoluchowski's model assumes that a number of B molecules, for example, are diffusing toward a stationary molecule A and solves the radial diffusion equation to find the rate at which B molecules arrive at A. Reaction is assumed to occur when the molecules (represented as hard spheres of radii r_A and r_B) collide, being separated by a distance $R^* = (r_A + r_B)$. There is no reason to prefer B over A for the species that is diffusing, so an effective diffusion constant $D = D_A + D_B$ is used instead. The final result is

$$k_d = 4\pi R^* D N_A$$

where N_A is Avogadro's number, not the number density of A molecules. Bimolecular rate constants have units $L\ mol^{-1}\ s^{-1}$, from which we can extract a typical value for R^* by substituting $10^{-9}\ m^2\ s^{-1}$ for the diffusion constant in the above expression. Typical values are of the order of 100 nm. Diffusion sets an upper limit for the rates of many solution-phase reactions, including enzyme-catalyzed reactions (see Section 18.8). Enzymes with the greatest catalytic efficiencies cannot convert substrates into products any faster than they encounter them. Enzymes whose rates are diffusion-limited are said to have reached "catalytic perfection."

18.8 CATALYSIS

A **catalyst** is a substance that takes part in a chemical reaction and speeds up the rate but undergoes no permanent chemical change itself. Catalysts therefore do not appear in the overall balanced chemical equation. But their presence very much affects the rate law, modifying and speeding existing pathways or, more commonly, providing completely new pathways by which a reaction can occur. Catalysts have significant effects on reaction rates even when they are present in very small amounts. Industrial chemistry devotes great effort to finding catalysts to accelerate

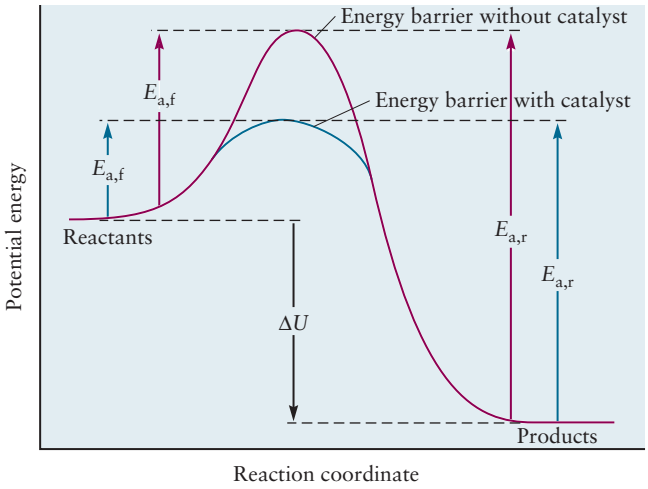

FIGURE 18.19 The most important way in which catalysts speed reactions is by reducing the activation energy. Both the uncatalyzed (red) and catalyzed (blue) reaction coordinates are shown.

particular desired reactions without increasing the generation of undesired products.

Catalysts increase reaction rates by providing alternate pathways for reactions to occur, pathways that lower the activation energy E_a, as shown in Figure 18.19. Catalysts lower the activation energies for both the forward *and* the reverse reaction by the same amount, however, which means that they increase the rate of approach to equilibrium as shown in Figure 14.7, for example. Catalysts do not change the thermodynamics of chemical reactions because Gibbs free energies, and therefore equilibrium constants, are state functions and changes in the values of state functions are independent of the path. Reactions that are not allowed thermodynamically will not proceed even under the influence of a catalyst. Catalysts are vitally important in the chemistry of life processes as well as in industrial chemistry. Virtually all biochemical reactions are catalyzed by enzymes, and catalysts are used in virtually all industrial reactions. Products are often removed as they are formed in industrial processes so that equilibrium is never reached and very high conversion efficiencies are realized. **Inhibitors,** in contrast, slow down the rates of chemical reactions, often by increasing activation energies or by physically blocking reactive sites. Inhibitors are important in industrial chemistry because they reduce the rates of undesirable side reactions, allowing the desired products to form in greater yield. They are also important in biology, where they influence the rates of enzyme-catalyzed reactions by blocking the active sites of enzymes.

Catalysis are classified into two types: homogeneous and heterogeneous. In **homogeneous catalysis** the catalyst is present in the same phase as the reactants, as when a gas-phase catalyst speeds up a gas-phase reaction, or a species dissolved in solution speeds up a reaction in solution. Chlorofluorocarbons and oxides of nitrogen are homogeneous catalysts responsible for the destruction of ozone in the stratosphere. These reactions are examined in more detail in Section 20.6. A second example is the catalysis of the oxidation–reduction reaction

$$Tl^+(aq) + 2\ Ce^{4+}(aq) \longrightarrow Tl^{3+}(aq) + 2\ Ce^{3+}(aq)$$

by silver ions in solution. The direct reaction of Tl^+ with a single Ce^{4+} ion to give Tl^{2+} as an intermediate is slow. The reaction can be speeded up by adding Ag^+ ions, which take part in a reaction mechanism of the form

$$Ag^+ + Ce^{4+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ag^{2+} + Ce^{3+} \qquad \text{(fast)}$$

$$Tl^+ + Ag^{2+} \xrightarrow{k_2} Tl^{2+} + Ag^+ \qquad \text{(slow)}$$

$$Tl^{2+} + Ce^{4+} \xrightarrow{k_3} Tl^{3+} + Ce^{3+} \qquad \text{(fast)}$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The Ag^+ ions are not permanently transformed by this reaction because those used up in the first step are regenerated in the second; they play the role of catalyst in significantly speeding the rate of the overall reaction.

In **heterogeneous catalysis** the catalyst is present as a phase distinct from the reaction mixture. The most important case is the catalytic action of certain solid surfaces on gas-phase and solution-phase reactions. A critical step in the production of sulfuric acid relies on a solid oxide of vanadium (V_2O_5) as catalyst. Many other solid catalysts are used in industrial processes. One of the best studied is the addition of hydrogen to ethylene to form ethane:

$$C_2H_4(g) + H_2(g) \longrightarrow C_2H_6(g)$$

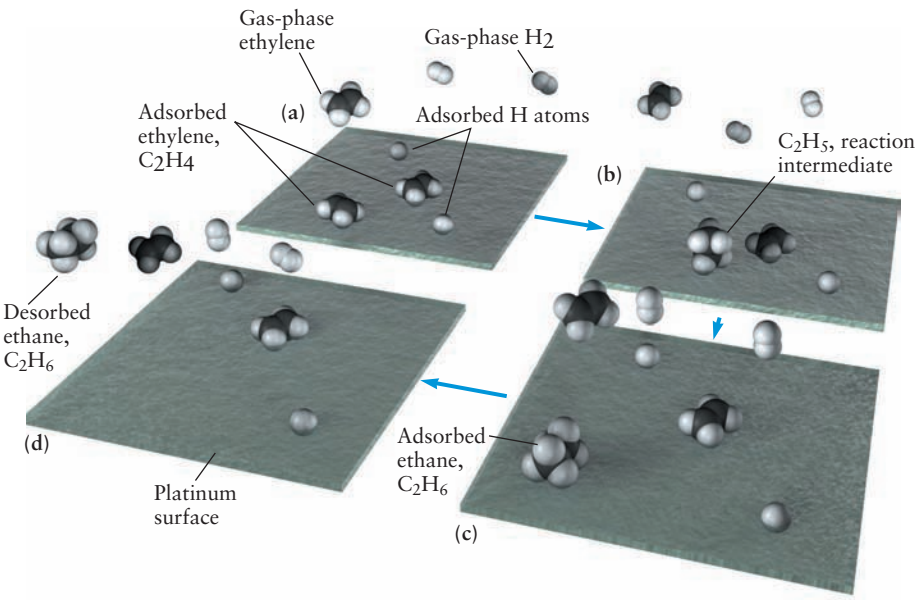
The process occurs extremely slowly in the gas phase but is catalyzed by a platinum surface (Fig. 18.20).

Another example is the solid catalyst used to reduce the emission of pollutants such as unburned hydrocarbons, carbon monoxide, and nitrogen oxides in the exhaust streams of automobile engines (Fig. 18.21). A **catalytic converter** is designed to simultaneously *oxidize* hydrocarbons and CO through the reactions

$$CO,\ C_xH_y,\ O_2 \xrightarrow{\text{Catalyst}} CO_2,\ H_2O$$

and *reduce* nitrogen oxides through the reactions

$$NO,\ NO_2 \xrightarrow{\text{Catalyst}} N_2,\ O_2$$



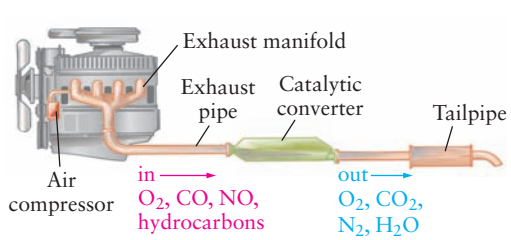


FIGURE 18.20 Platinum catalyzes the reaction $H_2 + C_2H_4$ by providing a surface that promotes the dissociation of H_2 to H atoms, which can then add to the C_2H_4 stepwise to give ethane, C_2H_6.

Clearly, the best catalyst for the reduction reactions may not be the best for the oxidation reactions, so two catalysts are combined. The noble metals, although expensive, are particularly useful. Typically, platinum and rhodium are deposited on a fine honeycomb mesh of alumina (Al_2O_3) to give a large surface area that increases the contact time of the exhaust gas with the catalysts. The platinum serves primarily as an oxidation catalyst and the rhodium as a reduction catalyst. Catalytic converters can be poisoned with certain metals that block their active sites and reduce their effectiveness. Because lead is one of the most serious such poisons, automobiles with catalytic converters must use unleaded fuel.

Enzyme Catalysis

The vast majority of chemical reactions in living organisms are catalyzed by **enzymes,** proteins that have evolved to enhance reaction rates by many orders of magnitude with exquisite selectivity. Classes of enzyme-catalyzed reactions include oxidation–reduction, hydrolysis, isomerization, and the transfer of functional groups, for example. The reactants (**substrates**) may be either small organic molecules or specific regions of much larger molecules such as proteins and nucleic acids. The oxidation of glucose to carbon dioxide and water in the series of metabolic reactions called glycolysis is an excellent example; glucose, a sugar, is perfectly stable on the shelf but is rapidly metabolized in cells to provide energy. As another example, consider the hydrolysis of urea by the enzyme urease, as represented by the following reaction.

$$H_3O^+(aq) + (NH_2)_2CO(aq) + H_2O(\ell) \xrightarrow{\text{Urease}} 2NH_4^+(aq) + HCO_3^-(aq)$$

The ratio of the rate constants for the catalyzed and uncatalyzed reactions is called the catalytic power, which for urease is an astonishing factor of 10^{14}. In the subsections that follow we introduce you to the general characteristics of enzymes, present a discussion of the kinetics of enzyme-catalyzed reactions, and introduce you to some mechanisms of enzyme-catalyzed reactions.

Enzyme Kinetics

Enzymes are proteins (polypeptides with molar masses of the order 10^4 g mol^{-1}) that selectively bind substrates in a small region called the active site, as shown in Figure 18.22. A particular enzyme is selective with respect both to substrate and to the reaction it catalyzes. Each individual step in a multistep metabolic pathway, for example, must produce actual yields of products in excess of 90% of the theoretical yield to avoid accumulation of undesirable side products.

Enzymes are identified using both common and systematic names, as in other areas of chemistry. Many common names were derived by adding the suffix *-ase* to the name of the substrate: urease catalyzes the hydrolysis of urea, and phosphatases catalyze the hydrolysis of phosphate ester bonds (RO—PO_3R'), for example. Other common names provide no clue whatsoever as to the nature of the substrate or the reaction. Catalase enhances the rate of hydrogen peroxide decomposition, and proteases are a class of enzymes that hydrolyze peptide bonds (RO—NHR′). The International Commission on Enzymes established a systematic classification of enzymes that divides them into six classes, based upon the general nature of the reactions they catalyze, and several subclasses within each class. The major classes and the reactions they catalyze include (1) *oxidoreductases*—redox reactions; (2) *transferases*—functional group transfer reactions, for example, methyl group transfer; (3) *hydrolases*—hydrolysis reactions; (4) *lyases*—addition to carbon–carbon double bonds; (5) *isomerases*—isomerization reactions; and (6) *ligases*—bond-forming reactions. Many enzymes require **cofactors** to carry out their catalytic functions. These are often metal ions, such as Fe^{2+}/Fe^{3+} in the cytochromes,

which catalyze electron-transfer reactions, or they may be small organic molecules called **coenzymes,** examples of which include vitamins.

Enzymes work by finding alternate pathways with lower activation energies, as represented by the graph in Figure 18.18. It is customary in enzyme kinetics to refer to the activation energy as a free energy of activation, symbolized as $\Delta G^{\ddagger}$, and to identify the driving forces for enzyme-catalyzed reactions in terms of the enthalpies and entropies of activation, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, as discussed in Section 18.6.

The kinetics of enzyme-catalyzed reactions are generally treated using the steady-state approximation in a form that has become known as **Michaelis–Menten** kinetics. The overall reaction is summarized by the following mechanism

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES}$$

$$\mathrm{ES} \xrightarrow{k_2} \mathrm{E} + \mathrm{P}$$

in which E represents the free enzyme, S is the substrate, ES represents the complex formed when the substrate binds to the active site, and P is the final product. The rate constants k_1 and k_{-1} are the forward and reverse rate constants of the first step, in which an equilibrium may be established, and k_2 is the rate constant of the second step, which is assumed to be irreversible. We find the initial rate (before any back reaction between P and E might occur) by invoking the steady-state approximation to find the concentration of the enzyme–substrate complex, [ES], as discussed in Section 18.4. The concentration of [ES] reaches a steady state when the rate of formation equals the rate of decay.

$$\frac{d[\mathrm{ES}]}{dt} = 0 = k_1[\mathrm{E}][\mathrm{S}] - k_{-1}[\mathrm{ES}] - k_2[\mathrm{ES}]$$

We could solve this equation to find [ES] in terms of [E], but it is not straightforward to measure the concentration of the free enzyme directly, so an alternative approach has been developed. The total concentration [ET] of enzyme present is the sum of the concentrations of the free enzyme [E] and the enzyme–substrate complex [ES], a quantity that is readily accessible experimentally. Setting $[\mathrm{E_T}] = [\mathrm{E}] + [\mathrm{ES}]$ allows us to make the substitution $[\mathrm{E}] = [\mathrm{E_T}] - [\mathrm{ES}]$ in the preceding steady-state equation to get

$$\frac{d[\mathrm{ES}]}{dt} = 0 = k_1[\mathrm{E_T}][\mathrm{S}] - k_1[\mathrm{ES}][\mathrm{S}] - k_{-1}[\mathrm{ES}] - k_2[\mathrm{ES}]$$

and solve for [ES] to give

$$[\mathrm{ES}] = \frac{k_1[\mathrm{E_T}][\mathrm{S}]}{(k_{-1} + k_2) + k_1[\mathrm{S}]}$$

We define the **Michaelis constant K_m** (in units of *molarity*) as

$$K_\mathrm{m} = \frac{k_{-1} + k_2}{k_1}$$

which allows us to express the steady state concentration of [ES] as

$$[\mathrm{ES}] = \frac{[\mathrm{E_T}][\mathrm{S}]}{K_\mathrm{m} + [\mathrm{S}]}$$

The rate of formation of product is then given by

$$\frac{d[\mathrm{P}]}{dt} = k_2[\mathrm{ES}] = \frac{k_2[\mathrm{E_T}][\mathrm{S}]}{K_\mathrm{m} + [\mathrm{S}]} \qquad [18.15]$$

which is called the Michaelis-Menten equation. Figure 18.23 shows a plot of the overall rate as a function of substrate concentration [S].

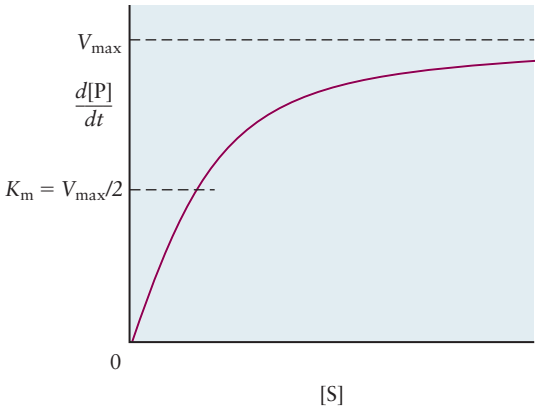

FIGURE 18.23 Michaelis-Menten plot of the dependence of the rate of an enzyme-catalyzed reaction on the concentration of the substrate, showing saturation behavior.

The rate is linear (first-order) at low substrate concentrations but rolls over to become independent of [S] at higher concentrations, saturating at a maximum rate V_{max}. The physical origin of this saturation behavior is easy to understand. The first step in the overall reaction is first order in E, first order in S, and second order overall. The rate increases with increasing [S], for a fixed concentration of enzyme, until all of the available actives sites have bound substrate, after which point no further increase in rate with increasing [S] occurs. We can calculate V_{max} from Equation 18.15 by taking the limit in which [S] >> K_m and setting $K_m = 0$ in the denominator to get $V_{max} = k_2[ET]$. The Michaelis–Menten equation is often written in the following alternative form to emphasize the central role of V_{max} in enzyme kinetics.

$$\frac{d[P]}{dt} = k_2[ES] = \frac{V_{max}[S]}{K_m + [S]}$$

Rearranging this equation into the form

$$K_m = [S]\left[\left(\frac{V_{max}}{dP/dt}\right) - 1\right]$$

allows us to find K_m experimentally. $K_m = [S]$ when $dP/dt = V_{max}/2$, so we simply measure the substrate concentration for which the rate is exactly half the maximum rate, as indicated on the graph in Figure 18.23. This procedure is only approximate, however, because it may be very difficult to arrange conditions that permit the accurate determination of V_{max}.

The **turnover number** k_{cat} is an important measure of catalytic activity for enzyme-catalyzed reactions. It is defined as the number of substrate molecules converted into product per enzyme molecule per second (turnover numbers are defined in analogous ways for other kinds of catalysts as well) and is easily calculated by measuring the maximum rate for a known enzyme concentration. The maximum rate for a given total enzyme concentration is obtained from the alternative form of the Michaelis-Menten equation by making [S] >> K_m and recognizing that [ES] = [E_T] at saturation, from which we get

$$k_{cat} \equiv k_2 = \frac{V_{max}}{E_T}$$

Turnover numbers for different enzymes vary over an enormously wide range; each catalase molecule can decompose 40 million molecules of hydrogen peroxide per second, whereas the turnover number of chymotrypsin (see the *Connection to Biology* in Chapter 7) is about 100 and that of lysozyme is about 0.5.

Enzymes rarely operate near saturation under physiological conditions, so it is interesting to consider another measure of catalytic efficiency for low substrate concentrations. Recall from Section 18.4 that reactions for which $k_2 >> k_{-1}$[M]

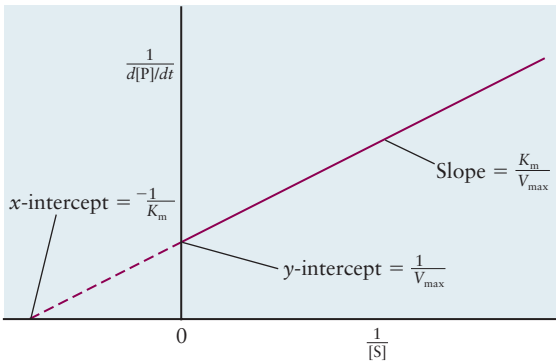

FIGURE 18.24 A graph of the linear form of the Michaelis-Menten equation that shows how the parameters K_m and V_{max} are determined.

show second-order kinetics; that is, the first step is rate-limiting. In the present case we can begin with the alternative form of the Michaelis-Menten equation, substitute $V_{max} = k_{cat}[E_T]$ and set $[S] = K_m$ to get

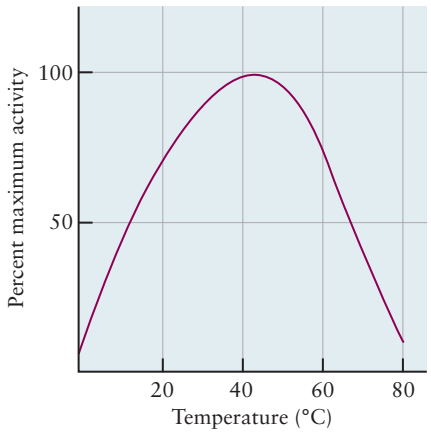
$$\frac{d[P]}{dt} = \left(\frac{k_{cat}}{K_m}\right)[E][S]$$

where [E] is the concentration of the free enzyme. The maximum rate for this first step is the rate at which E and S encounter one another; diffusion-limited rate constants are typically about 10^9 M^{-1} s^{-1} for small substrates (such as H_2O_2), and about an order of magnitude smaller for high molecular weight substrates, such as proteins and nucleic acids (see Section 18.6). Comparing experimental (k_{cat}/K_m) ratios to the diffusion-limited rate constants provides an important measure of the catalytic efficiency of enzymes. Finally, A linear version of the Michaelis–Menten equation makes it convenient to obtain both V_{max} and K_m graphically. We rewrite the equation in the following form

$$\frac{1}{d[P]/dt} = \left(\frac{K_m}{V_{max}}\right)\left(\frac{1}{[S]}\right) + \frac{1}{V_{max}}$$

and plot the inverse of the rate versus 1/[S], as shown in Figure 18.24. The slope is K_m/V_{max} and the y-intercept is $1/V_{max}$, allowing us to extract the values of both constants from one plot.

The kinetics of enzyme-catalyzed reactions are temperature-dependent, like most chemical reactions, but the rates begin to fall off gradually with temperature above 50–60°C or so, as shown in Figure 18.25. The rates increase with temperature, typically doubling every 10°C like many other reactions, but eventually beginning to decline as the three-dimensional structures of proteins, which are essential for their catalytic function, unfold and degrade.



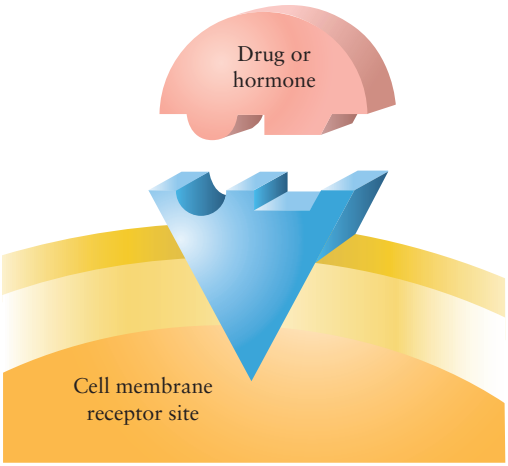


FIGURE 18.25 Plot of the activity of an enzyme versus temperature. The increase in rate at low temperatures is described by the Arrhenius equation whereas the falloff in rate at higher temperatures is due to loss of structure necessary for function.

Mechanisms of Enzyme-Catalyzed Reactions

The high degree of specificity observed for enzyme-catalyzed reactions was first attributed to a "lock-and-key" mechanism, in which binding of substrates (the key) was effected through molecular recognition by the active site of enzymes (the lock), as suggested by the adjacent sketch.

Lock and key mechanism.

Enzymes are considerably more flexible than suggested by the lock-and-key model, however, and the realization that enzyme–substrate interactions were more dynamic than suggested by that model led to the development of the **induced fit** hypothesis, in which the binding of substrate by active sites is a cooperative endeavor. The conformation of the enzyme and the substrate change dynamically during binding, catalysis, and product release to destabilize the ES and EP (enzyme-product) complexes and stabilize the transition state (or create a new one). The specificity of this process is illustrated schematically in Figure 18.26 for the enzyme hexokinase, which adds a phosphate group to six-carbon sugars but not to smaller molecules, even those of similar size and shape like glycerol ($C_3H_5(OH)_3$). The protein consists of two subunits (domains) with a cleft in between, in which the residues of the active site reside. Binding of glucose causes a conformational change in the protein that brings the two domains into closer contact, thus creating the active site. This induced-fit mechanism explains how enzymes have evolved to confer such great selectivity; catalysis depends upon the properties of both the enzyme and the substrate, a very restrictive set of requirements.

Plotting the free-energy system as a function of reaction coordinate helps us understand how enzymes catalyze reactions from the point of view of chemical thermodynamics. Molecular models (see later) help us visualize the mechanisms

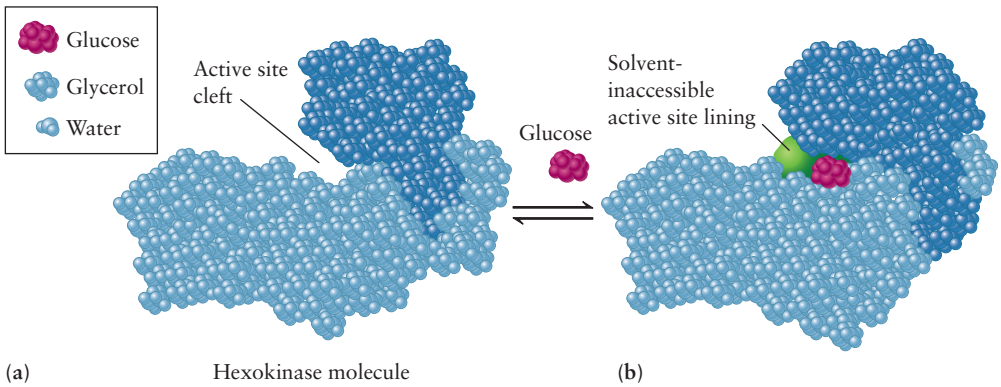

FIGURE 18.26 The enzyme hexokinase showing (a) the active site before binding substrate and (b) binding of glucose accompanied by global structural changes that brings the two domains together and closes off the active site.

by which they operate. Figure 18.27 shows a plot of the Gibbs free energy for the uncatalyzed reaction (a) as well as for the enzyme-catalyzed reaction (b). The activated complex for the uncatalyzed reaction is represented by the symbol $X^{\dagger}$, and the enzyme transition-state complex in the enzyme-catalyzed reaction is represented by the symbol $EX^{\dagger}$. The energy of the $EX^{\dagger}$complex is certainly lower than the energy of the $X^{\dagger}$complex for the uncatalyzed reaction, which suggests a mechanism for accelerating the rate by lowering the activation energy barrier. Notice, however, that there is a shallow well that corresponds to the binding energy of the ES complex. Enzymes only catalyze reactions when they destabilize (lower the energy of) the transition state complex more than they stabilize the ES complex. Let's see how this comes about by separately analyzing the enthalpic and entropic contributions to the Gibbs free energy associated with binding of substrate.

Attractive intermolecular interactions (see Section 10.2) ensure that the binding of substrate is exothermic, which favors spontaneity. Strong binding of substrate, however, is undesirable, for it would create a permanent ES complex, making an enzyme unavailable for catalysis. The key to efficient catalytic activity is the fine tuning of the ES stabilization energy that allows for selective molecular recognition and binding without rendering the enzyme inactive. Two effects counteract the strong driving force provided by enthalpy. First, there is a loss of entropy that accompanies the formation of the ES complex from E and S, particularly due to the reduction in entropy of small molecule substrates as they effectively leave solution. Second, the ES complex is destabilized to some extent by strain, distortion, and loss of solvent. Figure 18.27 shows how the combination of transition state stabilization and ES complex destabilization leads to a reduction in the activation energy.

What are the mechanisms by which enzymes actually work to catalyze reactions? Structures of the active sites of enzymes, with and without bound substrates, have been investigated in great detail by X-ray crystallography in the solid state and by a number of spectroscopic techniques, such as NMR (see Section 20.4), in solution. These studies, supported by molecular dynamics simulations, have led to the conclusion that the "preorganization" of the active site prepares it for its catalytic role in which it directs the substrate to adopt the conformation most favorable for effecting the reaction of interest. We have already shown, in the *Connection to Biology* in Chapter 7, how the three amino acid residues that comprise the active site of the enzyme chymotrypsin are organized in space to optimally carry out the hydrolysis of peptide bonds. Protein motion is essential to catalysis: to configure the active site to recognize and bind substrates in optimal conformations, to locate catalytic groups near where they are needed, facilitate bond breaking and bond formation, and, finally, to assist in the conversion to products and their release.

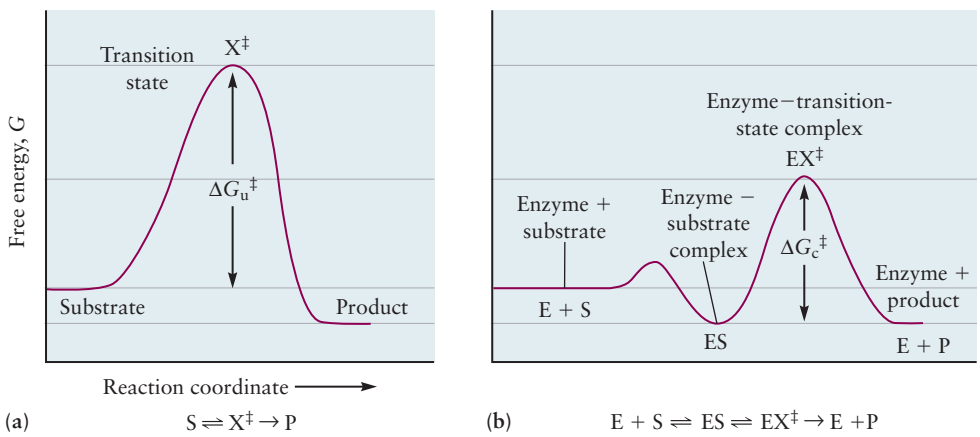

FIGURE 18.27 (a) Free energy profile for the uncatalyzed conversion of substrate to product. (b) Energy profile for the enzyme-catalyzed reaction that shows the preferential stabilization of the enzyme transition-state complex with respect to the enzyme substrate complex.

CHAPTER SUMMARY

Chemical kinetics is the study of the rates of chemical reactions and the factors that control those rates. The rates of chemical reactions depend on the concentrations of all of the reactants and products as well as the temperature. The concentration dependence of reaction rates is given by empirical rate laws in which the rate depends on the concentration of each reactant raised to some power that is not, in general, related to the stoichiometric coefficients in the balanced equation for the reaction. Rate laws may be determined by measuring the initial rate of a reaction as a function of initial concentration or by inspecting the concentration-time profile over the course of the reaction. Concentrations decrease exponentially with time for first order reactions and the half-life is a characteristic time scale for the reaction. Most chemical reactions occur as a series of elementary reactions, which constitute the reaction mechanism. The steady state approximation provides a simple framework to analyze the kinetics of multistep reactions. This approximation, which is widely used in many areas of chemistry and biochemistry, shows how a reaction may display either first- or second-order kinetics, depending on starting concentrations. It also accounts for the rate-limiting step, which determines the overall rate of the reaction. Spectroscopic detection or chemical trapping of reaction intermediates is a powerful way to establish a reaction mechanism. The rates of all elementary reactions increase with increasing temperature. As temperatures rise, more molecules have enough energy to overcome the activation barrier and proceed to form products. Microscopic theories have been developed that provide molecular-level understanding of the factors that govern the rates of chemical reactions. These theories are based on the collision theory, which asserts that the rates are proportional to the rates of collisions times the probability of particular collisions leading to reaction. The probabilities are expressed in terms of the reactive cross section, which is interpreted as the effective size of a molecule that ensures reaction upon every collision. Catalysts increase the rates of chemical reactions without being either consumed or produced. Synthetic catalysts are widely used in industrial processes, and natural catalysts called enzymes catalyze and regulate the rates of virtually all biological processes. Catalysts work by lowering the activation barrier for chemical reactions.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 18.1 – Rates of Chemical Reactions

Describe experimental methods for measuring average and instantaneous rates (Problems 1–2).

- The rates of chemical reactions are measured by determining the concentrations of reactants and products as a function of time. Concentrations may be measured by a variety of chemical or instrumental methods. The average rate is the change in concentration measured over a period of time divided by the time. The instantaneous rate is the slope of a line that is tangent to the concentration-time plot at the time of interest.

Section 18.2 – Rate Laws

Deduce rate laws and reaction orders from experimental measurements of the dependence of reaction rates on concentrations (Problems 5–8).

- Rate laws and reaction orders are deduced from the concentration dependence of the reaction rate as follows. The reaction is run under two conditions with the concentration of only one reactant being changed; if the rate doubles when the concentration of that reactant doubles, then the reaction is first-order with respect to that reactant; if it quadruples, then it is second order. The process is repeated, changing the concentrations of each of the reactants in a pair of ex-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

periments while keeping all of the other concentrations and the other conditions the same. The rate constant is determined from any single experiment, once the dependence on concentrations has been determined, by dividing the rate by the product of the concentrations raised to their respective orders.

Use the integrated rate laws for first- and second-order reactions to calculate the concentrations remaining after a certain elapsed time (Problems 9–18).

- Concentrations at a given elapsed time are calculated by solving the rate equations, inserting the initial conditions and the rate constant as known values.
  - First order reactions $c = c_0\, e^{-kt}$
  - Second order reactions $\dfrac{1}{c} = \dfrac{1}{c_0} + 2kt$

18.3 – Reaction Mechanisms

Describe the relationship between the equilibrium constant for an elementary reaction and the corresponding forward and reverse rate constants (Problems 23–24).

- The equilibrium constant is the ratio of rate constants for the forward and reverse reactions $K_{eq} = k_f/k_r$ as required by the principle of detailed balance for elementary processes.

18.4 – Reaction Mechanisms and Rate

Deduce the rate law from a mechanism characterized by a single rate-determining step (Problems 25–30).

- The rate law for a mechanism characterized by a single rate-limiting step is given by the rate law for that elementary process, which is determined by inspection.

Use the steady-state approximation to deduce rate laws when no single rate-determining step exists (Problems 31–34).

- The general rate law given by the steady-state approximation is
  $\text{rate} = \dfrac{k_1 k_2[\text{A}][\text{M}]}{k_2 + k_{-1}[\text{M}]}$ with limiting forms: rate $= k_1[\text{A}][\text{M}]$ at low pressure and rate $= (k_1/k_{-1})k_2[\text{A}]$ at high pressure.

18.5 – Effect of Temperature on Reaction Rates

Calculate Arrhenius factors and activation energies from measurements of the temperature dependence of rate constants (Problems 35–40).

- Arrhenius factors are calculated by plotting ln k versus $1/T$, the slope of which is $-E_a/R$.

Discuss the connection between activation energy and the energy distribution of molecules, and relate the forward and reverse activation energies to each other through thermodynamics (Problems 41–42).

- The activation energy is the minimum amount of energy necessary to initiate a chemical reaction. The fraction of molecules whose energy is greater than or equal to the activation energy is determined by the area under the curve of the Maxwell–Boltzmann energy distribution between E_a and infinity. The fraction of molecules with energy greater than E_a increases with increasing temperature. The difference between the activation energies for the forward and reverse reactions is the enthalpy change of the reaction.

18.6 – Molecular Theories of Elementary Reactions

Outline the quantitative calculation of rate constants, using the collision theory of gases (Problems 43–44).

- Collision theory calculates the rates of collisions between molecules using the kinetic theory of gases, and estimates the rates of reactive collisions by asserting that reactions occur only when the relative kinetic energy of the colliding molecules along the collision direction exceeds a minimum energy ε_a.

18.7 – Reactions in Solution

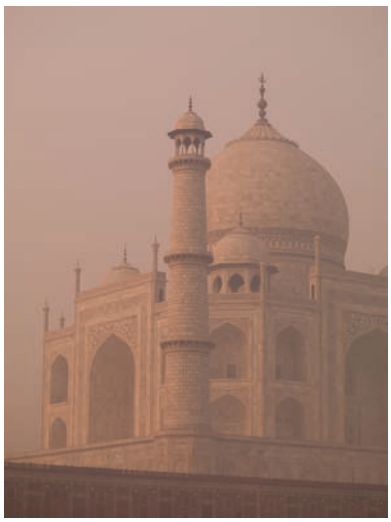
Identify reactions as diffusion-controlled or activation-energy controlled (Problems 45–46).

- Diffusion-controlled reactions are second-order reactions with rate-limiting steps determined by an effective diffusion constant that is the sum of the diffusion constants of the reactants. Activation-energy controlled reactions are first-order, with the second step being rate-limiting, allowing equilibrium to be established in the first step.

18.8 – Catalysis

Describe several types of catalysts and their effects on chemical reactions.

- Catalysts increase the rates of chemical reactions by lowering the activation barrier, typically by providing alternate paths.
- Homogeneous catalysts are present in the same phase as the reaction being catalyzed, whereas heterogeneous catalysts are present in a different phase.
- Enzymes are biological catalysts that bind substrates with exquisite selectivity, position reactants at optimal locations, and stabilize transition states, all of which leads to lower activation barriers than those in the uncatalyzed reaction.



Relate the rate of an enzyme-catalyzed reaction to the concentrations of substrate and enzyme in the reaction mixture (Problems 47–48).

- Enzyme-catalyzed reactions often follow the Michaelis–Menten equation, which shows saturation of the rate at high substrate concentrations.

$$\frac{d[\mathrm{P}]}{dt} = k_2[\mathrm{ES}] = \frac{k_2[\mathrm{E_T}][\mathrm{S}]}{K_\mathrm{m} + [\mathrm{S}]}$$

CUMULATIVE EXERCISE

Sulfite and Sulfate Kinetics in Atmospheric Chemistry

Keith Levit/Shutterstock.com

Air pollution is damaging the white marble of one of the world's most famous monuments, the Taj Mahal. Particulate matter and acid rain both contribute to the problem.

Sulfur dioxide dissolves in water droplets (fog, clouds, and rain) in the atmosphere and reacts according to the equation

$$\mathrm{SO_2}(aq) + 2\ \mathrm{H_2O}(\ell) \longrightarrow \mathrm{HSO_3^-}(aq) + \mathrm{H_3O^+}(aq)$$

$\mathrm{HSO_3^-}(aq)$ (hydrogen sulfite ion) is then slowly oxidized by oxygen that is also dissolved in the droplets:

$$2\ \mathrm{HSO_3^-}(aq) + \mathrm{O_2}(aq) + 2\ \mathrm{H_2O}(\ell) \longrightarrow 2\ \mathrm{SO_4^{2-}}(aq) + 2\ \mathrm{H_3O^+}(aq)$$

Although the second reaction has been studied for many years, only recently was it shown to proceed by the steps

$$2\ \mathrm{HSO_3^-}(aq) + \mathrm{O_2}(aq) \longrightarrow \mathrm{S_2O_7^{2-}}(aq) + \mathrm{H_2O}(\ell) \qquad \text{(fast)}$$

$$\mathrm{S_2O_7^{2-}}(aq) + 3\ \mathrm{H_2O}(\ell) \longrightarrow 2\ \mathrm{SO_4^{2-}}(aq) + 2\ \mathrm{H_3O^+}(aq) \qquad \text{(slow)}$$

The reactive intermediate, $\mathrm{S_2O_7^{2-}}(aq)$, which had not been detected in earlier studies of this reaction, is well known in other reactions. It is the *disulfate* ion.

In an experiment at 25°C, a solution was mixed with the realistic initial concentrations of 0.270 M $\mathrm{HSO_3^-}(aq)$ and 0.0135 M $\mathrm{O_2}(aq)$. The initial pH was 3.90. The following table tells what happened in the solution, beginning at the moment of mixing.

Time(s)	$[HSO_3^-]$ (M)	$[O_2]$ (M)	$[S_2O_7^{2-}]$ (M)	$[HSO_4^-] + [SO_4^{2-}]$ (M)
0.000	0.270	0.0135	0.000	0.000
0.010	0.243	0.000	13.5×10^{-3}	0.000
10.0	0.243	0.000	11.8×10^{-3}	03.40×10^{-3}
45.0	0.243	0.000	7.42×10^{-3}	12.2×10^{-3}
90.0	0.243	0.000	4.08×10^{-3}	18.8×10^{-3}
150.0	0.243	0.000	1.84×10^{-3}	23.3×10^{-3}
450.0	0.243	0.000	0.034×10^{-3}	26.9×10^{-3}
600.0	0.243	0.000	0.005×10^{-3}	27.0×10^{-3}

(a) Determine the average rate of increase of the total of the concentrations of the sulfate plus hydrogen sulfate ions during the first 10 s of the experiment.

(b) Determine the average rate of disappearance of hydrogen sulfite ion during the first 0.010 s of the experiment.

(c) Explain why the hydrogen sulfite ion stops disappearing after 0.010 s.

(d) Plot the concentration of disulfate ion versus time on graph paper, and use the graph to estimate the instantaneous rate of disappearance of disulfate ion 90.0 s after the reaction starts.

(e) Determine the order with respect to the disulfate ion of the second step of the conversion, and the rate constant of that step.

(f) Determine the half-life of the second step of the conversion process.

(g) At 15°C the rate constant of the second step of the conversion is only 62% of its value at 25°C. Compute the activation energy of the second step.

(h) The first step of the conversion occurs much faster when 1.0×10^{-6} M $Fe^{2+}(aq)$ ion is added (but the rate of the second step is unaffected). What role does Fe^{2+} play?

(i) Write a balanced equation for the overall reaction that gives sulfuric acid from SO_2 dissolved in water droplets in the air.

Answers

(a) 3.40×10^{-4} mol L^{-1} s^{-1}

(b) 2.7 mol L^{-1} s^{-1}

(c) All of the oxygen is consumed, so the first step of the process is over.

(d) 5.43×10^{-5} mol L^{-1} s^{-1}

(e) First order; $k = 0.0133$ s^{-1}

(f) 52 s

(g) 34 kJ mol^{-1}

(h) Fe^{2+} acts as a catalyst.

(i) $2\ SO_2(aq) + O_2(aq) + 6\ H_2O(\ell) \longrightarrow SO_4^{2-}(aq) + 4\ H_3O^+(aq)$

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

Rates of Chemical Reactions

1. Use Figure 18.3 to estimate graphically the instantaneous rate of production of NO at $t = 200$ s.

2. Use Figure 18.3 to estimate graphically the instantaneous rate of production of NO at $t = 100$ s.

3. Give three related expressions for the rate of the reaction

$$N_2(g) + 3\ H_2(g) \longrightarrow 2\ NH_3(g)$$

assuming that the concentrations of any intermediates are constant and that the volume of the reaction vessel does not change.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Give four related expressions for the rate of the reaction

$$2\ H_2CO(g) + O_2(g) \longrightarrow 2\ CO(g) + 2\ H_2O(g)$$

assuming that the concentrations of any intermediates are constant and that the volume of the reaction vessel does not change.

Rate Laws

5. Nitrogen oxide reacts with hydrogen at elevated temperatures according to the following chemical equation:

$$2\ NO(g) + 2\ H_2(g) \longrightarrow N_2(g) + 2\ H_2O(g)$$

It is observed that, when the concentration of H_2 is cut in half, the rate of the reaction is also cut in half. When the concentration of NO is multiplied by 10, the rate of the reaction increases by a factor of 100.
(a) Write the rate expression for this reaction, and give the units of the rate constant k.
(b) If [NO] were multiplied by 3 and [H_2] by 2, what change in the rate would be observed?

6. In the presence of vanadium oxide, $SO_2(g)$ reacts with an excess of oxygen to give $SO_3(g)$:

$$SO_2(g) + \tfrac{1}{2}\ O_2(g) \xrightarrow{V_2O_5} SO_3(g)$$

This reaction is an important step in the manufacture of sulfuric acid. It is observed that tripling the SO_2 concentration increases the rate by a factor of 3, but tripling the SO_3 concentration decreases the rate by a factor of $1.7 \approx \sqrt{3}$. The rate is insensitive to the O_2 concentration as long as an excess of oxygen is present.
(a) Write the rate expression for this reaction, and give the units of the rate constant k.
(b) If [SO_2] is multiplied by 2 and [SO_3] by 4 but all other conditions are unchanged, what change in the rate will be observed?

7. In a study of the reaction of pyridine (C_5H_5N) with methyl iodide (CH_3I) in a benzene solution, the following set of initial reaction rates was measured at 25°C for different initial concentrations of the two reactants:

[C_5H_5N] (mol L^{-1})	[CH_3I] (mol L^{-1})	Rate (mol L^{-1} s^{-1})
1.00×10^{-4}	1.00×10^{-4}	7.5×10^{-7}
2.00×10^{-4}	2.00×10^{-4}	3.0×10^{-6}
2.00×10^{-4}	4.00×10^{-4}	6.0×10^{-6}

(a) Write the rate expression for this reaction.
(b) Calculate the rate constant k and give its units.
(c) Predict the initial reaction rate for a solution in which [C_5H_5N] is 5.0×10^{-5} M and [CH_3I] is 2.0×10^{-5} M.

8. The rate for the oxidation of iron(II) by cerium(IV)

$$Ce^{4+}(aq) + Fe^{2+}(aq) \longrightarrow Ce^{3+}(aq) + Fe^{3+}(aq)$$

is measured at several different initial concentrations of the two reactants:

[Ce^{4+}] (mol L^{-1})	[Fe^{2+}] (mol L^{-1})	Rate (mol L^{-1} s^{-1})
1.1×10^{-5}	1.8×10^{-5}	2.0×10^{-7}
1.1×10^{-5}	2.8×10^{-5}	3.1×10^{-7}
3.4×10^{-5}	2.8×10^{-5}	9.5×10^{-7}

(a) Write the rate expression for this reaction.
(b) Calculate the rate constant k and give its units.
(c) Predict the initial reaction rate for a solution in which [Ce^{4+}] is 2.6×10^{-5} M and [Fe^{2+}] is 1.3×10^{-5} M.

9. The reaction $SO_2Cl_2(g) \longrightarrow SO_2(g) + Cl_2(g)$ is first order, with a rate constant of $2.2 \times 10^{-5}\ s^{-1}$ at 320°C. The partial pressure of $SO_2Cl_2(g)$ in a sealed vessel at 320°C is 1.0 atm. How long will it take for the partial pressure of $SO_2Cl_2(g)$ to fall to 0.50 atm?

10. The reaction $FClO_2(g) \longrightarrow FClO(g) + O(g)$ is first order with a rate constant of $6.76 \times 10^{-4}\ s^{-1}$ at 322°C.
(a) Calculate the half-life of the reaction at 322°C.
(b) If the initial partial pressure of $FClO_2$ in a container at 322°C is 0.040 atm, how long will it take to fall to 0.010 atm?

11. The decomposition of benzene diazonium chloride

$$C_6H_5N_2Cl \longrightarrow C_6H_5Cl + N_2$$

follows first-order kinetics with a rate constant of $4.3 \times 10^{-5}\ s^{-1}$ at 20°C. If the initial partial pressure of $C_6H_5N_2Cl$ is 0.0088 atm, calculate its partial pressure after 10.0 hours.

12. At 600 K, the rate constant for the first-order decomposition of nitroethane

$$CH_3CH_2NO_2(g) \longrightarrow C_2H_4(g) + HNO_2(g)$$

is $1.9 \times 10^{-4}\ s^{-1}$. A sample of $CH_3CH_2NO_2$ is heated to 600 K, at which point its initial partial pressure is measured to be 0.078 atm. Calculate its partial pressure after 3.0 hours.

13. Chloroethane decomposes at elevated temperatures according to the reaction

$$C_2H_5Cl(g) \longrightarrow C_2H_4(g) + HCl(g)$$

This reaction obeys first-order kinetics. After 340 s at 800 K, a measurement shows that the concentration of C_2H_5Cl has decreased from 0.0098 mol L^{-1} to 0.0016 mol L^{-1}. Calculate the rate constant k at 800 K.

14. The isomerization reaction

$$CH_3NC \longrightarrow CH_3CN$$

obeys the first-order rate law

$$\text{rate} = -k[CH_3NC]$$

in the presence of an excess of argon. Measurements at 500 K reveal that in 520 s the concentration of CH_3NC decreases to 71% of its original value. Calculate the rate constant k of the reaction at 500 K.

15. At 25°C in CCl_4 solvent, the reaction

$$I + I \longrightarrow I_2$$

is second order in the concentration of the iodine atoms. The rate constant k has been measured as 8.2×10^9 L mol^{-1} s^{-1}. Suppose the initial concentration of I atoms is 1.00×10^{-4} M. Calculate their concentration after 2.0×10^{-6} s.

16. HO_2 is a highly reactive chemical species that plays a role in atmospheric chemistry. The rate of the gas-phase reaction

$$HO_2(g) + HO_2(g) \longrightarrow H_2O_2(g) + O_2(g)$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is second order in $[HO_2]$, with a rate constant at 25°C of 1.4×10^9 L mol^{-1} s^{-1}. Suppose some HO_2 with an initial concentration of 2.0×10^{-8} M could be confined at 25°C. Calculate the concentration that would remain after 1.0 s, assuming no other reactions take place.

17. The rate for the reaction

$$OH^-(aq) + NH_4^+(aq) \longrightarrow H_2O(\ell) + NH_3(aq)$$

is first order in both OH^- and NH_4^+ concentrations, and the rate constant k at 20°C is 3.4×10^{10} L mol^{-1} s^{-1}. Suppose 1.00 L of a 0.0010 M NaOH solution is rapidly mixed with the same volume of 0.0010 M NH_4Cl solution. Calculate the time (in seconds) required for the OH^- concentration to decrease to a value of 1.0×10^{-5} M.

18. The rate for the reaction

$$OH^-(aq) + HCN(aq) \longrightarrow H_2O(\ell) + CN^-(aq)$$

is first order in both OH^- and HCN concentrations, and the rate constant k at 25°C is 3.7×10^9 L mol^{-1} s^{-1}. Suppose 0.500 L of a 0.0020 M NaOH solution is rapidly mixed with the same volume of a 0.0020 M HCN solution. Calculate the time (in seconds) required for the OH^- concentration to decrease to a value of 1.0×10^{-4} M.

Reaction Mechanisms

19. Identify each of the following elementary reactions as unimolecular, bimolecular, or termolecular, and write the rate expression.

(a) $HCO + O_2 \longrightarrow HO_2 + CO$
(b) $CH_3 + O_2 + N_2 \longrightarrow CH_3O_2 + N_2$
(c) $HO_2NO_2 \longrightarrow HO_2 + NO_2$

20. Identify each of the following elementary reactions as unimolecular, bimolecular, or termolecular, and write the rate expression.

(a) $BrONO_2 \longrightarrow BrO + NO_2$
(b) $HO + NO_2 + Ar \longrightarrow HNO_3 + Ar$
(c) $O + H_2S \longrightarrow HO + HS$

21. Consider the following reaction mechanism:

$$H_2O_2 \longrightarrow H_2O + O$$
$$O + CF_2Cl_2 \longrightarrow ClO + CF_2Cl$$
$$ClO + O_3 \longrightarrow Cl + 2\ O_2$$
$$Cl + CF_2Cl \longrightarrow CF_2Cl_2$$

(a) What is the molecularity of each elementary step?
(b) Write the overall equation for the reaction.
(c) Identify the reaction intermediate(s).

22. Consider the following reaction mechanism:

$$NO_2Cl \longrightarrow NO_2 + Cl$$
$$Cl + H_2O \longrightarrow HCl + OH$$
$$OH + NO_2 + N_2 \longrightarrow HNO_3 + N_2$$

(a) What is the molecularity of each elementary step?
(b) Write the overall equation for the reaction.
(c) Identify the reaction intermediate(s).

23. The rate constant of the elementary reaction

$$BrO(g) + NO(g) \longrightarrow Br(g) + NO_2(g)$$

is 1.3×10^{10} L mol^{-1} s^{-1} at 25°C, and its equilibrium constant is 5.0×10^{10} at this temperature. Calculate the rate constant at 25°C of the elementary reaction

$$Br(g) + NO_2(g) \longrightarrow BrO(g) + NO(g)$$

24. The compound $IrH_3(CO)(P(C_6H_5)_3)_2$ exists in two forms: the meridional ("mer") and facial ("fac"). At 25°C in a nonaqueous solvent, the reaction mer $\longrightarrow$ fac has a rate constant of 2.33 s^{-1}, and the reaction fac $\longrightarrow$ mer has a rate constant of 2.10 s^{-1}. What is the equilibrium constant of the mer-to-fac reaction at 25°C?

Reaction Mechanisms and Rate

25. Write the overall reaction and rate laws that correspond to the following reaction mechanisms. Be sure to eliminate intermediates from the answers.

(a) $A + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C + D$ (fast equilibrium)
$C + E \xrightarrow{k_2} F$ (slow)

(b) $A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B + C$ (fast equilibrium)
$C + D \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E$ (fast equilibrium)
$E \xrightarrow{k_3} F$ (slow)

26. Write the overall reaction and the rate laws that correspond to the following reaction mechanisms. Be sure to eliminate intermediates from the answers.

(a) $2\ A + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} D$ (fast equilibrium)
$D + B \xrightarrow{k_2} E + F$ (slow)
$F \xrightarrow{k_3} G$ (fast)

(b) $A + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C$ (fast equilibrium)
$C + D \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} F$ (fast equilibrium)
$F \xrightarrow{k_3} G$ (slow)

27. HCl reacts with propene (CH_3CHCH_2) in the gas phase according to the overall reaction

$$HCl + CH_3CHCH_2 \longrightarrow CH_3CHClCH_3$$

The experimental rate expression is

$$\text{rate} = k[HCl]^3[CH_3CHCH_2]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

(a) $HCl + HCl \rightleftharpoons H + HCl_2$ (fast equilibrium)
$H + CH_3CHCH_2 \longrightarrow CH_3CHCH_3$ (slow)
$HCl_2 + CH_3CHCH_3 \longrightarrow CH_3CHClCH_3 + HCl$ (fast)

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(b) $HCl + HCl \rightleftharpoons H_2Cl_2$ (fast equilibrium)
$HCl + CH_3CHCH_2 \rightleftharpoons CH_3CHClCH_3^*$ (fast equilibrium)
$CH_3CHClCH_3^* + H_2Cl_2 \longrightarrow CH_3CHClCH_3 + 2\ HCl$ (slow)

(c) $HCl + CH_3CHCH_2 \rightleftharpoons H + CH_3CHClCH_2$ (fast equilibrium)
$H + HCl \rightleftharpoons H_2Cl$ (fast equilibrium)
$H_2Cl + CH_3CHClCH_2 \longrightarrow HCl + CH_3CHClCH_3$ (slow)

28. Chlorine reacts with hydrogen sulfide in aqueous solution

$$Cl_2(aq) + H_2S(aq) \longrightarrow S(s) + 2\ H^+(aq) + 2\ Cl^-(aq)$$

in a second-order reaction that follows the rate expression

$$\text{rate} = k[Cl_2][H_2S]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

(a) $Cl_2 + H_2S \longrightarrow H^+ + Cl^- + Cl^+ + HS^-$ (slow)
$Cl^+ + HS^- \longrightarrow H^+ + Cl^- + S$ (fast)

(b) $H_2S \rightleftharpoons HS^- + H^+$ (fast equilibrium)
$HS^- + Cl_2 \longrightarrow 2\ Cl^- + S + H^+$ (slow)

(c) $H_2S \rightleftharpoons HS^- + H^+$ (fast equilibrium)
$H^+ + Cl_2 \rightleftharpoons H^+ + Cl^- + Cl^+$ (fast equilibrium)
$Cl^+ + HS^- \longrightarrow H^+ + Cl^- + S$ (slow)

29. Nitryl chloride is a reactive gas with a normal boiling point of −16°C. Its decomposition to nitrogen dioxide and chlorine is described by the equation

$$2\ NO_2Cl \longrightarrow 2\ NO_2 + Cl_2$$

The rate expression for this reaction has the form

$$\text{rate} = k[NO_2Cl]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

(a) $NO_2Cl \longrightarrow NO_2 + Cl$ (slow)
$Cl + NO_2Cl \longrightarrow NO_2 + Cl_2$ (fast)

(b) $2\ NO_2Cl \rightleftharpoons N_2O_4 + Cl_2$ (fast equilibrium)
$N_2O_4 \longrightarrow 2\ NO_2$ (slow)

(c) $2\ NO_2Cl \rightleftharpoons ClO_2 + N_2O + ClO$ (fast equilibrium)
$N_2O + ClO_2 \rightleftharpoons NO_2 + NOCl$ (fast equilibrium)
$NOCl + ClO \longrightarrow NO_2 + Cl_2$ (slow)

30. Ozone in the upper atmosphere is decomposed by nitrogen oxide through the reaction

$$O_3 + NO \longrightarrow O_2 + NO_2$$

The experimental rate expression for this reaction is

$$\text{rate} = k[O_3][NO]$$

Which, if any, of the following mechanisms are consistent with the observed rate expression?

(a) $O_3 + NO \longrightarrow O + NO_3$ (slow)
$O + O_3 \longrightarrow 2\ O_2$ (fast)
$NO_3 + NO \longrightarrow 2\ NO_2$ (fast)

(b) $O_3 + NO \longrightarrow O_2\ NO_2$ (slow)

(c) $NO + NO \rightleftharpoons N_2O_2$ (fast equilibrium)
$N_2O_2 + O_3 \longrightarrow NO_2 + 2\ O_2$ (slow)

31. Consider the mechanism of problem 25(a). Suppose *no* assumptions are made about the relative rates of the steps. By making a steady-state approximation for the concentration of the intermediate (C), express the rate of production of the product (F) in terms of the concentrations of A, B, D, and E. In what limit does this reduce to the result of problem 25(a)?

32. Consider the mechanism of problem 25(b). Suppose *no* assumptions are made about the relative rates of the steps. By making a steady-state approximation for the concentrations of the intermediates (C and E), express the rate of production of the product (F) in terms of the concentrations of A, B, and D. In what limit does this reduce to the result of problem 25(b)?

33. The mechanism for the decomposition of NO_2Cl is

$$NO_2Cl \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NO_2 + Cl$$

$$NO_2Cl + Cl \xrightarrow{k_2} NO_2 + CL_2$$

By making a steady-state approximation for [Cl], express the rate of appearance of Cl_2 in terms of the concentrations of NO_2Cl and NO_2.

34. A key step in the formation of sulfuric acid from dissolved SO_2 in acid precipitation is the oxidation of hydrogen sulfite ion by hydrogen peroxide:

$$HSO_3^-(aq) + H_2O_2(aq) \longrightarrow HSO_4^-(aq) + H_2O(\ell)$$

The mechanism involves peroxymonosulfurous acid, SO_2OOH^-:

$$HSO_3^-(aq) + H_2O_2(aq) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SO_2OOH^-(aq) + H_2O(\ell)$$

$$SO_2OOH^-(aq) + H_3O^+(aq) \xrightarrow{k_2} HSO_4^-(aq) + H_3O^+(aq)$$

By making a steady-state approximation for the reactive intermediate concentration, $[SO_2OOH^-(aq)]$, express the rate of formation of $HSO_4^-(aq)$ in terms of the concentrations of $HSO_3^-(aq)$, $H_2O_2(aq)$, and $H_3O^+(aq)$.

Effect of Temperature on Reaction Rates

35. The rate of the elementary reaction

$$Ar + O_2 \longrightarrow Ar + O + O$$

has been studied as a function of temperature between 5000 and 18,000 K. The following data were obtained for the rate constant *k:*

Temperature (K)	k (L mol^{-1} s^{-1})
5,000	5.49×10^6
10,000	9.86×10^8
15,000	5.09×10^9
18,000	8.60×10^9

(a) Calculate the activation energy of this reaction.
(b) Calculate the factor A in the Arrhenius equation for the temperature dependence of the rate constant.

36. The gas-phase reaction

$$H + D_2 \longrightarrow HD + D$$

is the exchange of isotopes of hydrogen of atomic mass 1 (H) and 2 (D, deuterium). The following data were obtained for the rate constant k of this reaction:

Temperature (K)	k (L mol^{-1} s^{-1})
299	1.56×10^4
327	3.77×10^4
346	7.6×10^4
440	10^6
549	1.07×10^6
745	8.7×10^7

(a) Calculate the activation energy of this reaction.
(b) Calculate the factor A in the Arrhenius equation for the temperature dependence of the rate constant.

37. The rate constant of the elementary reaction

$$BH_4^-(aq) + NH_4^+(aq) \longrightarrow BH_3NH_3(aq) + H_2(g)$$

is $k = 1.94 \times 10^{-4}$ L mol^{-1} s^{-1} at 30.0°C, and the reaction has an activation energy of 161 kJ mol^{-1}.
(a) Compute the rate constant of the reaction at a temperature of 40.0°C.
(b) After equal concentrations of $BH_4^-(aq)$ and $NH_4^-(aq)$ are mixed at 30.0°C, 1.00×10^4 s is required for half of them to be consumed. How long will it take to consume half of the reactants if an identical experiment is performed at 40.0°C?

38. Dinitrogen tetraoxide (N_2O_4) decomposes spontaneously at room temperature in the gas phase:

$$N_2O_4(g) \longrightarrow 2\ NO_2(g)$$

The rate law governing the disappearance of N_2O_4 with time is

$$-\frac{d[N_2O_4]}{dt} = k[N_2O_4]$$

At 30°C, $k = 5.1 \times 10^6$ s^{-1} and the activation energy for the reaction is 54.0 kJ mol^{-1}.
(a) Calculate the time (in seconds) required for the partial pressure of $N_2O_4(g)$ to decrease from 0.10 atm to 0.010 atm at 30°C.
(b) Repeat the calculation of part (a) at 300°C.

39. The activation energy for the isomerization reaction of CH_3NC in Problem 14 is 161 kJ mol^{-1}, and the reaction rate constant at 600 K is 0.41 s^{-1}.
(a) Calculate the Arrhenius factor A for this reaction.
(b) Calculate the rate constant for this reaction at 1000 K.

40. Cyclopropane isomerizes to propylene according to a first-order reaction:

$$\text{cyclopropane} \longrightarrow \text{propylene}$$

The activation energy is $E_a = 272$ kJ mol^{-1}. At 500°C, the reaction rate constant is 6.1×10^{-4} s^{-1}.
(a) Calculate the Arrhenius factor A for this reaction.
(b) Calculate the rate constant for this reaction at 25°C.

41. The activation energy of the gas-phase reaction

$$OH(g) + HCl(g) \longrightarrow H_2O(g) + Cl(g)$$

is 3.5 kJ mol^{-1}, and the change in the internal energy in the reaction is $\Delta U = -66.8$ kJ mol^{-1}. Calculate the activation energy of the reaction

$$H_2O(g) + Cl(g) \longrightarrow OH(g) + HCl(g)$$

42. The compound HOCl is known, but the related compound HClO, with a different order for the atoms in the molecule, is not known. Calculations suggest that the activation energy for the conversion HOCl ⟶ HClO is 311 kJ mol^{-1} and that for the conversion HClO ⟶ HOCl is 31 kJ mol^{-1}. Estimate ΔU for the reaction HOCl ⟶ HClO.

Molecular Theories of Elementary Reactions

43. Use collision theory to estimate the preexponential factor in the rate constant for the elementary reaction

$$NOCl + NOCl \longrightarrow 2\ NO + Cl_2$$

at 25°C. Take the average diameter of an NOCl molecule to be 3.0×10^{-10} m and use the steric factor P from Table 18.1.

44. Use collision theory to estimate the preexponential factor in the rate constant for the elementary reaction

$$NO_2 + NO_2 \longrightarrow 2\ NO + O_2$$

at 500 K. Take the average diameter of an NO_2 molecule to be 2.6×10^{-10} m and use the steric factor P from Table 18.1.

Reactions in Solution

45. The rate constant for the reaction $CH_3Br + Cl^- \longrightarrow CH_3Cl + Br^-$ in acetone is 5.9×10^{-3} L mol^{-1} s^{-1}. Is this reaction diffusion-controlled or limited by a large activation energy?

46. The rate constant for the reaction $H^+ + HS^- \longrightarrow H_2S$ in aqueous solution is 7.5×10^{10} L mol^{-1} s^{-1}. Is this reaction diffusion-controlled or limited by a large activation energy?

Catalysis

47. Certain bacteria use the enzyme penicillinase to decompose penicillin and render it inactive. The Michaelis–Menten constants for this enzyme and substrate are $K_m = 5 \times 10^{-5}$ mol L^{-1} and $k_2 = 2 \times 10^3$ s^{-1}.
(a) What is the maximum rate of decomposition of penicillin if the enzyme concentration is 6×10^{-7} M?
(b) At what substrate concentration will the rate of decomposition be half that calculated in part (a)?

48. The conversion of dissolved carbon dioxide in blood to HCO_3^- and H_3O^+ is catalyzed by the enzyme carbonic anhydrase. The Michaelis–Menten constants for this enzyme and substrate are $K_m = 8 \times 10^{-5}$ mol L^{-1} and $k_2 = 6 \times 10^5$ s^{-1}.
(a) What is the maximum rate of reaction of carbon dioxide if the enzyme concentration is 5×10^{-6} M?
(b) At what CO_2 concentration will the rate of decomposition be 30% of that calculated in part (a)?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ADDITIONAL PROBLEMS

49. Hemoglobin molecules in blood bind oxygen and carry it to cells, where it takes part in metabolism. The binding of oxygen

$$\text{hemoglobin}(aq) + O_2(aq) \longrightarrow \text{hemoglobin} \cdot O_2(aq)$$

is first order in hemoglobin and first order in dissolved oxygen, with a rate constant of 4×10^7 L mol^{-1} s^{-1}. Calculate the initial rate at which oxygen will be bound to hemoglobin if the concentration of hemoglobin is 2×10^{-9} M and that of oxygen is 5×10^{-5} M.

* 50. Suppose 1.00 L of 9.95×10^{-3} M $S_2O_3^{2-}$ is mixed with 1.00 L of 2.52×10^{-3} M H_2O_2 at a pH of 7.0 and a temperature of 25°C. These species react by two competing pathways, represented by the balanced equations

$$S_2O_3^{2-} + 4\ H_2O_2 \longrightarrow 2\ SO_4^{2-} + H_2O + 2\ H_3O^+$$

$$2\ S_2O_3^{2-} + H_2O_2 + 2\ H_3O^+ \longrightarrow S_4O_6^{2-} + 4\ H_2O$$

At the instant of mixing, the thiosulfate ion ($S_2O_3^{2-}$) is observed to be disappearing at the rate of 7.9×10^{-7} mol L^{-1} s^{-1}. At the same moment, the H_2O_2 is disappearing at the rate of 8.8×10^{-7} mol L^{-1} s^{-1}.

(a) Compute the percentage of the $S_2O_3^{2-}$ that is, at that moment, reacting according to the first equation.

(b) It is observed that the hydronium ion concentration drops. Use the data and answer from part (a) to compute how many milliliters per minute of 0.100 M H_3O^+ must be added to keep the pH equal to 7.0.

51. 8.23×10^{-3} mol of InCl(s) is placed in 1.00 L of 0.010 M HCl(aq) at 75°C. The InCl(s) dissolves quite quickly, and then the following reaction occurs:

$$3\ In^+(aq) \longrightarrow 2\ In(s) + In^{3+}(aq)$$

As this disproportionation proceeds, the solution is analyzed at intervals to determine the concentration of $In^+(aq)$ that remains.

Time (s)	[In^+] (mol L^{-1})
0	8.23×10^{-3}
240	6.41×10^{-3}
480	5.00×10^{-3}
720	3.89×10^{-3}
1000	3.03×10^{-3}
1200	3.03×10^{-3}
10,000	3.03×10^{-3}

(a) Plot ln [In^+] versus time, and determine the apparent rate constant for this first-order reaction.

(b) Determine the half-life of this reaction.

(c) Determine the equilibrium constant K for the reaction under the experimental conditions.

* 52. A compound called di-*t*-butyl peroxide [abbreviation DTBP, formula $(CH_3)_3COOC(CH_3)_3$] decomposes to give acetone [$(CH_3)_2CO$] and ethane (C_2H_6):

$$(CH_3)_3COOC(CH_3)_3\,(g) \longrightarrow 2\ (CH_3)_2CO(g) + C_2H_6(g)$$

The *total* pressure of the reaction mixture changes with time, as shown by the following data at 147.2°C:

Time (min)	P_{tot} (atm)	Time (min)	P_{tot} (atm)
0	0.2362	26	0.3322
2	0.2466	30	0.3449
6	0.2613	34	0.3570
10	0.2770	38	0.3687
14	0.2911	40	0.3749
18	0.3051	42	0.3801
20	0.3122	46	0.3909
22	0.3188		

(a) Calculate the partial pressure of DTBP at each time from these data. Assume that at time 0, DTBP is the only gas present.

(b) Are the data better described by a first-order or a second-order rate expression with respect to DTBP concentration?

53. The reaction of OH^- with HCN in aqueous solution at 25°C has a forward rate constant k_f of 3.7×10^9 L mol^{-1} s^{-1}. Using this information and the measured acid ionization constant of HCN (see Table 15.2), calculate the rate constant k_r in the first-order rate law rate = k_r[CN^-] for the transfer of hydrogen ions to CN^- from surrounding water molecules:

$$H_2O(\ell) + CN^-(aq) \longrightarrow OH^-(aq) + HCN(aq)$$

54. Carbon dioxide reacts with ammonia to give ammonium carbamate, a solid. The reverse reaction also occurs:

$$CO_2(g) + 2\ NH_3(g) \rightleftharpoons NH_4OCONH_2(s)$$

The forward reaction is first order in $CO_2(g)$ and second order in $NH_3(g)$. Its rate constant is 0.238 atm^{-2} s^{-1} at 0.0°C (expressed in terms of partial pressures rather than concentrations). The reaction in the reverse direction is zero order, and its rate constant, at the same temperature, is 1.60×10^{-7} atm s^{-1}. Experimental studies show that, at all stages in the progress of this reaction, the net rate is equal to the forward rate minus the reverse rate. Compute the equilibrium constant of this reaction at 0.0°C.

55. For the reactions

$$I + I + M \longrightarrow I_2 + M$$

$$Br + Br + M \longrightarrow Br_2 + M$$

the rate laws are

$$-\frac{d[I]}{dt} = k_I[I]^2[M]$$

$$-\frac{d[Br]}{dt} = k_{Br}[Br]^2[M]$$

The ratio k_I/k_{Br} at 500°C is 3.0 when M is an Ar molecule. Initially, $[I]_0 = 2[Br]_0$, while [M] is the same for both reactions and is much greater than $[I]_0$. Calculate the ratio of the

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

time required for [I] to decrease to half its initial value to the same time for [Br] at 500°C.

56. In some reactions there is a competition between kinetic control and thermodynamic control over product yields. Suppose compound A can undergo two elementary reactions to stable products:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B \quad \text{or} \quad A \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C$$

For simplicity we assume first-order kinetics for both forward and reverse reactions. We take the numerical values $k_1 = 1 \times 10^8\ s^{-1}$, $k_{-1} = 1 \times 10^2\ s^{-1}$, $k_2 = 1 \times 10^9\ s^{-1}$, and $k_{-2} = 1 \times 10^4\ s^{-1}$.

(a) Calculate the equilibrium constant for the equilibrium

$$B \rightleftharpoons C$$

From this value, give the ratio of the concentration of B to that of C at equilibrium. This is an example of thermodynamic control.

(b) In the case of kinetic control, the products are isolated (or undergo additional reaction) before the back reactions can take place. Suppose the back reactions in the preceding example (k_{-1} and k_{-2}) can be ignored. Calculate the concentration ratio of B to C reached in this case.

57. Compare and contrast the mechanisms for the two gas-phase reactions

$$H_2 + Br_2 \longrightarrow 2\ HBr$$

$$H_2 + I_2 \longrightarrow 2\ HI$$

58. In Section 18.4 the steady-state approximation was used to derive a rate expression for the decomposition of $N_2O_5(g)$:

$$\text{rate} = \frac{k_1 k_2 [M][N_2O_5]}{k_2 + k_{-1}[M]} = k_{\text{eff}}[N_2O_5]$$

At 300 K, with an excess of nitrogen present, the following values of k_{eff} as a function of total pressure were found:

P (atm)	k_{eff} (s^{-1})	P (atm)	k_{eff} (s^{-1})
9.21	0.265	0.625	0.116
5.13	0.247	0.579	0.108
3.16	0.248	0.526	0.104
3.03	0.223	0.439	0.092
		0.395	0.086

Use the data to estimate the value of k_{eff} at very high total pressure and the value of k_1 in L mol^{-1} s^{-1}.

59. The decomposition of ozone by light can be described by the mechanism

$$O_3 + \text{light} \xrightarrow{k_1} O_2 + O$$

$$O + O_2 + M \xrightarrow{k_2} O_3 + M$$

$$O + O_3 \xrightarrow{k_3} 2\ O_2$$

with the overall reaction being

$$2\ O_3 + \text{light} \longrightarrow 3\ O_2$$

The rate constant k_1 depends on the light intensity and the type of light source used. By making a steady-state approximation for the concentration of oxygen atoms, express the rate of formation of O_2 in terms of the O_2, O_3, and M concentrations and the elementary rate constants. Show that only the ratio k_3/k_2, and not the individual values of k_2 and k_3, affects the rate.

* 60. In Section 18.4 we considered the following mechanism for the reaction of Br_2 with H_2:

$$Br_2 + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Br + Br + M$$

$$Br + H_2 \xrightarrow{k_2} HBr + H$$

$$H + Br_2 \xrightarrow{k_3} HBr + Br$$

Although this is adequate for calculating the *initial* rate of reaction, before product HBr builds up, there is an additional process that can participate as the reaction continues:

$$HBr + H \xrightarrow{k_4} H_2 + Br$$

(a) Write an expression for the rate of change of [H].

(b) Write an expression for the rate of change of [Br].

(c) As hydrogen and bromine atoms are both short-lived species, we can make the steady-state approximation and set the rates from parts (a) and (b) to 0. Express the steady-state concentrations [H] and [Br] in terms of concentrations of H_2, Br_2, HBr, and M. [*Hint:* Try adding the rate for part (a) to that for part (b).]

(d) Express the rate of production of HBr in terms of concentrations of H_2, Br_2, HBr, and M.

61. The following observations have been made about a certain reacting system: (i) When A, B, and C are mixed at about equal concentrations in neutral solution, two different products are formed, D and E, with the amount of D about 10 times as great as the amount of E. (ii) If everything is done as in (i) except that a trace of acid is added to the reaction mixture, the same products are formed, except that now the amount of D produced is much smaller than (about 1% of) the amount of E. The acid is not consumed in the reaction. The following mechanism has been proposed to account for some of these observations and others about the order of the reactions:

(1) $A + B \underset{k_{-1}}{\overset{k_2}{\rightleftharpoons}} F$ (rapid equilibrium)

(2) $C + F \xrightarrow{k_2} D$ (negligible reverse rate)

(3) $C + F \xrightarrow{k_3} E$ (negligible reverse rate)

(a) Explain what this proposed scheme of reactions implies about the dependence (if any) of the rate of formation of D on the concentrations of A, of B, and of C. What about the dependence (if any) of the rate of formation of E on these same concentrations? (b) What can you say about the relative magnitudes of k_2 and k_3? (c) What explanation can you give for observation (ii) in view of your answer to (b)?

62. Iron(II) ion is oxidized by chlorine in aqueous solution, the overall equation being

$$2\ Fe^{2+} + Cl_2 \longrightarrow 2\ Fe^{3+} + 2\ Cl^-$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

It is found experimentally that the rate of the overall reaction is decreased when either the iron(III) ion or the chloride-ion concentration is increased. Which of the following possible mechanisms is consistent with the experimental observations?

(a) (1) $Fe^{2+} + Cl_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Fe^{3+} + Cl^- + Cl$ (rapid equilibrium)

(2) $Fe^{2+} + Cl \xrightarrow{k_2} Fe^{3+} + Cl^-$ (negligible reverse rate)

(b) (3) $Fe^{2+} + Cl_2 \underset{k_{-3}}{\overset{k_3}{\longrightarrow}} Fe(IV) + 2\ Cl^-$ (rapid equilibrium)

(4) $Fe(IV) + Fe^{2+} \xrightarrow{k_4} 2\ Fe^{3+}$ (negligible reverse rate)

where Fe(IV) is Fe in the (+IV) oxidation state.

63. Manfred Eigen, a German physical chemist working during the 1970s and 1980s, earned a Nobel Prize for developing the "temperature-jump" method for studying kinetics of very rapid reactions in solution, such as proton transfer. Eigen and his co-workers found that the specific rate of proton transfer from a water molecule to an ammonia molecule in a dilute aqueous solution is $k = 2 \times 10^5\ s^{-1}$. The equilibrium constant K_b for the reaction of ammonia with water is 1.8×10^{-5} M. What, if anything, can be deduced from this information about the rate of transfer of a proton from NH_4^+ to a hydroxide ion? Write equations for any reactions you mention, making it clear to which reaction(s) any quoted constant(s) apply.

64. Consider the reaction

$$A + B \rightleftharpoons C + D$$

with all reactants and products gaseous (for simplicity) and an equilibrium constant K. (a) Assume that the elementary steps in the reaction are those indicated by the stoichiometric equation (in each direction), with specific rate constants for the forward reaction and the reverse reaction, respectively, k_f and k_r. Derive the relation between k_f, k_r, and K. Comment on the general validity of the assumptions made about the relation of elementary steps and the stoichiometric equation and also on the general validity of K. (b) Assume that the reaction as written is exothermic. Explain what this implies about the change of K with temperature. Explain also what it implies about the relation of the activation energies of the forward and reverse reactions and how this relation is consistent with your statement about the variation of K with temperature.

65. The gas-phase decomposition of acetaldehyde can be represented by the overall chemical equation

$$CH_3CHO \longrightarrow CH_4 + CO$$

It is thought to occur through the sequence of reactions

$$CH_3CHO \longrightarrow CH_3 + CHO$$

$$CH_3 + CH_3CHO \longrightarrow CH_4 + CH_2CHO$$

$$CH_2CHO \longrightarrow CO + CH_3$$

$$CH_3 + CH_3 \longrightarrow CH_3CH_3$$

Show that this reaction mechanism corresponds to a chain reaction, and identify the initiation, propagation, and termination steps.

66. Lanthanum(III) phosphate crystallizes as a hemihydrate, $LaPO_4 \cdot \frac{1}{2}\ H_2O$. When it is heated, it loses water to give anhydrous lanthanum(III) phosphate:

$$2(LaPO_4 \cdot \tfrac{1}{2}\ H_2O(s)) \longrightarrow 2\ LaPO_4(s) + H_2O(g)$$

This reaction is first order in the chemical amount of $LaPO_4 \cdot \frac{1}{2}\ H_2O$. The rate constant varies with temperature as follows:

Temperature (°C)	k (s^{-1})
205	2.3×10^{-4}
219	3.69×10^{-4}
246	7.75×10^{-4}
260	12.3×10^{-4}

Compute the activation energy of this reaction.

67. The water in a pressure cooker boils at a temperature greater than 100°C because it is under pressure. At this higher temperature, the chemical reactions associated with the cooking of food take place at a greater rate.
(a) Some food cooks fully in 5 min in a pressure cooker at 112°C and in 10 minutes in an open pot at 100°C. Calculate the average activation energy for the reactions associated with the cooking of this food.
(b) How long will the same food take to cook in an open pot of boiling water in Denver, where the average atmospheric pressure is 0.818 atm and the boiling point of water is 94.4°C?

68. (a) A certain first-order reaction has an activation energy of 53 kJ mol^{-1}. It is run twice, first at 298 K and then at 308 K (10°C higher). All other conditions are identical. Show that, in the second run, the reaction occurs at double its rate in the first run.
(b) The same reaction is run twice more at 398 K and 408 K. Show that the reaction goes 1.5 times as fast at 408 K as it does at 398 K.

* 69. The gas-phase reaction between hydrogen and iodine

$$H_2(g) + I_2(g) \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 2\ HI(g)$$

proceeds with a forward rate constant at 1000 K of k_f = 240 L $mol^{-1}\ s^{-1}$ and an activation energy of 165 kJ mol^{-1}. By using this information and data from Appendix D, calculate the activation energy for the reverse reaction and the value of k_r at 1000 K. Assume that ΔH and ΔS for the reaction are independent of temperature between 298 and 1000 K.

70. The following reaction mechanism has been proposed for a chemical reaction:

$$A_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A + A \quad \text{(fast equilibrium)}$$

$$A + B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} AB \quad \text{(fast equilibrium)}$$

$$AB + CD \xrightarrow{k_3} AC + BD \quad \text{(slow)}$$

(a) Write a balanced equation for the overall reaction.
(b) Write the rate expression that corresponds to the preceding mechanism. Express the rate in terms of concentrations of reactants only (A_2, B, CD).
(c) Suppose that the first two steps in the preceding mechanism are endothermic and the third one is exothermic. Will an increase in temperature increase the reaction rate constant, decrease it, or cause no change? Explain.

71. How would you describe the role of the CF_2Cl_2 in the reaction mechanism of Problem 21?

72. In Section 18.7 we wrote a mechanism in which silver ions catalyze the reaction of Tl^+ with Ce^{4+}. Determine the rate law for this mechanism by making a steady-state approximation for the concentration of the reactive intermediate Ag^{2+}.

73. The rates of enzyme catalysis can be lowered by the presence of inhibitor molecules I, which bind to the active site of the enzyme. This adds the following additional step to the reaction mechanism considered in Section 18.7:

$$E + I \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} EI \qquad \text{(fast equilibrium)}$$

Determine the effect of the presence of inhibitor at total concentration $[I]_0 = [I] + [EI]$ on the rate expression for formation of products derived at the end of this chapter.

74. The enzyme lysozyme kills certain bacteria by attacking a sugar called *N*-acetylglucosamine (NAG) in their cell walls. At an enzyme concentration of 2×10^{-6} M, the maximum rate for substrate (NAG) reaction, found at high substrate concentration, is 1×10^{-6} mol L^{-1} s^{-1}. The rate is reduced by a factor of 2 when the substrate concentration is reduced to 6×10^{-6} M. Determine the Michaelis–Menten constants K_m and k_2 for lysozyme.

CUMULATIVE PROBLEMS

75. The rate of the gas-phase reaction

$$H_2 + I_2 \longrightarrow 2\ HI$$

is given by

$$\text{rate} = -\frac{d[I_2]}{dt} = k[H_2][I_2]$$

with $k = 0.0242$ L mol^{-1} s^{-1} at 400°C. If the initial concentration of H_2 is 0.081 mol L^{-1} and that of I_2 is 0.036 mol L^{-1}, calculate the initial rate at which heat is absorbed or emitted during the reaction. Assume that the enthalpy change at 400°C is the same as that at 25°C.

76. The rate of the reaction

$$2\ ClO_2(aq) + 2\ OH^-(aq) \longrightarrow ClO_3^-(aq) + ClO_2^-(aq) + H_2O(\ell)$$

is given by

$$\text{rate} = k[ClO_2]^2[OH^-]$$

with $k = 230$ L^2 mol^{-2} s^{-1} at 25°C. A solution is prepared that has initial concentrations $[ClO_2] = 0.020$ M, $[HCN] = 0.095$ M, and $[CN^-] = 0.17$ M. Calculate the initial rate of the reaction.

77. A gas mixture was prepared at 500 K with total pressure 3.26 atm and a mole fraction of 0.00057 of NO and 0.00026 of O_3. The elementary reaction

$$NO + O_3 \longrightarrow NO_2 + O_2$$

has a second-order rate constant of 7.6×10^7 L mol^{-1} s^{-1} at this temperature. Calculate the initial rate of the reaction under these conditions.

78. The activation energy for the reaction

$$2\ NO_2 \longrightarrow 2\ NO + O_2$$

is $E_a = 111$ kJ mol^{-1}. Calculate the root-mean-square velocity of an NO_2 molecule at 400 K and compare it to the velocity of an NO_2 molecule with kinetic energy E_a/N_A.

A spent fuel rod assembly being lowered into a cooling pond for long term storage. The blue glow is Cerenkov radiation, which is emitted by energetic charged particles as they travel through water.

Matter and energy are separately conserved in ordinary chemical reactions, and the identities of the atoms don't change as the bonds of the reactants are broken and those of the products are formed. A number of key experiments conducted around the turn of the nineteenth century established conclusively that elements could be transformed into one another by radioactive decay, an observation that required the formulation of new conservation laws. Einstein's special theory of relativity provided the solution to this problem by introducing the concept of mass–energy equivalence, which is summarized by the famous equation $E = mc^2$. Mass and energy are fundamentally equivalent, they can be intercon-

verted, and it is only their sum that is conserved. The special theory of relativity accounted for the transmutation of the elements and also predicted that enormous quantities of energy could be generated by the conversion of very small quantities of mass. The field of **nuclear chemistry** encompasses a broad range of topics that include: fundamental studies of the structure and properties of nuclei; their reactions, including radioactive decay; areas of geochemistry and astrophysics in which nuclear processes are important; and a diverse array of applications, particularly those in medicine. We introduce you to the basic concepts of nuclear chemistry and discuss a number of familiar applications in this chapter.

19.1 RADIOACTIVITY

J. J. Thomson and W. Wien discovered and characterized two new, and quite different, kinds of particles that comprise matter: a light particle with a negative charge that appeared to be a common constituent of all atoms, and a number of much heavier, positively charged particles whose relative masses depended on the elements from which they were produced (see Section 1.4). Although it was generally agreed that these particles were the building blocks of atoms, it was not at all clear how they were assembled. The discovery and characterization of natural radioactivity during this period provided important clues about the nature of these building blocks and how they were assembled to form atoms.

The German physicist Wilhelm Roentgen discovered a new kind of radiation in 1895, while investigating the properties of cathode rays using a Crookes tube. He observed that an image was created on a piece of photographic film lying underneath a Crookes tube that had been wrapped with black paper. Roentgen immediately set out to determine the source and character of the radiation that had exposed the film, realizing that it could not have been exposed by light emitted from the tube. He established that the emission originated from the tube's electrodes and that it could expose film as far as several meters away. The radiation was not deflected by magnetic fields, like cathode rays or canal rays, which led Roentgen to conclude that it was a new kind of electromagnetic radiation that he called X-rays, merely to distinguish them from other kinds of electromagnetic radiation. He found that X-rays easily penetrated paper, wood, single sheets of aluminum foil, stacks of aluminum foil more than a centimeter thick, and, perhaps most importantly, his hand. Roentgen could clearly see the bones of his hand, outlined by weaker images of his skin and flesh. The medical X-ray had been born.

Radioactivity from natural sources was discovered shortly thereafter by the French physicists Henri Becquerel and Marie and Pierre Curie. Becquerel showed that uranium metal and its salts darkened photographic plates that were shielded from light by black paper. He identified these rays as electrons by measuring their charge-to-mass ratio, using the approach developed by Thomson. Marie Curie initiated a systematic search for radioactivity among the elements using a very simple and rapid screening procedure; she simply measured the current generated when radioactive elements ionized the air contained in a small cell. Madame Curie soon discovered radioactive thorium, and she began to isolate other radioactive substances from their ores by chemical separation, in collaboration with her husband Pierre. They isolated a new radioactive element from bismuth, with similar chemical properties, and named it polonium in honor of her native country. Their second discovery was the radioactive element radium, with chemical properties similar to barium. The Curies demonstrated that these elements were transformed into other elements by radioactive decay, in violation of one of the key postulates of Dalton's atomic theory, a result that stimulated intense interest in discovering the mechanism of radioactive decay.

The nature of the radiation emitted from the elements was first characterized (or at least named) by the New Zealand physicist Ernest Rutherford. He had inves-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tigated the ionization of air by X-rays as a student in Cambridge, which provided him with the experimental background he needed to investigate natural radioactivity. Rutherford first demonstrated that the radiation emitted by uranium was not refracted (bent) by materials, like light passing through glass, and was therefore not a form of electromagnetic radiation like X-rays. He then measured how effectively the radiation was absorbed by different thicknesses of aluminum placed between the source and a piece of photographic film or an electrometer. The intensity initially fell off very quickly with thickness and then much more slowly, which suggested that the radiation was complex, with two components that Rutherford named α and β, on the basis of penetrating ability. α particles are completely blocked by a single sheet of paper (0.05 mm thick), whereas β rays penetrate millimeters into most materials. Paul Villard, a French chemist and physicist, discovered a third kind of natural radioactivity in 1900, one that could penetrate several inches of lead. These rays were called γ rays because of their greater penetrating power. γ rays were not deflected by electric or magnetic fields, which established that they were not charged particles. They were refracted by materials such as aluminum and were determined to be a form of electromagnetic radiation.

The English chemist Frederick Soddy, in collaboration with Rutherford, interpreted the radioactive decay series of uranium and thorium in terms of a sequential transmutation of elements from parent to daughter accompanied by the emission of α or β particles. Soddy proposed the concept of isotopes, which was confirmed by Thomson using mass spectrometry, as discussed in Chapter 1. Rutherford produced the first artificial transmutation of an element in the laboratory by bombarding nitrogen gas with α particles and detecting protons, from which it was later concluded that ^{14}N had been converted into ^{17}O in a nuclear reaction. He also showed, at about this same time, that α particles were He atoms that carried two units of positive charge by measuring their charge-to-mass ratios, and by physically trapping and identifying the He gas produced. These key experiments provided the foundation upon which the fields of nuclear physics and chemistry have been built.

Detecting and Measuring Radioactivity

Many methods have been developed to detect, identify, and quantitatively measure the products of nuclear reactions. Some are quite simple, but others require complex electronic instrumentation. Perhaps the simplest radiation detector is the **photographic emulsion,** first used by Becquerel in 1896 when he reported his observation that potassium uranyl sulfate ($K_2UO_2(SO_4)_2 \cdot 2H_2O$) could expose a photographic plate that was shielded from light. Similar detectors are still used today in the form of film badges that are worn to monitor exposure to penetrating radiation in workplaces such as laboratories that use radioactive isotopes as labels, medical radiology facilities, and nuclear power plants, for example. These detectors measure cumulative exposure; the degree of darkening is proportional to the quantity of radiation received during a specified monitoring period.

Rutherford and his students used a screen coated with zinc sulfide to visually detect the arrival of alpha particles by observing the pinpoint scintillations of light they produce. They plotted the number of scintillations per minute as a function of scattering angle, against which Rutherford compared the results of scattering models that led to the most accurate estimate of the size of the gold nucleus. That simple device has been developed into the modern **scintillation counter.** Instead of a ZnS screen, the modern scintillation counter uses a crystal of sodium iodide, in which a small fraction of the Na^+ ions have been replaced by thallium (Tl^+) ions. The Na(Th)I crystal emits a pulse of light when it absorbs a beta particle or a gamma ray, and a photomultiplier tube detects and counts the light pulses. The intensity of the radiation is measured by counting the rate at which light pulses are emitted, and the energy of the radiation is measured by the intensity of the pulses. High-

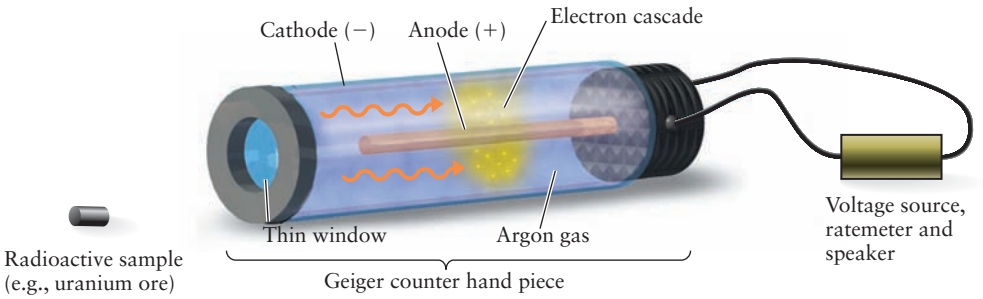

FIGURE 19.1 In a Geiger tube, radiation ionizes gas in the tube, freeing electrons that are accelerated to the anode wire in a cascade. Their arrival creates an electrical pulse, which is detected by a ratemeter. The ratemeter displays the accumulated pulses as the number of ionization events per minute.

energy photons or particles produce a large number of lower-energy photons, with the number being proportional to the energy of the incident radiation, so these detectors are useful in measuring energy distributions in nuclear physics experiments or detecting radiation from multiple sources within a given sample.

The **Geiger counter** (Fig. 19.1) consists of a cylindrical tube, usually made of glass, coated internally with metal to provide a negative electrode, with a wire down the center for a positive electrode. The tube is filled to a total pressure of about 0.1 atm with a mixture of 90% argon and 10% ethyl alcohol vapor, and a potential difference of about 1000 V is applied across the electrodes. When a high-energy electron (beta particle) enters the tube, it produces positive ions and electrons. The light electrons are quickly accelerated toward the positively charged wire. As they advance, they encounter and ionize other neutral atoms. An avalanche of electrons builds up, and a large electron current flows into the central wire. This causes a drop in the potential difference, which is recorded, and the electrical discharge is quenched by the alcohol molecules. In this way single beta particles produce electrical pulses that can be amplified and counted. Portable Geiger counters are widely used in uranium prospecting and to measure radiation in workplaces. Various tube sizes are used to detect different levels of radiation, and modifications must be made to detect γ rays efficiently because of their low absorption cross sections. **Proportional counters** are devices that are similar to Geiger counters but with the ability to measure energies like scintillation counters. They are filled with inert gases (typically He or Ar) along with a small partial pressure of a polyatomic molecule like CH_4 that improves the instrument response time. The magnitude of each current pulse in these counters is proportional to the energy of the incident particles, hence the name. Proportional counters can be modified to detect neutrons by using $^{10}BF_3$ as the fill gas, which efficiently captures neutrons to form an unstable nucleus that decays by emitting α particles, which are readily detected. Finally, most modern detectors are solid-state semiconductor devices in which a particle or ray of ionizing radiation creates a number of electron-hole pairs in a semiconductor junction (see Section 22.7) producing a current pulse that is proportional to the energy of the incident radiation.

19.2 NUCLEAR STRUCTURE AND NUCLEAR DECAY PROCESSES

Let's begin by reviewing the essential features of nuclear structure introduced in Section 1.4 and introducing you to elements of a more complete picture of nuclear structure that will help you visualize nuclear decay processes. Nuclei are built up from two kinds of **nucleons,** protons and neutrons, with the number of protons being given by the **atomic number** Z and the number of neutrons being given by the **neutron number** N. The mass number A is the sum of the number of protons and neutrons; $A = Z + N$. **Nuclides** are distinct atomic species characterized by their atomic number Z, mass number A, and nuclear energy state (analogous to the elec-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tronic states of atoms). Each nuclide is identified by the symbol ${}^{A}_{Z}Z$, where Z is the chemical symbol for the element and the subscript z is the atomic number. **Isotopes** are elements with the same number of protons but different numbers of neutrons, **isotones** are nuclides with the same number of neutrons but different numbers of protons, and **isobars** are nuclides with the same mass number but different numbers of protons and neutrons. You should already be familiar with isotopes; isotones have similar nuclear properties in the same way that isotopes have similar chemical properties, and isobars play an important role in helping us understand the driving forces and mechanisms associated with nuclear decay processes.

The symbols for and masses of selected elementary particles and atoms are listed in Table 19.1. The atomic number is given by the left subscript and the mass number by the left superscript for nucleons. The symbol for the electron is ${}^{0}_{-1}e^{-}$ and that of its antimatter counterpart the **positron** is ${}^{0}_{1}e^{+}$, with the charge also being specified by the left subscript and the mass number (essentially zero, relative to the nucleons) being specified by the left superscript. There is some redundancy in this notation, as the chemical symbol of the element implies its atomic number and the charges of the electron and positron are written in two places. This redundancy is useful when balancing nuclear reaction. Masses of the elementary particles are listed both in atomic mass units (u) as well as in kilograms, but the masses of the atoms are listed only in atomic mass units. An **atomic mass unit** is defined as exactly

TABLE 19.1

Masses of Selected Elementary Particles and Atoms

Elementary Particle	Symbol	Mass (u)	Mass (kg)
Electron, beta particle	${}^{0}_{-1}e^{-}$	0.000548579911	$9.1093819 \times 10^{-31}$
Positron	${}^{0}_{1}e^{+}$	0.000548579911	$9.1093819 \times 10^{-31}$
Proton	${}^{0}_{1}p^{+}$	1.0072764669	$1.6726216 \times 10^{-27}$
Neutron	${}^{0}_{1}n$	1.0086649158	$1.6749272 \times 10^{-27}$

Atom	Mass (u)	Atom	Mass (u)
${}^{1}_{1}H$	1.007825032	${}^{23}_{11}Na$	22.9897697
${}^{2}_{1}H$	2.014101778	${}^{24}_{12}Mg$	23.9850419

1/12 the mass of a single atom of ^{12}C, which can be calculated by dividing the atomic mass of ^{12}C by Avogadro's number and converting the result to kilograms.

$$1 \text{ u} = 1.6605387 \times 10^{-27} \text{ kg}$$

Atomic mass units are very convenient units to use when carrying out calculations involving individual elementary particles and atoms. They are numerically equal to atomic masses expressed in grams per mole, and they allow us to do calculations without carrying along large negative powers of 10. The latter advantage is particularly apparent when calculating mass changes associated with nuclear reactions, as discussed later in Section 19.3.

The sizes and densities of nuclei have been determined using a variety of scattering techniques such as Rutherford (α particle) and neutron scattering. The radii of stable nuclei can be estimated using the following empirical rule

$$R = 1.2 \times 10^{-15} A^{1/3} \text{ m}$$

where A is the mass number. This rule has a very simple physical interpretation. We imagine that nuclei are spherical, with volumes that are determined simply by the number of nucleons they contain. The cube root relates the volume to the radius with the constant factor having been determined empirically. Nuclei are really tiny, with radii on the order of 10^{-15} m, about ten thousand times smaller than atomic radii. 1×10^{-15} m is a femtometer, abbreviated as fm, and it is often called a **fermi** in nuclear physics and chemistry, in honor of the Italian physicist Enrico Fermi. The femtometer is a very convenient unit with which to express distances on the nuclear length scale. Nuclei are also very dense, with densities given approximately by

$$\rho = \frac{\text{mass}}{\text{volume}} = \frac{(A)(\text{u})}{\frac{4}{3}\pi R^3} = \frac{(A)(\text{u})}{\frac{4}{3}\pi(1.2 \times 10^{-15} A^{1/3} \text{ m})^3} = 2.3 \times 10^{17} \text{ kg m}$$

in which A is the mass number, u is the atomic mass unit, and the empirical rule has been used to estimate nuclear radii. We see from this expression that the densities of all nuclei are approximately the same (the mass numbers in the numerator and the denominator cancel), which is consistent with our picture of the nucleus as an assembly of close-packed nucleons. Nuclear densities are almost unimaginably huge, about 200,000 metric tons per mm^3!

Nuclei have internal structures and energy levels that are analogous to those of atoms, and an understanding of that structure helps interpret and explain many nuclear phenomena in the same way that quantum mechanics allows us to explain the properties of atoms and molecules. We discuss nuclear structure in more detail in Section 19.8, *A Deeper Look . . .*, but introduce you to some elementary concepts here in order to help you visualize nuclear decay processes on the atomic scale. Figure 19.2a shows an artist's conception of the internal structure of a nucleus, with the protons colored in red and the neutrons colored in blue. Nucleon diameters are about 1 fm, and we consider them to be closely packed in the interior but more loosely arranged near the surface, as shown. The graph in Figure 19.2b shows the relatively constant density of the nuclear core with a less dense "skin" whose thickness is almost the same for all nuclides. Examining this image immediately raises the question "Why are nuclei stable at all?" because the Coulomb repulsion between the protons is enormous at these short separations. Let's calculate the Coulomb potential energy of a pair of protons separated by 1 fm to compare with the electrostatic potential energies we calculated for atoms in Chapter 3. We have two motivations in mind: (1) to establish a relevant energy scale for nuclear reactions and (2) to establish the general characteristics of the force law that binds nucleons together to form stable nuclei.

The potential energy of a system comprising two protons separated by 1 fm is

$$V(R) = \frac{e^2}{4\pi\epsilon_o R} = \frac{(1.602 \times 10^{-19} \text{ C})^2}{(1.13 \times 10^{-10} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})(1 \times 10^{-15} \text{ m})} = 2.306 \times 10^{-13} \text{ J}$$

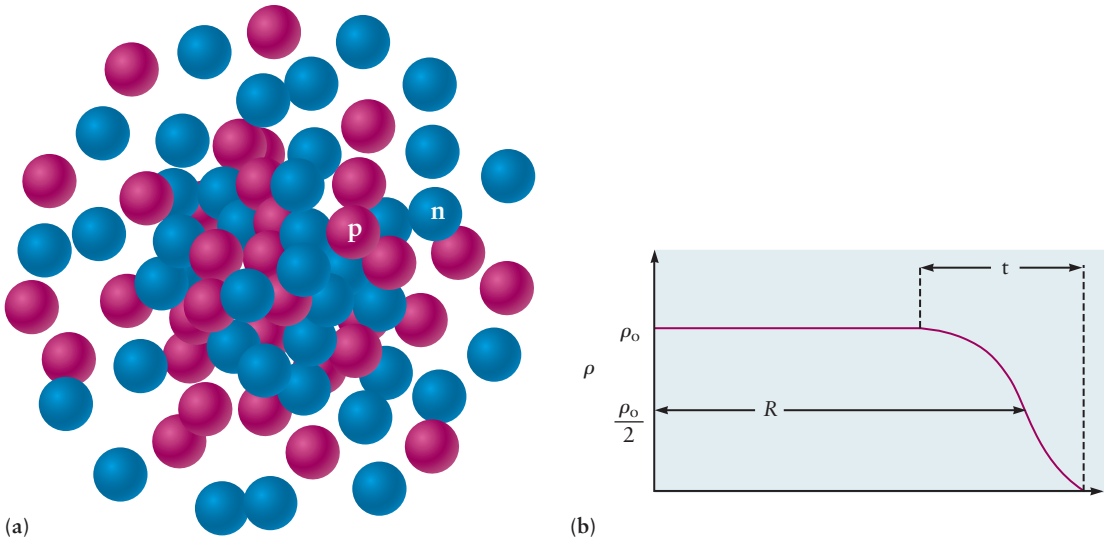

FIGURE 19.2 (a) Artist's conception of the structure of a nucleus, with the protons (p) colored red and the neutrons (n) colored blue. (b) Radial plot of the density of a nucleus. ρ_o is the density at the center of the nucleus, R is the radius at which the density falls to $\rho_{o/2}$, and t is the thickness of the skin as shown schematically.

which is about five orders of magnitude larger than the potential energy of two protons separated by 1 Å, as calculated in Section 3.3. Recall that we introduced the electron volt (eV) in Section 3.3 as a convenient alternative to the joule with which to express energy in atoms and molecules. The **million electron volt** (MeV), by analogy, is a more convenient unit with which to express the much larger energies associated with nuclear processes.

$$1 \text{ MeV} = 1.602176 \times 10^{-13} \text{ J}$$

$^4_2$He is a stable nucleus that contains two protons separated by about 1 fm. What is the nature of the attractive force that must be greater than the repulsive Coulomb force in order to bind helium's two protons to one another? The **strong force,** one of the four fundamental forces in nature, is responsible for binding nucleons together to form stable nuclei. It has the following properties: (1) It is independent of the charges of the nucleons. The attractive forces between pairs of neutrons, between pairs of protons, or between a proton and a neutron are all the same. (2) The potential energy curve is very deep (MeV) and short ranged (fm) with a very sharp cutoff. Evidence that supports this general picture of the nuclear potential is presented later, and model potential energy curves are discussed in more detail in Section 19.8, *A Deeper Look . . . .*

Nucleons themselves have an internal structure, an elementary understanding of which will help you visualize several of the nuclear decay processes. Protons and neutrons are each composed of three fundamental particles called **quarks,** which are characterized by their masses and charges. "Up" and "down" quarks are very light particles with charges $+2/3e$ and $-1/3e$, respectively; the proton contains two up quarks and one down quark with total charge $q_p = (+\frac{2}{3}e + \frac{2}{3}e - \frac{1}{3}e) = +e$, and the neutron contains two down quarks and one up quark with total charge $q_n = (-\frac{1}{3}e - \frac{1}{3}e + \frac{2}{3}e) = 0$. Figure 19.3 shows a schematic of a $^4_2$He atom that gives us a sense of the relative sizes of atoms, electrons, nuclei, protons, neutrons, and quarks. Protons and neutrons interconvert when a quark changes its type or "flavor." Protons are converted into neutrons when an up quark changes into a down quark, emitting a positron and a neutrino, whereas neutrons are converted into protons when a down quark changes into an up quark, emitting an electron and an antineutrino. These processes are represented by the following nuclear reactions

$$^1_1p^+ \longrightarrow {}^1_0n + {}^0_{+1}e^- + \nu$$
$$^1_0n \longrightarrow {}^1_1p^+ + {}^0_{-1}e^- + \tilde{\nu}$$

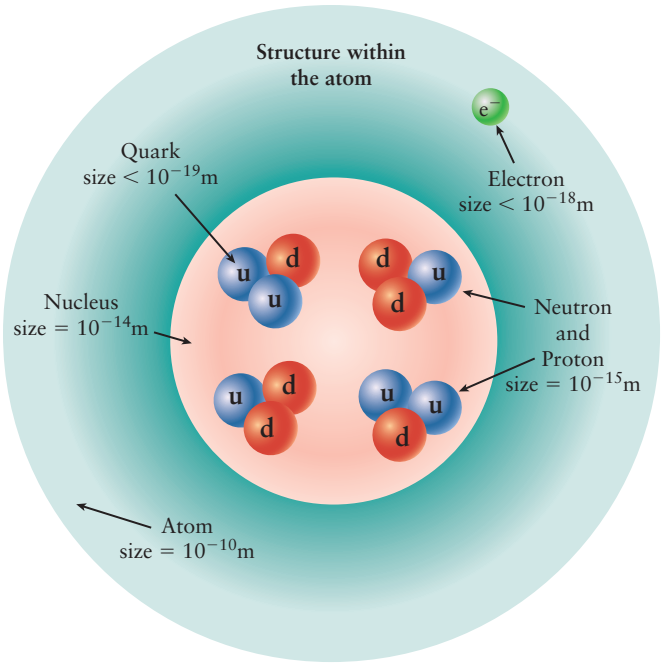

FIGURE 19.3 Artist's conception of the structure of a helium nucleus that contains two protons and two neutrons. The protons each have two up quarks and one down quark, and the neutrons have two down quarks and one up quark.

in which ${}_{1}^{1}p^{+}$ and ${}_{0}^{1}n$ represent a proton and a neutron, ${}_{+1}^{0}e^{+}$ and ${}_{-1}^{0}e^{-}$ represent a positron and an electron, and ν and $\tilde{\nu}$ represent a neutrino and an antineutrino, respectively. We discuss writing and balancing nuclear reactions later, but we call your attention to the following two pairs of particles: the positron and the electron, and the neutrino and the antineutrino. These particles are matter–antimatter pairs, both particles of the pair having the same mass but different charges in the former pair, and the same mass but different spin in the case of the latter pair. The antimatter particles exist only transiently because they are annihilated when they collide with their ordinary matter counterparts. Collisions between electrons and positrons annihilate both particles, resulting in the emission of a pair of γ rays, a process of central importance in positron emission tomography discussed in the accompanying *Connection to Medicine*.

Nuclear Decay Processes

There are thousands of known isotopes of the elements, only about 275 of which are considered "stable"; that is, they show no evidence of radioactive decay whatsoever. Figure 19.4 shows a plot of the neutron number N as a function of the atomic number Z for a large number of nuclides. The stable nuclides (blue dots) follow a line with slope $N/Z = 1$ for $Z < 40$ or so and another line with slope $N/Z \approx 1.5$ for $Z > 40$. Radioactive nuclides are represented by red dots, and regions over which a given radioactive decay mode dominates are identified. The radioactive isotopes decay by the three basic processes characterized by Rutherford, which we examine in more detail here. Table 19.2 lists the characteristics of these processes, which are organized into three classes: α, β, and γ, with β decay having three distinct, but related, modes. Changes in the atomic number, neutron number, mass number, and charge are given for each decay mode, as well as typical energies of the emitted particle, an example, and conditions that favor decay by each process. Let's examine the general characteristics of each of these classes before discussing them in detail.

Alpha decay is the spontaneous emission of α particles (${}_{2}^{4}\text{He}$ nuclei) from heavy nuclei ($Z > 83$) that reduces the Coulomb repulsion between protons; the parent nucleus loses two protons and two neutrons. There are three different modes of β decay: β^{-} (electron) emission, β^{+} (positron) emission, and EC (electron capture).

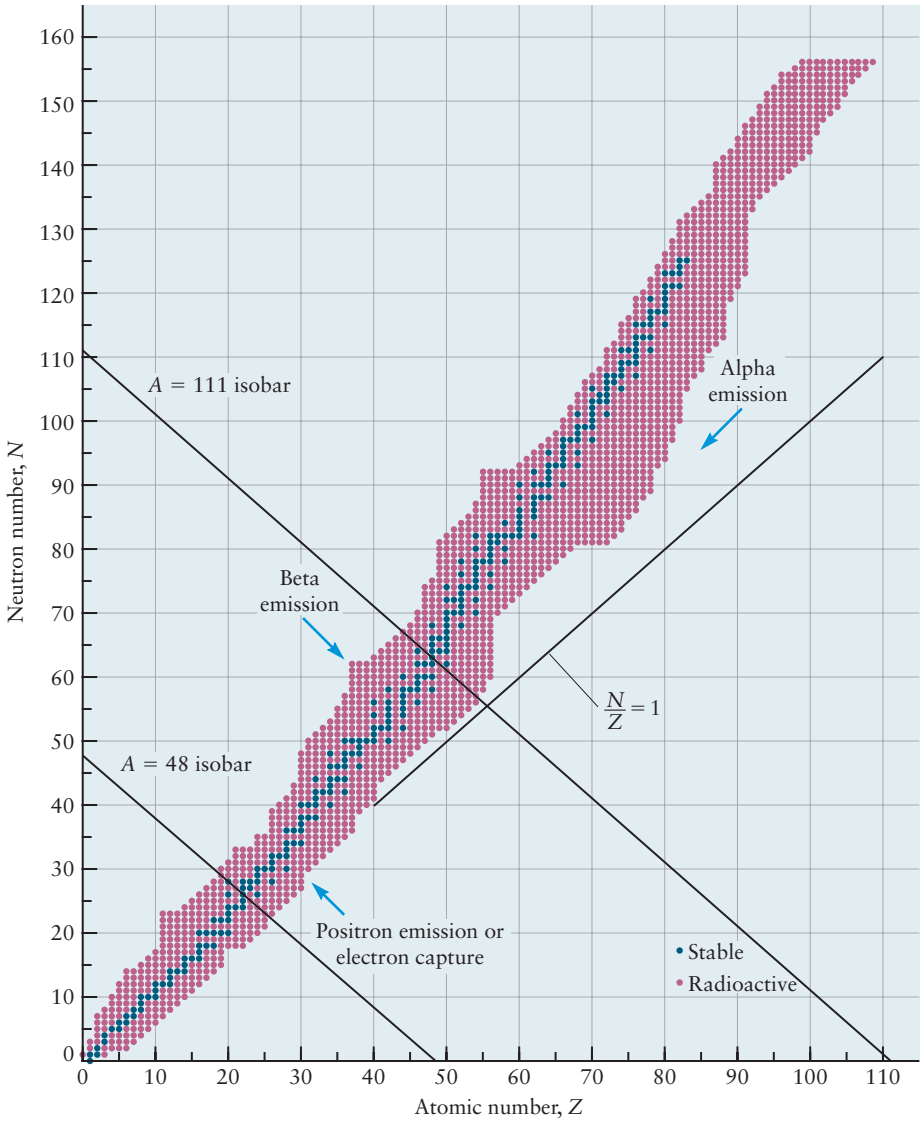

FIGURE 19.4 A plot of N versus Z for a number of nuclides, with the stable nuclides represented by blue dots and the unstable nuclides represented by red dots. The stable nuclides lie along a "line of stability," with slope $N/Z = 1$ (shown) for the lighter elements, increasing to 1.5 for the heavier elements. Regions in which particular decay processes dominate are labeled. The $A = 48$ and $A = 111$ isobars shown are two families of nuclides with mass numbers 48 and 111, respectively.

TABLE 19.2

Characteristics of Radioactive Decay

Decay Type	Emitted Particle	ΔZ	ΔN	ΔA	Typical Energy of Emitted Particle	Example	Occurrence
α	$^4He^{2+}$	−2	−2	−4	$4 \le E_\alpha \le 10$ MeV	$^{238}U \longrightarrow {}^{234}Th + \alpha$	$Z > 83$
β^-	Energetic e^-, $\bar{\nu}_e$	+1	−1	0	$0 \le E_{\beta^-} \le 2$ MeV	$^{14}C \longrightarrow {}^{14}N + \beta^- + \bar{\nu}_e$	$(N/Z) > (N/Z)_{stable}$
β^+	Energetic e^+, ν_e	−1	+1	0	$0 \le E_{\beta^+} \le 2$ MeV	$^{22}Na \longrightarrow {}^{22}Ne + \beta^+ + \nu_e$	$(N/Z) < (N/Z)_{stable}$ light nuclei
EC	ν_e	−1	+1	0	$0 \le E_\nu \le 2$ MeV	$e^- + {}^{207}Bi \longrightarrow {}^{207}Pb + \nu_e$	$(N/Z) < (N/Z)_{stable}$ heavy nuclei
γ	Photon	0	0	0	$0.1 \le E_\gamma \le 2$ MeV	$^{60}Ni^* \longrightarrow {}^{60}Ni + \gamma$	Any excited nucleus
IC	Electron	0	0	0	$0.1 < E_e < 2$ MeV	$^{125}Sb^m \longrightarrow {}^{125}Sb + e^-$	Cases where γ-ray emission is inhibited

These processes convert neutrons into protons (and vice versa) to bring the N/Z ratio closer to the line of stability. Neutron-rich nuclei decay by electron emission, whereas proton-rich nuclei decay either by positron emission or by electron capture. The decay energy is shared among all particles in electron and positron emission, whereas almost all of the energy is carried away by the neutrino in electron capture. γ-ray emission occurs when nuclei in excited states decay to states of lower energy, by analogy to the emission of electromagnetic radiation by atoms and molecules in electronically excited states. Internal conversion (IC) is the relaxation of an excited nuclear state by electron emission. We mention, but do not discuss, two other decay modes for nuclei located very far from the line of stability. Nuclides with very large N/Z ratios can decay by **proton emission,** in which protons simply "boil off" from nuclei. Conversely, nuclides with very small N/Z ratios can decay by **neutron emission,** in which neutrons "boil off." Finally, unstable nuclei can decay by spontaneous **fission** in which they split up into two daughter nuclei of roughly equal size. Nuclear fission is discussed in Section 19.6.

Nuclear reactions are written and balanced much like chemical reactions, with both the mass number A and the electric charge being conserved. We represent the elementary particles by the symbols ${}^{0}_{-1}e^{-}$, ${}^{1}_{1}p^{+}$, and ${}^{1}_{0}n$ to help remind us to include their mass number and charge when balancing nuclear reaction. Examples include

$$^{235}_{92}\mathrm{U} + {}^{1}_{0}n \longrightarrow {}^{236}_{92}\mathrm{U}$$

$$^{232}_{90}\mathrm{Th} \longrightarrow {}^{228}_{88}\mathrm{Ra} + {}^{4}_{2}\mathrm{He}$$

$$^{3}_{1}\mathrm{H} \longrightarrow {}^{3}_{2}\mathrm{He} + {}^{0}_{-1}e$$

Alpha Decay

Proton-rich nuclei can decay into more stable isotopes by emitting α particles (${}^{4}_{2}\mathrm{He}$ nuclei), which reduces the atomic number Z and the neutron number N by 2, resulting in a decrease of the mass number A of 4. Figure 19.5 is a pictorial representation of α decay. Most of the energy is carried away by the lighter α particles, with a small fraction appearing as recoil energy of the heavier daughter nuclei. There are many examples of α decay that can be taken from the three naturally occurring decay series that begin with ^{238}U, ^{235}U, and ^{232}Th. These include:

$$^{238}_{92}\mathrm{U} \longrightarrow {}^{234}_{90}\mathrm{Th} + {}^{4}_{2}\mathrm{He}$$

$$^{222}_{86}\mathrm{Ru} \longrightarrow {}^{218}_{84}\mathrm{Po} + {}^{4}_{2}\mathrm{He}$$

$$^{210}_{84}\mathrm{Po} \longrightarrow {}^{206}_{82}\mathrm{Pb} + {}^{4}_{2}\mathrm{He}$$

from the ^{238}U series (see Fig. 19.5). The first reaction has an extremely long half-life, some billions of years, whereas the second and third reactions have half-lives on the order of days (see Section 19.4). Radon produced by decay of ^{238}U in rocks can accumulate in homes and buildings, where it is estimated to cause more than 20,000 lung cancer deaths annually in the United States (see Cumulative Exercise). ^{210}Po is present in tobacco, where it contributes to lung cancer deaths in smokers in addition to that caused by chemical carcinogens.

Beta Decay

Proton-deficient nuclei can decay by transforming a neutron into a proton, which results in the emission of a β^{-} particle and an antineutrino ($\tilde{\nu}$) as shown in Figure 19.6. We use the symbol ${}^{0}_{-1}e$ for the emitted electron to help us balance nuclear reactions, the superscript giving the relative mass and the subscript the charge. The daughter nuclide produced by β^{-} decay has the same mass number A as the parent,

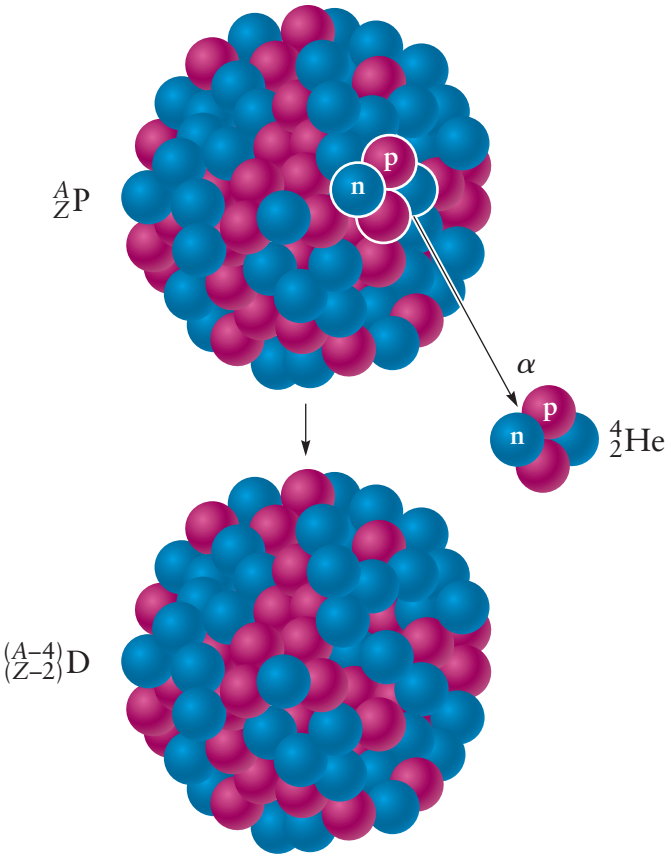

FIGURE 19.5 Schematic representation of α decay. P and D refer to the parent and daughter nuclides, respectively.

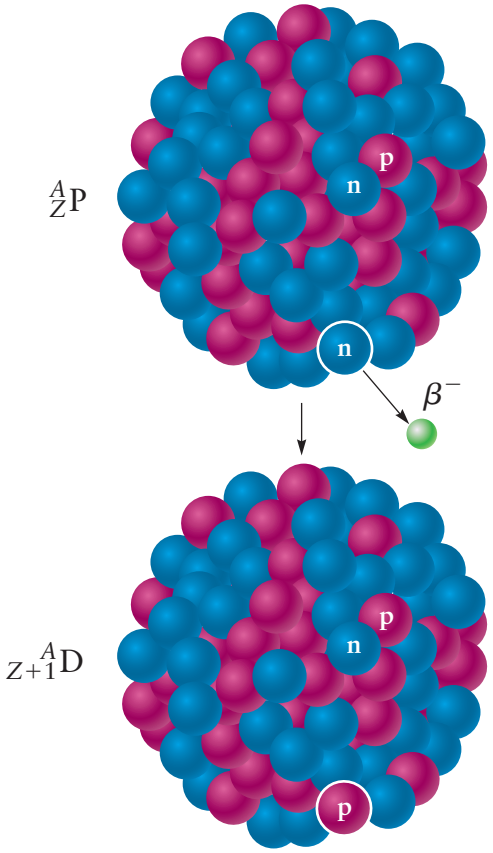

FIGURE 19.6 Schematic representation of β^- (electron) emission.

but its atomic number Z has been increased by 1 because a neutron has been transformed into a proton. The energy liberated is carried off in the form of kinetic energy by the beta particle (electron) and the antineutrino, because the daughter nucleus produced is heavy enough that its recoil energy is small and can be neglected. Examples of β^- decay include

$$^{14}_{6}\text{C} \longrightarrow {}^{14}_{7}\text{N} + {}^{0}_{-1}e^{-} + \tilde{\nu}$$

$$^{32}_{15}\text{P} \longrightarrow {}^{32}_{16}\text{S} + {}^{0}_{-1}e^{-} + \tilde{\nu}$$

$$^{90}_{38}\text{Sr} \longrightarrow {}^{90}_{39}\text{Y} + {}^{0}_{-1}e^{-} + \tilde{\nu}$$

The first reaction is key in radiocarbon dating (see Section 19.4). ^{32}P is commonly used as a **radiotracer** in biology to follow biological reactions involving phosphorus, and ^{90}Sr is one of the longer-lived radioactive isotopes still present in Belarus following the disastrous explosion of the Chernobyl nuclear power plant.

Positron Emission

Proton-rich nuclei may decay by emitting β^+ particles as an alternative to α decay. A proton is converted to a neutron, leading to the emission of a high-energy positron ($^{0}_{1}e^{+}$) and a neutrino (ν), as shown in Figure 19.7. The mass number A of the daughter nuclide is unchanged, but the atomic number Z has *decreased* by 1. The kinetic energy ($-\Delta E$) is distributed between the positron and the neutrino.

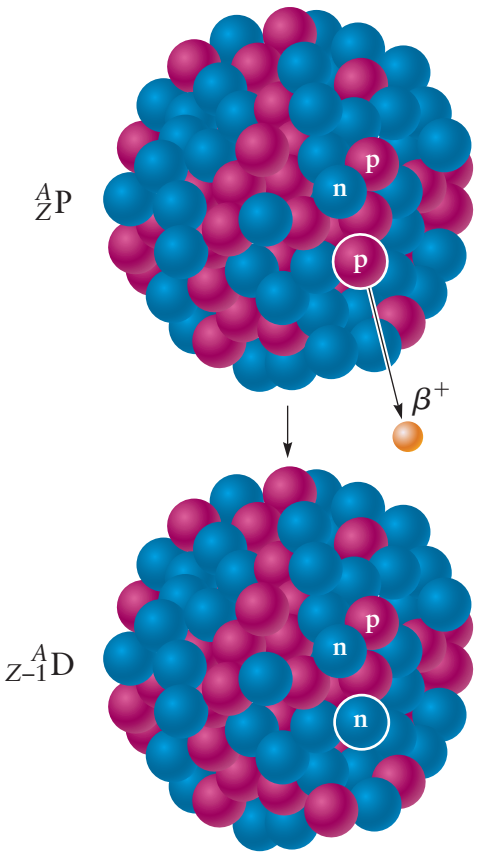

FIGURE 19.7 Schematic representation of β^+ (positron) emission.

Examples of **positron emission** include

$$^{11}_{6}\mathrm{C} \longrightarrow {}^{11}_{5}\mathrm{B} + {}^{0}_{1}e^{+} + \nu$$

$$^{18}_{9}\mathrm{F} \longrightarrow {}^{18}_{8}\mathrm{O} + {}^{0}_{1}e^{+} + \nu$$

These isotopes are used in positron emission tomography, an important medical imaging technique described in the *Connection to Medicine*.

Electron Capture

Electron capture is another process by which proton-rich nuclei decay, converting a proton to a neutron; it is an important alternative when energetic considerations don't allow positron emission (see Section 19.3). The nucleus captures an orbital electron, thereby converting a proton into a neutron, as shown in Figure 19.8. The mass number is unchanged and the atomic number decreases by 1, as in positron emission, but the only particle emitted is a neutrino. An example is

$$^{231}_{92}\mathrm{U} + {}^{0}_{-1}e^{-} \longrightarrow {}^{231}_{91}\mathrm{Pa} + \nu$$

The three beta decay processes may be summarized by the flowing equations in which P represents the parent nucleus, D represents the daughter nucleus, and the rest of the symbols have their usual meanings.

$$^{A}_{Z}\mathrm{P} \longrightarrow {}^{A}_{Z+1}\mathrm{D} + \beta^{-} + \nu$$

$$^{A}_{Z}\mathrm{P} \longrightarrow {}^{A}_{Z-1}\mathrm{D} + \beta^{+} + \nu$$

$$^{0}_{-1}e^{-} + {}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A}_{Z-1}\mathrm{D} + \nu$$

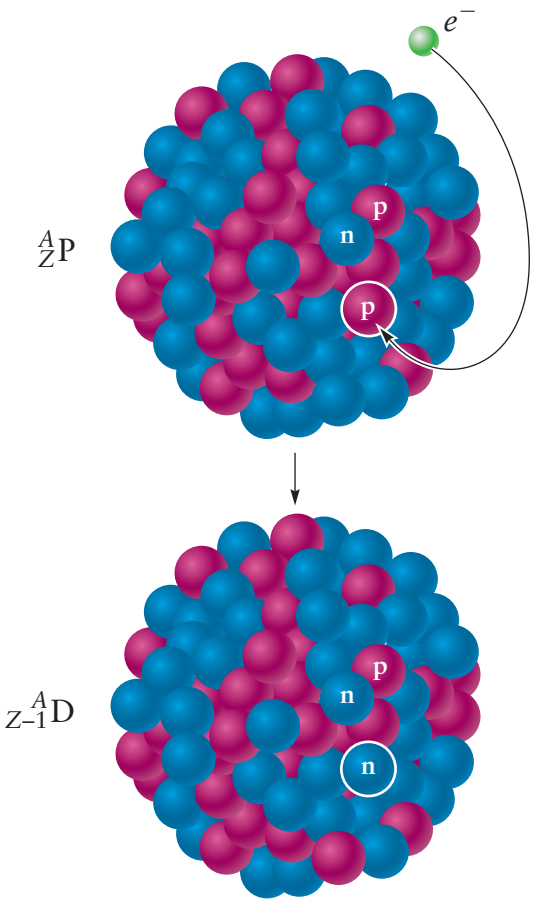

FIGURE 19.8 Schematic representation of electron capture.

19.3 MASS–ENERGY RELATIONSHIPS

What is the driving force for spontaneous nuclear decay? It must, of course, be determined by the second law of thermodynamics, and so we focus on the change in the Gibbs free energy, which is the appropriate state function for processes carried out under conditions of constant temperature and pressure. Spontaneous processes under these conditions are those for which $\Delta G < 0$. It turns out (as we show later) that the change in the Gibbs free energy for nuclear reactions is dominated by the enormous energy released, so our criterion for spontaneous nuclear decay becomes $\Delta E < 0$. Let's see if we can identify characteristics of parent and daughter nuclei that allow us to predict which decay processes are spontaneous.

Einstein showed the equivalence of mass and energy in his special theory of relativity as expressed by the famous relation

$$E = mc^2 \qquad [19.1]$$

There are two important consequences of this result. First, it predicts that matter and energy can be converted into one another and that the conversion of very small quantities of mass can produce very large quantities of energy. Second, the laws of conservation of mass and conservation of energy must be modified; it is only their sum that must be conserved. Equation 19.1 implies that there is a change in mass associated with the change in energy for any reaction, which we can calculate using

$$\Delta E = c^2\,\Delta m \qquad [19.2]$$

This equation implies that all exothermic reactions must be accompanied by a loss in mass, so our thermodynamic criterion for spontaneity $\Delta E < 0$ can be rewritten

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

in terms of mass as $\Delta m < 0$. Let's examine the mass changes associated with some simple nuclear reactions to see if this conclusion is true and to calculate the associated energy changes.

A simple nuclear reaction to consider is the decay of a free neutron into a proton and an electron according to the following reaction

$$^{1}_{0}n \longrightarrow {}^{1}_{1}p + {}^{0}_{-1}e$$

Neutrons are stable inside the nucleus, but they decay with a half-life of about 10 minutes in free space. The mass of the neutron is 1.0086649 u, the mass of the proton is 1.007276 u, and the mass of the electron is 0.000548 u. We calculate the mass change associated with the decay of the neutron as

$$\Delta m = m_{\text{p}} + m_{\text{e}} + m_{\text{n}} = -8.4 \times 10^{-4}\ \text{u}$$

and confirm that mass is indeed lost in this spontaneous nuclear transformation. The energy associated with the decay of the neutron is

$$\begin{aligned}\Delta E = c^2\Delta m &= (3 \times 10^{8}\ \text{m})^2(-8.4 \times 10^{-4}\ \text{u})(1.6605 \times 10^{-27}\ \text{kg u}^{-1}) \\ &= 1.25 \times 10^{-13}\ \text{J} = 0.78\ \text{MeV}\end{aligned}$$

which is about a million times greater than energy changes associated with ordinary chemical reactions. It is convenient to calculate changes in energy directly from changes in mass. We define an **energy equivalent** to 1 u as 931.494 MeV, which allows us to calculate the energy released from the decay of a neutron using

$$\Delta E = (-8.39869 \times 10^{-4}\ \text{u})(931.494\ \text{MeV u}^{-1}) = 0.782\text{MeV}$$

Energy Changes in Nuclear Reactions

Let's now calculate the energy changes associated with various nuclear decay processes discussed earlier, beginning with β^- decay as represented by the following reaction

$$^{A}_{Z}\text{P} \longrightarrow {}^{A}_{Z+1}\text{D} + \beta^- + \tilde{\nu}_{\text{e}}$$

Nuclear reactions are spontaneous when $\Delta m < 0$, which we can express as

$$m[^{A}_{Z}\text{P}] > m[{}^{A}_{Z+1}\text{D}^+] + m[{}^{0}_{-1}e]$$

because the mass of the antineutrino ($\tilde{\nu}$) is almost zero. The masses in this inequality are those of the parent and daughter *nuclei* and the emitted electron, the daughter nucleus being positively charged when initially created. We can rewrite this equation in terms of *atomic* masses by adding Z electrons to both sides of the expression, the right-hand side now representing a positive ion and the emitted electron, which can combine to form a neutral daughter atom, resulting in

$$m[^{A}_{Z}\text{P}] > m[{}^{A}_{Z+1}\text{D}]$$

as our criterion for spontaneous β^- decay. Comparing the atomic masses of the parent and daughter nuclei listed in Table 19.1 allows us to determine immediately whether a particular transformation can occur via β^- decay or not. The energy change associated with a particular reaction is calculated using

$$\Delta E = c^2\Delta m = c^2\{m[{}^{A}_{Z+1}\text{D}] - m[^{A}_{Z}\text{P}]\}$$

with the liberated energy being carried off in the form of kinetic energy of the lighter particles, the electron and the antineutrino. There are no restrictions on how the available energy is distributed between these two particles, so the kinetic energy of emitted electrons falls in a continuous range between 0 and $E_{\text{max}} \equiv -\Delta E$, as shown in Figure 19.9.

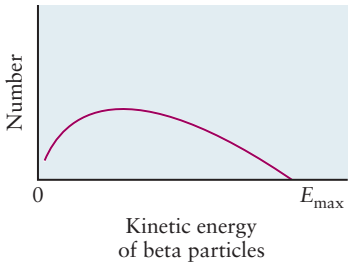

FIGURE 19.9 Emitted beta particles have a distribution of kinetic energies up to a cutoff value of E_{max}.

EXAMPLE 19.1

Calculate the maximum kinetic energy of the electron in the decay

$$^{14}_{6}\mathrm{C} \longrightarrow {}^{14}_{7}\mathrm{N} + {}^{0}_{-1}e^{-} + \tilde{\nu}$$

Solution

Table 19.1 gives the masses of the relevant atoms. From them we calculate

$$\Delta m = m[{}^{14}_{7}\mathrm{N}] - m[{}^{14}_{6}\mathrm{C}] = 14.0030740 - 14.0032420 = -0.0001680 \text{ u}$$

$$\Delta E = (-1.68 \times 10^{-4}\text{u})(931.5 \text{ MeVu}^{-1}) = -0.156 \text{ MeV}$$

The maximum kinetic energy of the electron E_{max} is 0.156 MeV.

Related Problem: 2

Positron (β^+) emission is represented by the reaction

$$^{A}_{Z}\mathrm{P} \longrightarrow {}_{Z-1}{}^{A}\mathrm{D} + \beta^{+} + \nu_{e}$$

with the criterion for spontaneous decay being

$$m[{}^{A}_{Z}\mathrm{P}] > m[{}_{Z-1}{}^{A}\mathrm{D}^{-}] + m[{}^{0}_{+1}e]$$

in which the masses given are those of the bare nuclei. We convert this inequality to one expressed in terms of *atomic* masses, as before, by adding Z electrons to both sides of the expression. We now have $Z + 1$ electrons on the right-hand side, in contrast to the expression for β^- decay, however, so we get

$$m[{}^{A}_{Z}\mathrm{P}] > m[{}_{Z-1}{}^{A}\mathrm{D}] + m[{}^{0}_{-1}e] + m[{}^{0}_{+1}e] = m[{}_{Z-1}{}^{A}\mathrm{D}^{-}] + 2m[{}^{0}_{-1}e]$$

because the mass of the positron is the same as the mass of the electron. Positron emission is spontaneous only when the mass of the parent nuclide *exceeds* the mass of the daughter nuclide by at least $2m[{}^{0}_{-1}e] = 0.0011$ u, equivalent to an additional energy difference given by $\Delta E = 2c^2 m[{}^{0}_{-1}e] = 1.022$ MeV, which is the cost of creating the positron. The energy released in β^+ decay is distributed between the positron and the neutrino, with no restrictions, so the kinetic energy of emitted positrons varies continuously from 0 to $-\Delta E$, just as for electrons emitted in β^- decay.

EXAMPLE 19.2

Calculate the maximum kinetic energy of the positron emitted in the decay

$$^{11}_{6}\mathrm{C} \longrightarrow {}^{11}_{5}\mathrm{B} + {}^{0}_{1}e^{+} + \nu$$

Solution

The change in mass is

$$\Delta m = m[{}^{11}_{5}\mathrm{B}] + 2m[{}^{0}_{1}e^{+}] - m[{}^{11}_{6}\mathrm{C}] = 11.0093055 + 2(0.00054858) - 11.011433$$

$$= -0.00130 \text{ u}$$

The energy released is then

$$\Delta E = -(0.00130 \text{ u})(931.5 \text{ MeV u}^{-1}) = -0.960 \text{ MeV}$$

The maximum kinetic energy of the positron E_{max} is +0.960 MeV.

Related Problem: 1

Nature has found an alternate way to convert protons into neutrons without paying the cost associated with positron emission. Electron capture is spontaneous when

$$m[{}^{A}_{Z}\mathrm{P}] > m[{}^{A}_{Z-1}\mathrm{D}^{-}]$$

a much less restrictive requirement than that for positron emission. This decay mode is an important alternative to positron emission for the heavier neutron-deficient nuclei for which the mass changes are not large enough to permit positron emission, for example, in the reaction

$${}^{231}_{92}\mathrm{U} + {}^{0}_{-1}e \longrightarrow {}^{231}_{91}\mathrm{Pa} + \nu$$

The change in mass is

$$\Delta m = m[{}^{231}_{91}\mathrm{Pa}] - m[{}^{231}_{92}\mathrm{U}] = 231.03588 - 231.03689 = -0.00041 \text{ u}$$

which is less than zero but not by $2m[{}^{0}_{-1}e](0.0011 \text{ u})$, which is required for positron emission.

Alpha decay is represented by the following reaction:

$${}^{A}_{Z}\mathrm{P} \longrightarrow {}^{A-4}_{Z-2}\mathrm{D} + {}^{4}_{2}\mathrm{He}$$

and the requirement for spontaneous α decay is

$$\Delta m = m[{}^{A-4}_{Z-2}\mathrm{D}] + m[{}^{4}_{2}\mathrm{He}] - m[{}^{A}_{Z}\mathrm{P}] < 0$$

with most of the energy being carried away by the lighter helium atom.

Nuclear Binding Energies

We gained considerable insight into atomic structure by examining periodic trends in ionization energies, as discussed in Chapters 3 and 5. Let's follow a similar approach to see what we can learn about nuclear structure and properties that allows us to understand the general shape of the line of stability and the dominant decay modes of the unstable nuclei (see Fig. 19.4), as well as the energetics of nuclear decay just discussed. We define the nuclear **binding energy** as the energy required to dissociate a particular nucleus into its constituent nucleons. This definition is analogous to those for bond dissociation energies or ionization energies, which are also positive numbers. Nuclear binding energies can be calculated from the data given in Table 19.1 by subtracting the masses of the nucleons and the electrons of an atom from its atomic mass.

We look for periodic trends in nuclear binding energies by plotting the average binding energy *per nucleon* E_B/A as a function of mass number A, as shown in Figure 19.10. There are four nucleons in the ${}^{4}_{2}\mathrm{He}$ nucleus, so the binding energy *per nucleon* is

$$\frac{E_B}{4} = \frac{28.2957 \text{ MeV}}{4} = 7.07392 \text{ MeV}$$

We used a similar approach earlier to study atomic structure in which we plotted ionization energies as a function of the atomic number Z.

The plot shown in Figure 19.10 reveals a number of interesting features about nuclear structure and bonding. The average binding energy per nucleon is essentially constant for most nuclei, about 8 MeV, as shown by the flat region of the insert for $A > 20$ or so. This observation suggests that the strong force is very short-ranged, as asserted earlier. If the strong force were long-ranged, like the Coulomb force, for example, we would expect that *each* of A nucleons would be attracted to the other $A - 1$ nucleons, that the total binding energy would be proportional to $A(A - 1)$, and that the binding energy per nucleon would be proportional

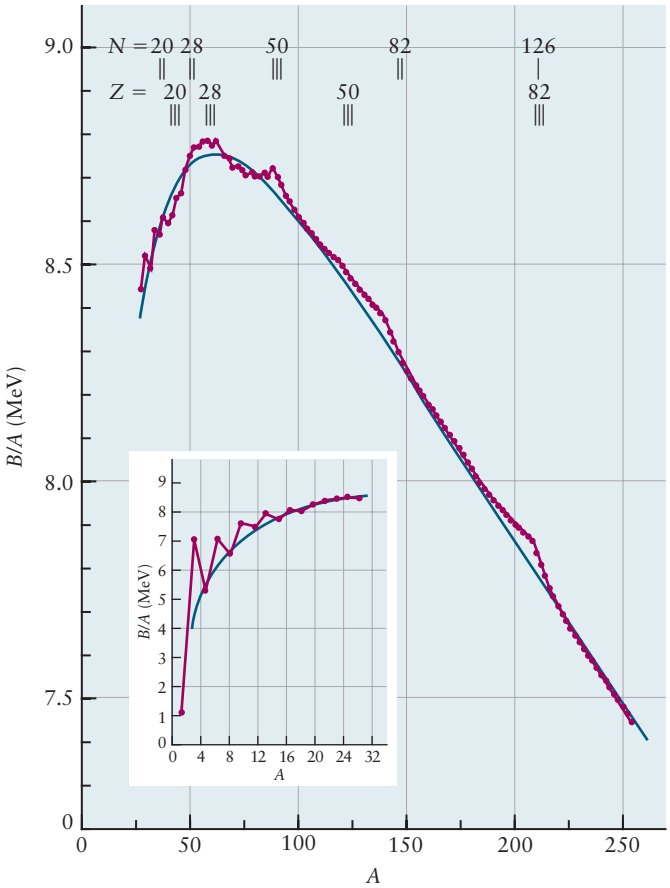

FIGURE 19.10 Average binding energy per nucleon as a function of mass number *A*. Magic numbers of neutrons and protons are located by the vertical lines at the top of the figure.

to $A - 1$ and not A, as observed. The roughly constant value of the average *net* binding energy per nucleon also suggests that the attractive strong force is independent of nucleon charge, where we have added the qualifier *net* to remind us that the average binding energies plotted include the average Coulomb repulsion among the protons. The gradual decline in the binding energy observed with increasing A is due to the greater influence of the Coulomb repulsion as the number of protons increases. Iron, nickel, and their neighbors in the periodic table are the most stable nuclei, as indicated by the peak in the plot. The lighter nuclei can achieve greater stability through fusion, whereas the heavier nuclei can become more stable through radioactive decay or nuclear fission.

The binding energy per nucleon of the lighter nuclei increases with increasing A before leveling off at $A = 20$ or so (see insert). We can rationalize this observation by building up the configurations of these nuclei using the Aufbau principle. Imagine starting with ${}_1^1\text{H}$ and adding neutrons to form the hydrogen isotopes, then a proton to form helium, and so on. The first neutron added is attracted to one nucleon, the proton, whereas the second neutron added is attracted to two nucleons, and so forth. The binding energy per nucleon should increase as nucleons are added until we reach a close-packed configuration with one nucleon surrounded by 12 nearest neighbors (see Section 21.2). Once this configuration has been achieved, the binding energy per nucleon should level off, as observed. The binding energy per nucleon begins to decrease above $A = 60$ or so. Most of the nucleons in the heavier nuclei are located in the interior of the nucleus, but a greater *fraction* of nucleons are located at the surface as the sizes of the nuclei decrease. These surface nucleons are bound to fewer other nucleons than those in the interior of heavier nuclei, thus decreasing the binding energy per nucleon.

Some nuclei appear to be particularly stable, as indicated by peaks in the curve that appear for particular values of Z and N. These peaks are associated with cer-

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tain "magic numbers" of protons or neutrons that appear to confer extra stability. The magic numbers are 2, 8, 20, 28, 50, 82, and 126, a pattern that is similar to one that identifies the stable closed shells of atoms, 2, 10, 18, 36, etc. Examples of nuclei with magic numbers of protons include the isotopes of He, O, Ca, and Ni, with $Z = 2$, 8, 20, and 28, respectively. Isotopes with magic numbers of neutrons are also magic; examples include ^{36}S, ^{37}C, and ^{38}Ar. Isotopes with magic numbers of both protons and neutrons are called "doubly magic" nuclei, and they are exceptionally stable. The best known examples are $^{4}_{2}He$ and $^{16}_{8}O$, but others include $^{40}_{20}Ca$, $^{48}_{20}Ca$, and $^{48}_{28}Ni$. The last two are particularly interesting examples of the influence of magic numbers on stability. $^{48}_{20}Ca$ is a very neutron-rich light nucleus that we would predict not to be very stable, based upon considerations discussed earlier, but it has a half-life of the order of 10^{20} years and is considered stable for all practical purposes. $^{48}_{28}Ni$, on the other hand, lying at the extreme end of the proton-rich nuclei with $A = 48$, was not thought to exist at all, though it has been discovered recently but with a very short half-life. The stability of the $^{4}_{2}He$ nucleus, the α particle, is particularly striking; its binding energy per nucleon is equivalent to those of the heavier elements, because it is a doubly magic nucleus. The exceptional stability of the α particle accounts for the important role it plays in nuclear decay processes. Losing an α particle reduces the Coulomb repulsion between protons, which increases the stability of the daughter nuclide, without affecting the average binding energy per nucleon.

EXAMPLE 19.3

Calculate the binding energy of $^{4}_{2}He$ from the data in Table 19.1, and express it both in joules and in million electron volts (MeV).

Solution

The change in mass associated with the formation of $^{4}_{2}He$ is

$$\Delta m = 2m[^{1}_{1}H] + 2m[^{1}_{0}n] - m[^{4}_{2}He]$$

$$= 2(1.00782503) + 2(1.00866492) - 4.00260325 = 0.03037665 \text{ u}$$

Einstein's relation then gives

$$\Delta E = (0.03037665 \text{ u})(1.6605387 \times 10^{-27} \text{ kg u}^{-1})(2.9979246 \times 10^{-8} \text{ m s}^{-1})^2$$

$$= 4.533465 \times 10^{-12} \text{ J}$$

$$E_B = 4.533465 \times 10^{-12}$$

If 1 mol of $^{4}_{2}He$ atoms were formed in this way, the change in energy would be greater by a factor of Avogadro's number N_A, giving $\Delta E = -2.73 \times 10^{12}$ J mol^{-1}. This is an enormous quantity, seven orders of magnitude greater than produced in ordinary chemical reactions.

The energy change, in MeV, accompanying the formation of a $^{4}_{2}He$ atom is

$$\Delta E = (-0.03037665 \text{ u})(931.494 \text{ MeV u}^{-1}) = 28.2957 \text{ MeV}$$

19.4 KINETICS OF RADIOACTIVE DECAY

The decay of any given unstable nucleus is a random event and is independent of the number of surrounding nuclei that have decayed. When the number of nuclei is large, we can be confident that during any given period a definite fraction of the original

number of nuclei will have undergone a transformation into another nuclear species. In other words, the rate of decay of a collection of nuclei is proportional to the number of nuclei present, showing that nuclear decay follows a first-order rate equation of the type discussed in Chapter 18. All the results developed in that chapter apply to the present situation; for example, the integrated rate law has the form

$$N = N_i\, e^{-kt}$$

where N_i is the number of nuclei originally present at $t = 0$. The decay constant k is related to a half-life $t_{1/2}$ through

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.6931}{k}$$

just as in the first-order gas-phase chemical kinetics of Section 18.2. The half-life is the time required for the nuclei in a sample to decay to one-half their initial number, and it can range from less than 10^{-21} s to more than 10^{24} years for unstable nuclei. Characterizing a nuclide with a half-life of 10^{24} years (orders of magnitude longer than the age of the universe) as unstable is not a mistake. Some nuclides formerly thought to be stable have been shown to be unstable, but with long half-lives, as experimental methods for detecting very low rates of disintegration have improved. Table 19.3 lists the half-lives and decay modes of some unstable nuclides.

There is one important practical difference between chemical kinetics and nuclear kinetics. In chemical kinetics the concentration of a reactant or product is

TABLE 19.3

Decay Characteristics of Some Radioactive Nuclei

Nuclide	$t_{1/2}$	Decay Mode†	Daughter
$^{3}_{1}H$ (tritium)	12.26 years	e^-	$^{3}_{2}He$
$^{8}_{4}Be$	$\sim 1 \times 10^{-16}$ s	α	$^{4}_{2}He$
$^{14}_{6}C$	5730 years	e^-	$^{14}_{7}N$

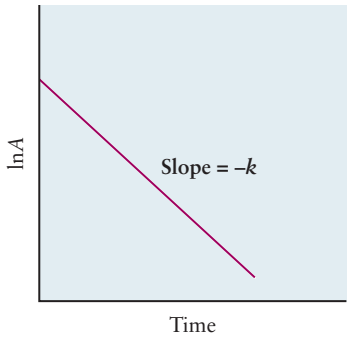

FIGURE 19.11 A graph of the logarithm of the activity of a radioactive nuclide against time is a straight line with slope $-k = -(\ln 2)/t_{1/2}$.

monitored over time, and the rate of a reaction is then found from the rate of change of that concentration. In nuclear kinetics the rate of occurrence of decay events, $-dN/dt$, is measured directly with a Geiger counter or other radiation detector. This decay rate—the average disintegration rate in numbers of nuclei per unit time—is called the **activity A.**

$$A = -\frac{dN}{dt} = kN \qquad [19.3]$$

Because the activity is proportional to the number of nuclei N, it also decays exponentially with time:

$$A = A_i e^{-kt} \qquad [19.4]$$

A plot of ln A against time t is linear with slope $-k = -(\ln 2)/t_{1/2}$, as Figure 19.11 shows. The activity A is reduced to half its initial value in a time $t_{1/2}$. Once A and k are known, the number of nuclei N at that time can be calculated from

$$N = \frac{A}{k} = \frac{At_{1/2}}{\ln 2} = \frac{At_{1/2}}{0.6931}$$

The S.I. unit of activity is the becquerel (Bq), defined as 1 radioactive disintegration per second. The Curie (Ci) is an older and much larger unit of activity, based upon the number of disintegrations from 1 g of radium per second. 1 Ci = 3.7×10^{10} Bq.

It is difficult to measure the decrease in activity over time for very long-lived isotopes, so half-lives for these isotopes are determined using a different method. The number of atoms of the radioisotope of interest is determined by measuring the mass of the element in the sample and the relative isotopic abundance the radioisotope using a mass spectrometer. The half-life is then determined using the first equation of this section as illustrated in the following example. Table 19.3 shows the wide variety of half-lives of some important radioactive nuclei.

EXAMPLE 19.4

Tritium (^{3}H) decays by beta emission to ^{3}He with a half-life of 12.26 years. A sample of a tritiated compound has an initial activity of 0.833 Bq. Calculate the number N_i of tritium nuclei in the sample initially, the decay constant k, and the activity after 2.50 years.

Solution

Convert the half-life to seconds:

$$t_{1/2} = (12.26 \text{ yr})(60 \times 60 \times 24 \times 365 \text{ s yr}^{-1}) = 3.866 \times 10^8 \text{ s}$$

The number of nuclei originally present was

$$N_i = \frac{A_i t_{1/2}}{\ln 2} = \frac{(0.833 \text{ s}^{-1})(3.866 \times 10^8 \text{ s})}{0.6931} = 4.65 \times 10^8 \ ^3\text{H nuclei}$$

The decay constant k is calculated directly from the half-life:

$$k = \frac{\ln 2}{t_{1/2}} = \frac{0.6931}{3.866 \times 10^8 \text{ s}} = 1.793 \times 10^{-9} \text{ s}^{-1}$$

To find the activity after 2.50 years, convert this time to seconds (7.884×10^7 s) and use

$$A = A_i e^{-kt} = (0.833 \text{ Bq}) \exp\left[-(1.793 \times 10^{-9} \text{ s}^{-1})(7.884 \times 10^7 \text{ s})\right] = 0.723 \text{ Bq}$$

Radioactive Dating

The decay of radioactive nuclides with known half-lives enables geochemists to measure the ages of rocks from their isotopic compositions. Suppose that a uranium-bearing mineral was deposited some 2 billion (2.00×10^9) years ago and has remained geologically unaltered to the present time. The ^{238}U in the mineral has decayed with a half-life of 4.51×10^9 years to form a series of short-lived intermediates, ending in the stable lead isotope ^{206}Pb (Fig. 19.12). The fraction of uranium remaining after 2.00×10^9 years is calculated to be

$$\frac{N}{N_i} = e^{-kt} = e^{-0.6931\, t/t_{1/2}} = \exp\left(\frac{-0.6931 \times 2.00 \times 10^9 \text{ yr}}{4.51 \times 10^9 \text{ yr}}\right) = 0.735$$

and the number of ^{206}Pb atoms is approximately

$$(1 - 0.735)N_i = 0.265\, N_i(^{238}U)$$

The ratio of abundances

$$\frac{N(^{206}Pb)}{N(^{238}U)} = \frac{0.265}{0.735} = 0.361$$

therefore is determined by the time elapsed since the deposit was originally formed—in this case, 2.00×10^9 years. Of course, to calculate the age of the mineral, we would work backward from the measured N (^{206}Pb)/N (^{238}U) ratio.

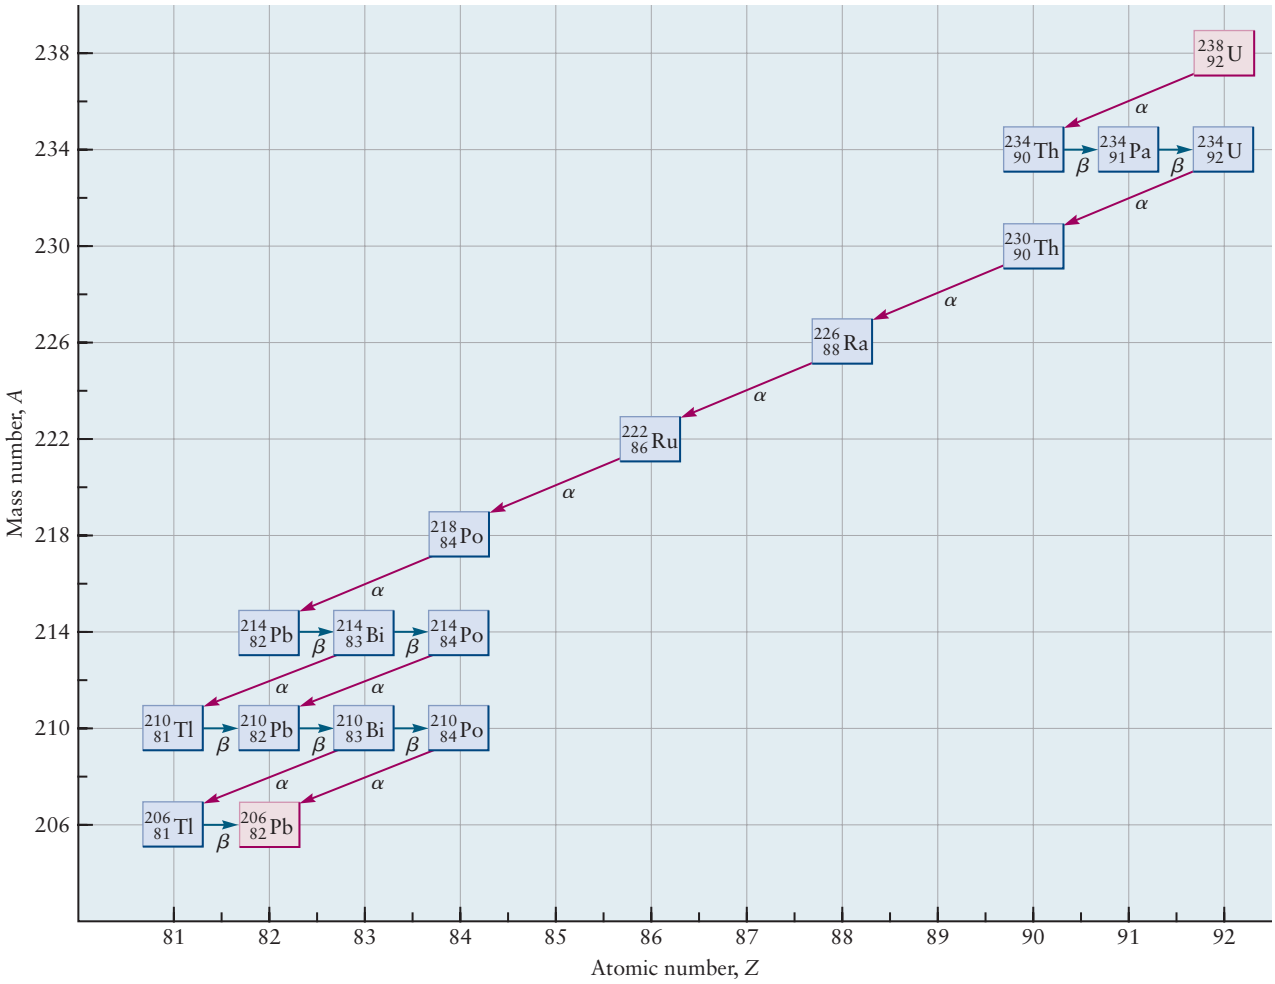

FIGURE 19.12 The radioactive nuclide ^{238}U decays via a series of alpha and beta emissions to the stable nuclide ^{206}Pb.

To use the method, it is necessary to be certain that the stable nuclide generated (^{206}Pb in this case) arises only from the parent species (^{238}U here) and that neither lead nor uranium has left or entered the rock over the course of geologic time. If possible, it is desirable to measure the ratios of several different isotopically paired species in the same rock sample. For example, ^{87}Rb decays to ^{87}Sr with a half-life of 4.9×10^{10} years, and one mode of ^{40}K decay (with a half-life of 1.28×10^{9} years) is to ^{40}Ar. Each pair should ideally yield the same age. Detailed analysis of a large number of samples suggests that the oldest surface rocks on earth are about 3.8 billion years old. An estimate of 4.5 billion years for the age of the earth and solar system comes from indirect evidence involving an isotopic analysis of meteorites, which are believed to have formed at the same time.

A somewhat different type of dating uses measurements of ^{14}C decay, which covers the range of human history and prehistory back to about 30,000 years ago. This unstable species (with a half-life of 5730 years) is produced continuously in the atmosphere. Very high-energy cosmic rays produce neutrons that collide with $^{14}_{7}\mathrm{N}$ nuclei to produce $^{14}_{6}\mathrm{C}$ by the reaction

$$^{14}_{7}\mathrm{N} + {}^{1}_{0}n \longrightarrow {}^{14}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{H}$$

The resulting ^{14}C enters the carbon reservoir on the Earth's surface, mixing with stable ^{12}C dissolved as $\mathrm{H}^{14}\mathrm{CO}_3^-$ in the oceans, as $^{14}\mathrm{CO}_2$ in the atmosphere, and in the tissues of plants and animals. This mixing, which is believed to have occurred at a fairly constant rate over the past 50,000 years, means that the ^{14}C in a living organism has a specific activity of close to 15.3 disintegrations per minute per gram of total carbon—that is, 0.255 Bq g^{-1}. When a plant or animal dies (for example, when a tree is cut down), the exchange of carbon with the surroundings stops and the amount of ^{14}C in the sample falls exponentially with time. We can measure the ages of archeological samples by measuring their ^{14}C activity. This ^{14}C dating method, developed by the American chemist W. F. Libby, has been calibrated against other dating techniques (such as counting the annual rings of bristlecone pines or examining the written records that may accompany a carbon-containing artifact) and has been found to be quite reliable over the time span for which it can be checked. This observation suggests that the rate of ^{14}C synthesis in the upper atmosphere has been relatively constant for thousands of years. The relative abundance of $^{14}\mathrm{CO}_2$ in the atmosphere has declined since the industrial revolution while the total amount of CO_2 has increased by about 30%, providing strong evidence that the combustion of fossil fuels is responsible for the increase in atmospheric CO_2 levels observed (see Section 20.6). Fossil fuels are hundreds of millions of years old and have no remaining ^{14}C left.The changing isotopic composition of atmospheric CO_2 will cause difficulty in applying ^{14}C dating in the future.

EXAMPLE 19.5

A wooden implement has a specific activity of ^{14}C of 0.195 Bq g^{-1}. Estimate the age of the implement.

Solution

The decay constant for ^{14}C is

$$k = \frac{0.6931}{5730 \text{ yr}} = 1.21 \times 10^{-4} \text{ yr}^{-1}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The initial specific activity was 0.255 Bq g^{-1}, and the measured activity now (after t years) is 0.195 Bq g^{-1}, so

$$A = A_i e^{-kt}$$

$$0.195 \text{ Bq g}^{-1} = 0.255 \text{ Bq g}^{-1} e^{-(1.21\times10^{-4})t}$$

$$\ln\left(\frac{0.195}{0.255}\right) = -(1.21\times10^{-4} \text{ yr}^{-1})t$$

$$t = 2200 \text{ yr}$$

The implement comes from a tree cut down approximately 2200 years ago.

Related Problems: 25, 26

19.5 RADIATION IN BIOLOGY AND MEDICINE

Radiation has both harmful and beneficial effects for living organisms. All forms of radiation cause damage in direct proportion to the amount of energy they deposit in cells and tissues. The damage takes the form of chemical changes in cellular molecules, which alter their functions and lead either to uncontrolled multiplication and growth of cells or to their death. Alpha particles lose their kinetic energy over very short distances in matter (typically 10 cm in air or 0.05 cm in water or tissues), producing intense ionization in their wakes until they accept electrons and are neutralized to harmless helium atoms. Radium, for example, is an alpha emitter that substitutes for calcium in bone tissue and destroys its capacity to produce both red and white blood cells. Beta particles, gamma rays, and X-rays have greater penetrating power than alpha particles and so present a radiation hazard even when their source is well outside an organism.

The amount of damage produced in tissue by any of these kinds of radiation is proportional to the number of particles or photons and to their energy. A given activity of tritium causes less damage than the same activity of ^{14}C, because the beta particles from tritium have a maximum kinetic energy of 0.0179 MeV, whereas those from ^{14}C have an energy of 0.156 MeV. What is important is the amount of ionization produced or the quantity of energy deposited by radiation. Several units have been defined for this purpose. The *rad* (*r*adiation *a*bsorbed *d*ose) is defined as the amount of radiation that deposits 10^{-2} J of energy per kilogram of tissue. The damage produced in human tissue depends on still other factors, such as the nature of the tissue, the kind of radiation, the total radiation dose, and the dose rate. To take all these into account, the *rem* (*r*oentgen *e*quivalent in *m*an) has been defined to measure the effective dosages of radiation received by humans. A physical dose of 1 rad of beta or gamma radiation translates into a human dose of 1 rem. Alpha radiation is more toxic; a physical dose of 1 rad of alpha radiation equals about 20 rems. The SI unit for absorbed radiation, analogous to the rad, is the gray (Gy); 1 Gy = 1 joule per kg of mass. So, 1 Gy = 100 rad. The SI unit for effective dosage of radiation is the sievert (Sv). The sievert is defined in the same way as the rem, except the delivered dose is expressed in Gy instead of rad; consequently, 1 Sv = 100 rem.

Exposure to radiation is unavoidable. The average person in the United States receives about 100 millirems (mrem) or 1 millisievert (mSv) annually from natural sources that include cosmic radiation and radioactive nuclides such as ^{40}K and ^{222}Rn. Another 50 to 100 mrem or 0.5 to 1.0 mSv (variable) come from human activities (including dental and medical X-ray examinations and airplane flights,

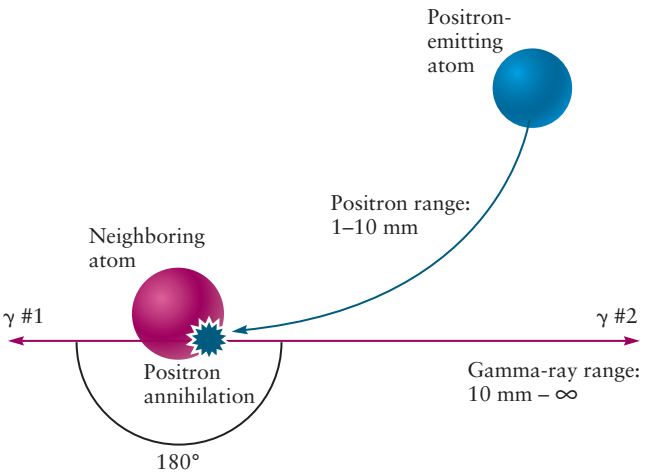
CONNECTION TO MEDICINE

Isotopes and Nuclear Medicine

Radiotracers



The discovery of artificial radioactivity in 1934, and the invention of the cyclotron (a particle accelerator) shortly thereafter, made it possible to study the mechanisms of chemical reactions at a level of detail not previously possible. Molecules were labeled in specific positions with radioisotopes (radiotracers) that were incorporated using standard synthetic methods, and the disposition of the tracers among the various products was determined by measuring their activity. The method was quickly adopted to study the mechanisms of biochemical and biological processes because it is extremely sensitive, and also because radioactive isotopes of the biologically important elements were easily prepared using cyclotrons. Early studies focused on phosphorus and iodine metabolism using ^{32}P and ^{131}I, respectively. Considerable insight into the mechanism of photosynthesis was provided by pioneering studies that used ^{18}O—labeled water to show the it was the source of the O_2 produced and not CO_2. $^{14}CO_2$ was also used to trace the location of carbon in the various carbohydrate products produced and establish the photosynthetic pathways involved.

Several dozen radioisotopes are now produced routinely for a variety of applications in medical diagnostics and radiation therapy. Neutron-deficient isotopes are generally made in medical cyclotrons, whereas proton-deficient isotopes are generally made in nuclear reactors. ^{99}Tc, a γ emitter, is the most widely used radioisotope because its 6-hour half-life is particularly convenient; it is long enough so that it can be transported from the source to the imaging center, but short enough that it emits γ-rays at a sufficiently high rate to ensure high accuracy. Compounds containing ^{99}Tc have been specifically designed to incorporate the tracer into tissues and structures of interest in order to image organs, bones, and tumors, as well as to monitor blood flow through the circulatory system, in particular the heart, brain, and lungs. Other radioisotopes are used to monitor thyroid function, and to image tumors and measure their metabolic activity. Positron emission tomography (PET), using ^{18}F, has become one of the most powerful of the radiotracer-based imaging techniques in recent years, with about 90% of PET scans being used to image tumors.

Positron Emission Tomography

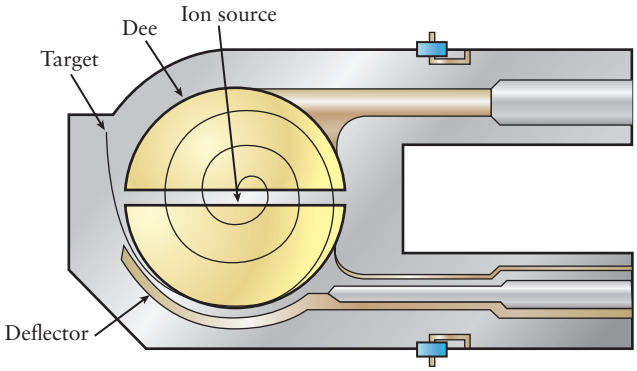
Positron emission tomography detects both members of a pair of γ-ray photons that are emitted when positrons and electrons annihilate one another in a collision, the location of the radiotracer being determined by working backward from the positions of the γ-rays measured by a large cylindrical detector. The reaction is written as follows, and a schematic of the electron–positron annihilation process is shown below.

$$^{0}_{1}e + {}^{0}_{-1}e \longrightarrow 2\ \gamma\ (511\ \text{MeV})$$

The most important radioisotopes used for PET imaging include ^{11}C, ^{13}N, ^{15}O, and ^{18}F, with half-lives of approximately 20, 10, 2, and 110 minutes respectively. They are synthesized by bombarding a target with high-energy (few MeV) particles in a cyclotron or a linear accelerator, as shown by the following nuclear reactions.

$$^{1}_{1}p + {}^{14}_{7}N \longrightarrow {}^{11}_{6}C + {}^{4}_{2}He$$

$$^{1}_{1}p + {}^{13}_{6}C + \longrightarrow {}^{13}_{7}N + {}^{1}_{0}n$$



$$^{2}_{1}H + {}^{14}_{7}N \longrightarrow {}^{15}_{8}O + {}^{1}_{0}n$$

$$^{1}_{1}p + {}^{18}_{8}O \longrightarrow {}^{18}_{9}F + {}^{1}_{0}n$$

The schematic of a cyclotron identifies its key features. Ions are injected into the center of the cyclotron, which is an evacuated chamber that contains a pair of D-shaped electrodes (dees) separated by a gap and a magnet that establishes a constant field perpendicular to the plane of the dees. A very high frequency-alternating voltage is applied to the dees, which causes the ions to accelerate each time they cross the gap. The magnetic field forces the ions to follow circular orbits of increasing radii with increasing kinetic energy, resulting in a spiral trajectory. They are eventually extracted and bombard the target as shown.

The radioisotopes must be incorporated into molecules very quickly after they are made; rapid organic synthetic methods developed at Brookhaven National

Laboratories were key to the widespread implementation of PET technology. The synthesis of 2-deoxy-2-(^{18}F)fluoro-D-glucose, (FDG), in particular, was significant because it enabled the relatively long-lived ^{18}F isotope to be incorporated into a sugar that is metabolized by all cells. ^{18}FDG is the dominant isotope used in cancer studies because it is preferentially taken up in cancer cells due to their high metabolic rates. One of the earliest applications of PET used ^{11}C to label drugs and investigate their mechanisms of action by imaging the brain. $^{15}O_2$ and $^{15}OH_2$ are used to measure blood flow in the heart and brain, as is $^{13}NH_3$, and the early pioneering studies of the interactions of drugs that cross the blood–brain barrier were conducted using drugs labeled with ^{11}C.

The combination of positron emission tomography with computerized tomography (CT) or magnetic resonance imaging (MRI) allows clinicians to acquire functional (metabolic) and structural (anatomical) images sequentially, enabling them to locate tumors with very high precision. The figure shows a PET/CT scanner in which the patient is transferred between the instruments on a gurney that preserves the patient's general alignment. Extremely small gold seeds (less than 1 mm) that are clearly visible in the CT images are implanted at several locations in patients to serve as accurate reference markers for position.

The recent development of 4D PET/CT takes the process one step further, allowing radiation oncologists to image patients in real time and monitor the movement of tumors as patients breathe. The method is so sophisticated that radiation from a pulsed linear accelerator can be delivered to the tumor at a particular time in the breathing cycle, avoiding irradiation of normal tissue and the radiation damage that it causes. The PET/CT scans shown illustrate the power of the method. The tumor is clearly visible in the upper image; the lower image shows that it has largely been destroyed after a course of radiation. The field of nuclear medicine continues to evolve to provide us with diagnostic and therapeutic tools of unprecedented power and scope.

which increase exposure to cosmic rays higher in the atmosphere). Permissible exposure levels are difficult to establish because there is no general agreement about the appropriate dose–response model for radiation damage among scientists and policy makers. The Environmental Protection Agency (EPA) uses a linear dose–response model, which asserts that damage is proportional to exposure, down to levels where control groups show no effect. It is well known, however, that there are biological repair mechanisms that protect organisms from damage at low exposures, and it might be more reasonable to establish a higher "no observable adverse effect level" or NOAEL. At the time of this writing the EPA appears to continue to embrace the more conservative linear dose–response model. The problem is made even more complex by the necessity to distinguish between tissue damage in an exposed individual and genetic damage, which may not become apparent for several generations. The adverse effects of single exposures are much easier to quantify. A single dose less than 0.25 Sv will likely cause no effect, a 1 Sv dose will cause severe illness, and a 5 Sv dose is fatal.

EXAMPLE 19.6

The beta decay of ^{40}K that is a natural part of the body makes all human beings slightly radioactive. An adult weighing 70.0 kg contains about 170 g of potassium. The relative natural abundance of ^{40}K is 0.0118%, its half-life is 1.28×10^9 years, and its beta particles have an average kinetic energy of 0.55 MeV.

(**a**) Calculate the total activity of ^{40}K in this person.

(**b**) Determine (in Gy per year) the annual radiation absorbed dose arising from this internal ^{40}K.

Solution

(**a**) First calculate the decay constant of ^{40}K in s^{-1}:

$$k = \frac{0.693}{t_{1/2}} = \frac{0.693}{(1.28 \times 10^9 \text{ yr})(365 \times 24 \times 60 \times 60 \text{ s yr}^{-1})}$$

$$= 1.72 \times 10^{-17} \text{ s}^{-1}$$

$$\text{number of } ^{40}K \text{ atoms} = \frac{170 \text{ g}}{40.0 \text{ g mol}^{-1}}(1.18 \times 10^{-4})(6.02 \times 10^{23} \text{ mol}^{-1})$$

$$= 3.02 \times 10^{20}$$

$$A = -\frac{dN}{dt} = kN = (1.72 \times 10^{-17} \text{ s}^{-1})(3.02 \times 10^{20}) = 5.19 \times 10^3 \text{ s}^{-1}$$

(**b**) Each disintegration of ^{40}K emits an average of 0.55 MeV of energy, and we assume that all of this energy is deposited within the body. From part (a), 5.19×10^3 disintegrations occur per second, and we know how many seconds are in a year. The total energy deposited per year is then

$$5.19 \times 10^3 \text{ s}^{-1} \times (60 \times 60 \times 24 \times 365 \text{ s yr}^{-1}) \times 0.55 \text{ MeV} = 9.0 \times 10^{10} \text{ MeV yr}^{-1}$$

Next, because a Gy is 1 J per kilogram of tissue, we express this answer in joules per year:

$$(9.0 \times 10^{10} \text{ MeV yr}^{-1})(1.602 \times 10^{-13} \text{ J MeV}^{-1}) = 0.0144 \text{ J yr}^{-1}$$

Each kilogram of body tissue receives 1/70.0 of this amount of energy per year, because the person weighs 70.0 kg. The dose is thus 21×10^{-5} J kg^{-1} yr^{-1}, which is equivalent to 0.21 Gy yr^{-1} or 21 mrad yr^{-1}. This is about a fifth of the annual background dosage received by a person.

Although radiation can do great harm, it confers great benefits in medical applications. The diagnostic importance of X-ray imaging hardly needs mention. Computerized axial tomography (CAT) provides high resolution three-dimensional images of bones, soft tissues, and tumors; it has become an indispensable tool in modern medicine. Ionizing radiation of all types (X-rays, gamma rays, and particles) are used both externally and internally to treat cancers. The beta-emitting ^{131}I nuclide finds use in the treatment of cancer of the thyroid because iodine is taken up preferentially by the thyroid gland. Precise control of X-ray and particle beam cross section shapes, coupled with precise alignment of the beams using CAT scans enable radiation oncologists to irradiate tumors selectively, eliminating damage to adjacent tissues as close as 1 mm to the perimeter of the beams.

Positron emission tomography (PET) is an important diagnostic technique using radiation (see *Connection to Medicine*). The vast majority of PET scans are used in oncology. Patients are injected with ^{18}F-labelled glucose that is taken up preferentially by tumors because cancer cells metabolize glucose at greater rates than normal cells. Not only do PET scans provide images that may be more detailed than those provided by MRI or CT scans, they also monitor the metabolic activity of tumors, allowing oncologists to assess whether they are malignant or benign and to follow their response to treatment.

Less direct benefits come from other applications. An example is the study of the mechanism of photosynthesis, in which carbon dioxide and water are combined to form glucose in the green leaves of plants.

$$6\ CO_2(g) + 6\ H_2O(\ell) \longrightarrow C_6H_{12}O_6(s) + 6\ O_2(g)$$

Radioactive tracers have been invaluable in establishing the mechanisms of organic and biochemical reactions. ^{14}C, for example, can be introduced into starting reagents using standard synthetic methods and its position in the products used to distinguish among several possible mechanisms. Radioactive tracers are also widely used in medical diagnosis. The radioimmunoassay technique, invented by Nobel laureate Rosalind Yalow, determines the levels of drugs and hormones in body fluids. Antigens (the drug or hormone of interest) are labeled with a radioactive tracer and bound to a known amount of antibody. Samples of blood containing unknown amounts of the antigen are added to the complex, and the unlabeled antigen displaces the labeled antigen, whose concentrations are determined by measuring its activity in solution after rinsing.

19.6 NUCLEAR FISSION

The nuclear reactions considered so far have been spontaneous, first-order decays of unstable nuclides. By the 1920s, physicists and chemists were using particle accelerators to bombard samples with high-energy particles to *induce* nuclear reactions. The English physicist James Chadwick (yet another illustrious Rutherford student) identified the neutron in 1932 as a product of the reaction between alpha particles and light nuclides such as ^{9}Be:

$$^{4}_{2}\mathrm{He} + {}^{9}_{4}\mathrm{Be} \longrightarrow {}^{1}_{0}n + {}^{12}_{6}\mathrm{C}$$

Shortly after Chadwick's discovery, a group of physicists in Rome, led by Enrico Fermi, began to study the interaction of neutrons with the nuclei of various elements. The experiments produced a number of radioactive species, and it was evident that the absorption of a neutron increased the $N:Z$ ratio in target nuclei above the stability line (see Fig. 19.4). One of the targets used was uranium, the heaviest naturally occurring element. Several radioactive products resulted, none of which had chemical properties characteristic of the elements between $Z = 86$ (radon) and

$Z = 92$ (uranium). It appeared to the Italian scientists in 1934 that several new transuranic elements ($Z > 92$) had been synthesized, and an active period of investigation followed.

In 1938 in Berlin, Otto Hahn and Fritz Strassmann sought to characterize these transuranic elements. They were bewildered to find that barium ($Z = 56$) was one of the products of the reaction between neutrons and uranium, with no evidence at all of the heavier transuranic elements that were expected. Hahn informed his former colleague Lise Meitner, and she conjectured that the products of the bombardment of uranium by neutrons were not transuranic elements but fragments of uranium atoms resulting from a process she termed **fission.** The implication of this phenomenon—the possible release of enormous amounts of energy—was immediately evident. When the outbreak of World War II appeared imminent in the summer of 1939, Albert Einstein wrote to President Franklin Roosevelt to inform him of the possible military uses of fission and of his concern that Germany might develop a nuclear explosive. In response to Einstein's concern, President Roosevelt authorized the Manhattan District Project in 1942, an intense, coordinated effort by a large number of physicists, chemists, and engineers to make a fission bomb of unprecedented destructive power.

The operation of the first atomic bomb hinged on the fission of uranium in a chain reaction induced by the absorption of neutrons. The two most abundant isotopes of uranium are ^{235}U and ^{238}U, whose natural relative abundances are 0.720% and 99.275%, respectively. Both isotopes undergo fission after absorbing neutrons, the latter only with "fast" neutrons and the former with both "fast" and "slow" neutrons. It was not known in the early days of neutron research that the probability of neutron absorption depended strongly on the velocity of the neutrons. By accident, Fermi and his colleagues discovered that experiments conducted on a wooden table led to a much higher yield of radioactive products than those performed on a marble-topped table. Fermi then repeated the irradiation experiments with a block of paraffin wax interposed between the radium–beryllium neutron source and the target sample, with the startling result that the induced level of radioactivity was greatly enhanced. Fermi found the explanation within hours: The high-energy neutrons emitted from the radium–beryllium source were reduced to thermal energy by collision with the low-mass nuclei of the paraffin molecules. Because of their lower energies, their probability of reaction with ^{235}U was greater and a higher yield was achieved. Hydrogen nuclei and the nuclei of other light elements such as ^{12}C (in graphite) are very effective in reducing the energies of high-velocity neutrons and are called **moderators.**

The fission of ^{235}U follows many different pathways, and some 34 elements have been identified among the fission products. In any single fission event two particular nuclides are produced together with two or three secondary neutrons; collectively, they carry away about 200 MeV of kinetic energy. Usually, the daughter nuclei have different atomic numbers and mass numbers so the fission process is asymmetric. Three of the many pathways are

$$ {}^{1}_{0}n + {}^{235}_{92}\mathrm{U} \longrightarrow \begin{cases} {}^{72}_{30}\mathrm{Zn} + {}^{162}_{62}\mathrm{Sm} + 2\,{}^{1}_{0}n \\ {}^{80}_{38}\mathrm{Sr} + {}^{153}_{54}\mathrm{Xe} + 3\,{}^{1}_{0}n \\ {}^{94}_{36}\mathrm{Kr} + {}^{139}_{56}\mathrm{Ba} + 3\,{}^{1}_{0}n \end{cases} $$

Figure 19.13 shows the distribution of the nuclides produced. More than one neutron is emitted per neutron absorbed, which leads to a branching chain reaction (see Section 18.4) with the number of neutrons growing exponentially with time (Fig. 19.14). Permitted to proceed unchecked, this reaction would quickly lead to the release of enormous quantities of energy. There are various processes by which neutrons can be lost, so it was not obvious that an uncontrolled chain reaction would occur or that a chain reaction could even be sustained at steady state. On December 2, 1942, Fermi and his associates demonstrated that a self-sustaining neutron chain reaction occurred in a uranium "pile" with a graphite moderator.

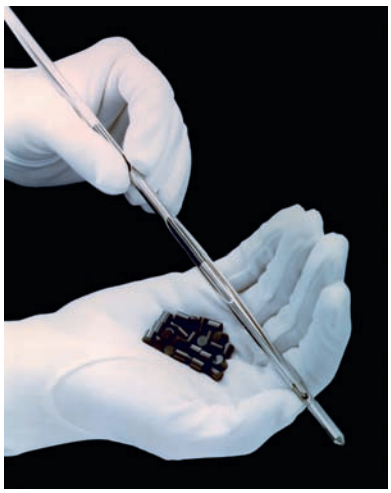
They limited its power output to $\frac{1}{2}$ J s^{-1} by inserting cadmium control rods to absorb neutrons, thereby balancing the rates of neutron generation and loss.

Fermi's work made two developments possible: (1) the exploitation of nuclear fission for the controlled generation of energy in nuclear reactors and (2) the production of ^{239}Pu, a slow- and fast-neutron fissionable isotope of plutonium, as an alternative to ^{235}U for the construction of atomic bombs. For the sudden release of energy required in an explosive, it was necessary to obtain ^{235}U or ^{239}Pu in a state free of neutron-absorbing impurities. Both alternatives were pursued simultaneously. The first option required enriching ^{235}U from its natural relative abundance of 0.72%. This was accomplished through gaseous diffusion (see Section 9.7). ^{239}Pu was recovered from the partially spent uranium fuel of large nuclear reactors by means of redox reactions, precipitation, and solvent extraction as the second option.

Although Fermi and his associates were the first scientists to demonstrate a self-sustaining nuclear chain reaction, a natural uranium fission reactor "went critical" about 1.8 billion years ago in a place now called Oklo, in the Gabon Republic of equatorial Africa. French scientists discovered in 1972 that the ^{235}U content of ore from a site in the open-pit mine at Oklo was only 0.7171%; the normal content of ore from other areas of the mine was 0.7207%. Although this deviation was not large, it was significant, and an investigation revealed that other elements were also present in the ore, in the exact proportions expected after nuclear fission. This discovery established that a self-sustaining nuclear reaction had occurred at Oklo. The geological age of the ore body was found to be about 1.8×10^9 years, and the original ^{235}U concentration is calculated to have been about 3%. From the size of the active ore mass and the depletion of ^{235}U, it is estimated that the reactor generated about 15,000 megawatt-years (5×10^{17} J) of energy over about 100,000 years.

Nuclear Power Reactors



Most **nuclear power reactors** in the United States (Fig. 19.15) use pellets of UO_2 that have been sintered to form hard ceramics, which are then inserted into fuel rods. The uranium is primarily ^{238}U, but the amount of ^{235}U is enriched above natural abundance to a level of about 3%. The moderator used to slow the neutrons (to increase the efficiency of the fission) is ordinary water in most cases, so these reactors are called "light-water" reactors. The controlled release of energy by nuclear

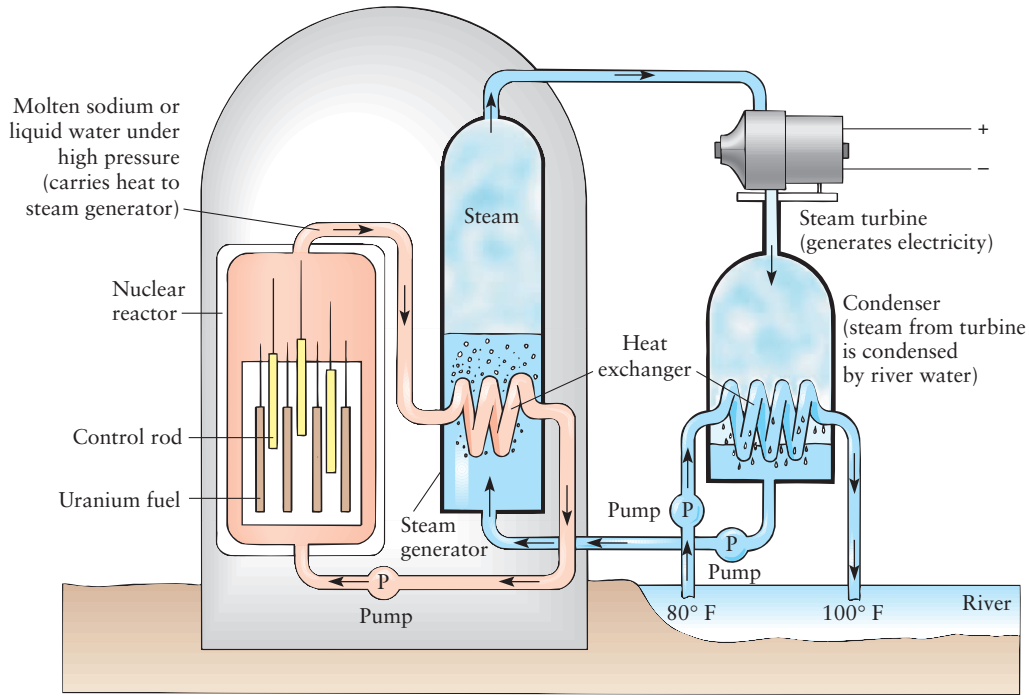
US Department of Energy/Photo Researchers, Inc.

UO_2 pellets and fuel rods

fission in power reactors demands a delicate balance between neutron generation and neutron loss. Control rods containing ^{112}Cd or ^{10}B, with large neutron capture efficiencies, effectively control the neutron flux. These rods are automatically inserted into or withdrawn from the fissioning system in response to changes in the neutron flux. As the nuclear reaction proceeds, the moderator (water) is heated and transfers its heat to a steam generator. The steam then goes to turbines that generate electricity (Fig. 19.16). The nonnuclear part of a nuclear power plant is essentially identical to that of a conventional fossil-fuel-fired power plant, the difference being the source of energy to heat the water.

The power reactors discussed so far rely on the fission of ^{235}U, an isotope in extremely limited supply. An alternative is to convert the much more abundant ^{238}U to fissionable plutonium (^{239}Pu) by neutron bombardment:

$$^{238}_{92}\mathrm{U} + {}^{1}_{0}n \longrightarrow {}^{239}_{93}\mathrm{Np} + {}^{0}_{-1}e^{-} \longrightarrow {}^{239}_{94}\mathrm{Pu} + 2\,{}^{0}_{-1}e^{-}$$



Fissionable ^{233}U can also be made from thorium:

$$^{232}_{90}\mathrm{Th} + {}^{1}_{0}n \longrightarrow {}^{233}_{91}\mathrm{Pa} + {}^{0}_{-1}e^{-} \longrightarrow {}^{233}_{92}\mathrm{U} + 2\,{}^{0}_{-1}e^{-}$$

Breeder reactors contain blankets of uranium or thorium that absorb neutrons and initiate the preceding reactions, generating new nuclear fuel in the process. An advanced technology for breeder reactors uses liquid sodium instead of water as the coolant, allowing the use of faster neutrons than in water-cooled reactors. The faster neutrons cause more complete consumption of radioactive fuels, increasing efficiency and greatly reducing radioactive waste.

The risks associated with the operation of nuclear reactors are small but not negligible, as the failure of the Three Mile Island reactor in the United States in 1979 and the disaster at Chernobyl in the former Soviet Union in 1987 demonstrated. If a reactor has to be shut down quickly, there is danger of a meltdown, in which the heat from the continuing fission processes melts the uranium fuel. Coolant must be circulated until heat from the decay of short-lived isotopes has been dissipated. The Three Mile Island accident resulted in a partial meltdown because some water coolant pumps were inoperative and others were shut down too soon, causing damage to the core and a slight release of radioactivity into the environ-

ment. The Chernobyl disaster was caused by a failure of the water-cooling system and a meltdown. The rapid and uncontrolled nuclear reaction that took place set the graphite moderator on fire and caused the reactor building to rupture, spreading radioactive nuclides with an activity estimated at 2×10^{20} Bq into the atmosphere. The Chernobyl disaster was really a chemical explosion in which the reaction between the graphite moderator (an unfortunate choice in retrospect) and water produced hydrogen gas and carbon dioxide. The explosive combustion of hydrogen blasted off the massive steel plate covering the reactor, allowing the release of tremendous amounts of radioactivity into the atmosphere. Unfortunately, the Chernobyl reactor was not housed in a containment structure designed to withstand such an explosion like those used in the United States.

Safe disposal of high-level nuclear waste (highly radioactive with long half-lives) is a serious and controversial issue. Waste is currently stored on-site in large pools of water. Centralized storage has been considered but current US policy is to focus on reprocessing to reduce the amount of high-level waste that would need long-term storage. Spent nuclear fuel can be vitrified (made into glass blocks), packed in barrels, and stored in stable geological formations. The half-life of ^{239}Pu is 24,000 years, and it has often been stated that we would need to provide a stable environment for 240,000 years to reduce the activity to 0.1% of its initial value. The Berkeley physicist Richard Muller has suggested that we compare the level of radioactivity of the waste to that which has already been mined and accept some probability greater than zero that there will be a leak. His calculations suggest that a facility that would provide a 99% level of confidence that there would be no leak would reduce the time needed to store the material to 300 years, by comparing the radioactivity resulting from such a leak not to zero but to the natural background levels found in the surrounding terrain.

19.7 NUCLEAR FUSION AND NUCLEOSYNTHESIS

Nuclear fusion is the union of two light nuclides to form a heavier nuclide with the release of energy. Fusion processes are often called **thermonuclear reactions** because they require that the colliding particles possess very high kinetic energies, corresponding to temperatures of millions of degrees, before they are initiated. They are the processes that occur in the sun and other stars. In 1939 the German physicists Hans Bethe (and, independently, Carl von Weizsäcker) proposed that the following reactions occur in normal stars (main sequence):

$$^{1}_{1}\mathrm{H} + {}^{1}_{1}\mathrm{H} \longrightarrow {}^{2}_{1}\mathrm{H} + {}^{0}_{1}e^{+} + \nu$$

$$^{2}_{1}\mathrm{H} + {}^{1}_{1}\mathrm{H} \longrightarrow {}^{3}_{2}\mathrm{He} + \gamma$$

$$^{3}_{2}\mathrm{He} + {}^{3}_{2}\mathrm{He} \longrightarrow {}^{4}_{2}\mathrm{He} + 2\ {}^{1}_{1}\mathrm{H}$$

In the first reaction, two high-velocity protons fuse to form a deuteron, with the emission of a positron and a neutrino that carry away (as kinetic energy) the additional 0.415 MeV of energy released. In the second reaction, a high-energy deuteron combines with a high-velocity proton to form a helium nucleus of mass 3 and a gamma ray. The third reaction completes the cycle with the formation of a normal helium nucleus $\left({}^{4}_{2}\mathrm{He}\right)$ and the regeneration of two protons. Each of these reactions is exothermic, but up to 1.25 MeV is required to overcome the repulsive barrier between the positively charged nuclei. The overall result of the cycle is to convert hydrogen nuclei to helium nuclei, and the process is called **hydrogen burning.**

As such a star ages and accumulates helium, it begins to contract under the influence of its immense gravity. As it contracts, its helium core heats up; when it

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

reaches a temperature of about 10^8 K, a stage of **helium burning** begins. The first reaction that occurs is

$$2\ {}^4_2\text{He} \rightleftharpoons {}^8_4\text{Be}$$

This reaction is written as an equilibrium because the ^{8}Be quickly reverts to helium nuclei with a half-life of only 2×10^{-16} s. Even with this short half-life, the ^{8}Be nuclei are believed to occasionally react with alpha particles to form stable ^{12}C:

$${}^8_4\text{Be} + {}^4_2\text{He} \longrightarrow {}^{12}_6\text{C}$$

The overall effect of the helium-burning phase of a star's life is to convert three helium nuclei to a carbon nucleus, just as helium was formed from four hydrogen nuclei in the hydrogen-burning phase. The density of the core of a star that is burning helium is on the order of 10^5 g cm^{-3}.

This process of **nucleosynthesis** continues beyond the formation of ^{12}C to produce ^{13}N, ^{13}C, ^{14}N, ^{15}O, ^{15}N, and ^{16}O. The stars in this stage are classified as red giants. Similar cycles occur until the temperature of a star core is about 4×10^9 K, its density is about 3×10^6 g cm^{-3}, and the nuclei are ^{56}Fe, ^{59}Co, and ^{60}Ni. These are the nuclei that have the maximum binding energy per nucleon. It is thought that the synthesis of still heavier nuclei occurs in the immense explosions of supernovae.

Heavy elements can also be produced in particle accelerators, which accelerate ions to high speeds, causing collisions that generate the new elements. Technetium, for example, is not found in nature but was first produced in 1937 when high-energy deuterons were directed at a molybdenum source:

$${}^{96}_{42}\text{Mo} + {}^2_1\text{H} \longrightarrow {}^{97}_{43}\text{Tc} + {}^1_0n$$

The first **transuranic element** was produced in 1940. Neptunium ($Z = 93$) results from the capture of a neutron by ^{238}U, followed by beta decay. Subsequent work by the American chemist Glenn Seaborg and others led to the production of plutonium ($Z = 94$) and heavier elements. In recent years, nuclides with Z as high as 118 have been made, but in tiny quantities. These nuclides have very short half-lives.

Controlled nuclear fusion is an attractive alternative to nuclear fission that could produce virtually unlimited quantities of energy from readily available sources of fuel with no adverse environmental impact. Two major efforts are underway to harness the power of the fusion of deuterium with tritium to form helium in a controlled way. There is virtually a limitless supply of deuterium that can be extracted from seawater, and tritium can be produced as a byproduct of the fusion reaction as discussed below. The reaction

$${}^2_1\text{H} + {}^3_1\text{H} \longrightarrow {}^4_2\text{He} + {}^1_0n$$

produces 17.6 MeV *per event,* which corresponds to about 340,000,000 kJ g^{-1} of fuel burned. To put this into perspective, a conventional power plant produces about 1 GW (10^9 W) of power, consuming about 2.5 million tons of coal per year. The same amount of energy produced by nuclear fusion would consume less than 10 kg of the hydrogen isotopes, so it is little wonder that nuclear fusion research and development is being so vigorously pursued.

Initiating controlled fusion is difficult because the two nuclei must come together with sufficient energy to overcome the repulsive Coulomb potential energy barrier, which is about 1 MeV for these hydrogen isotopes. This potential barrier can be thought of as an activation energy for the reaction; temperatures of the order of 100 million K are required for it to proceed at an acceptable rate (see Section 18.5). Two very different approaches have been developed over many years in attempts to achieve these extraordinarily high temperatures; they are called magnetic confinement and inertial confinement, respectively. Magnetic confinement fusion uses magnetic fields as "walls" to contain very high temperature plasmas (ionized gases) because there are no material walls that could survive under these conditions. The fuel is heated, in part, by the absorption of electromagnetic radiation in

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

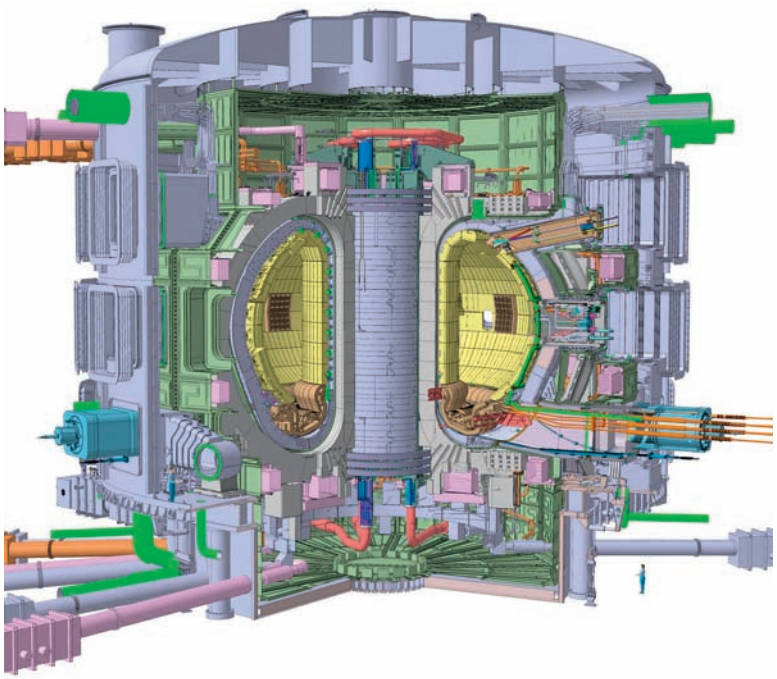
the same way that microwave ovens heat our food. Inertial confinement fusion, on the other hand, uses short bursts of very high-power laser radiation to compress and heat the fuel to very high temperatures and densities. The main difference between the two approaches is that magnetic confinement heats the fuel at somewhat lower pressures but for longer times, whereas inertial confinement both heats and compresses the fuel almost instantaneously.

There are currently two large-scale efforts underway to demonstrate that controlled nuclear fusion can generate more energy than that required for initiation, one focused on magnetic confinement and the other on inertial confinement. ITER (originally the International Thermonuclear Fusion Reactor but now said to be derived from the Latin word for "journey" for political reasons) is an international collaboration that is constructing a large tokamak in the south of France with the specific goal of producing 10 times as much energy as that required for initiation. The ITER tokamak is built around a donut-shaped vacuum chamber that contains a plasma (a gas of ionized particles, see Sec. 1.4). A large number of superconducting magnets generate a magnetic field some 200,000 times stronger than that of the earth, which confines the plasma to the interior of the vacuum chamber and prevents it from heating the walls. Figure 19.17 shows a schematic of the ITER tokamak. The design calls for an operating temperature of 150 million K and power output of 500 MW. The ITER tokamak has also been designed to produce tritium from the reaction of neutrons with lithium in the "blanket" that covers the interior surfaces of the vacuum vessel, the balanced reaction being

$$^{6}_{3}\mathrm{Li} + {}^{1}_{0}n \longrightarrow {}^{3}_{1}\mathrm{H} + {}^{4}_{2}\mathrm{He}$$

A demonstration power plant (DEMO) is intended to follow, based upon the anticipated success of the ITER experiment. The goal of that project is to demonstrate continuous fusion that produces sustained power in the 2 to 4 GW range, which is comparable to the largest existing conventional power plants.

The National Ignition Facility (NIF) is a project of the United States Department of Energy designed to demonstrate net energy production by inertial confinement fusion. The world's largest laser, with the greatest amount of energy per pulse, has been constructed and tested. A total of 192 amplified laser beams are focused onto a tiny, hollow beryllium sphere, about the size of a peppercorn, which contains a fraction of a milligram of the target mixture of deuterium and tritium in the form of a frozen solid held at 18 K (see Fig. 19.18).



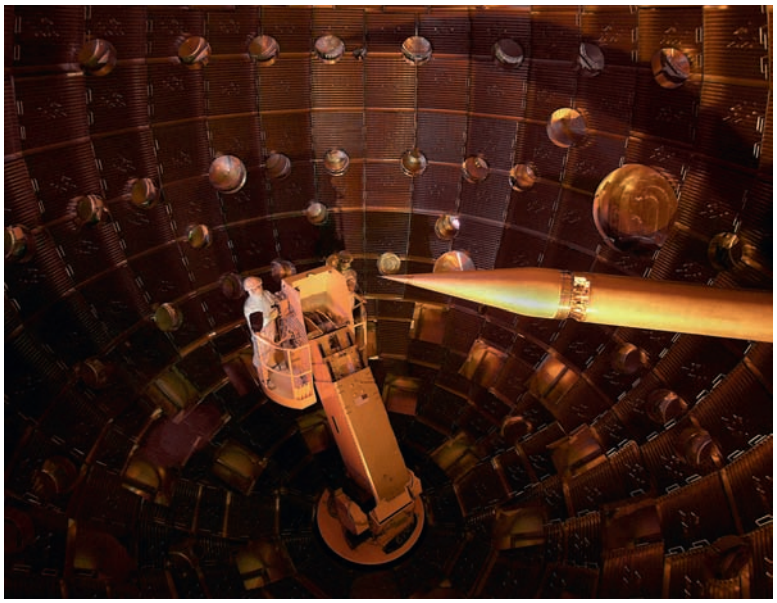


FIGURE 19.17 Cutaway of the ITER tokamak, showing the torus-shaped vacuum vessel (yellow) that is about 60 ft in diameter along with the external magnets. The entire machine will weigh some 23,000 tons.

(b)

(c)

Lawrence Livermore National Laboratory

FIGURE 19.18 (a) National Ignition Facility target chamber for inertial confinement fusion experiments. 192 laser beams enter through the ports shown and are focused onto the target, which is held at the tip of the positioner seen in the foreground. (b) Target holder (c) Laser beams focused on sample holder generate X-rays that cause the fuel pellet to implode, initiating fusion.

The laser beam generates more power than the entire U.S. electrical grid during its short pulse. The extremely high power compresses the fuel and heats it to the 100 million K required to initiate the fusion reaction. The system passed a critical test in March 2010, where it demonstrated a symmetrical implosion and temperatures greater than 3 million K that resulted from about 1 MJ of input energy. There are significant challenges that must be met before inertial confinement fusion becomes an important practical source of energy. The initial goal of the NIF is to produce 20 MJ of energy per pulse with the laser system currently capable of generating only about two pulses per day. Scaling this approach to provide power at levels that approach those provided by conventional power plants will require lasers capable of delivering perhaps 10 pulses per second that, in turn, would consume about 850,000 fuel pellets per day, which is a daunting challenge indeed.

A DEEPER LOOK

19.8 THE SHELL MODEL OF THE NUCLEUS

The shell model of the atom, as developed classically in Chapter 3 and quantum mechanically in Chapter 5, provides a sound conceptual framework for explaining and predicting the properties of atoms. A dense nucleus is surrounded by electrons arranged in a series of concentric shells of increasing radii. The number of electrons in each shell was first determined experimentally, from ionization energies, and later explained using quantum mechanics. Electrons in atoms are characterized by the four quantum numbers n, ℓ, m, and m_s which label their energy, orbital angular momentum, the z-component of the orbital angular momentum, and spin, respectively. The shell model of the nucleus, though significantly more complicated than

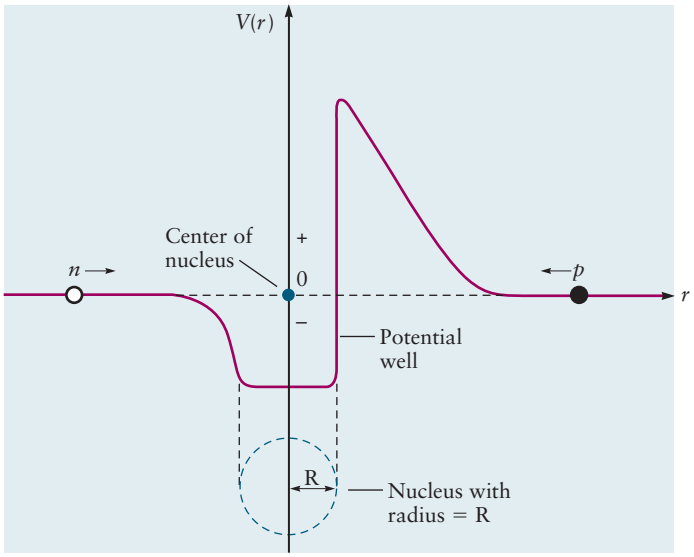

FIGURE 19.19 Potential energy function for a neutron (left) and a proton (right) interacting with a nucleus.

that of the atom, can be understood using the same approaches, and it provides considerable insight into the nature of nuclear processes at the subatomic level.

The shell model of the nucleus was developed independently by the Hungarian–American physicist Eugene Wigner, the German-born American physicist Maria Goeppert-Mayer, and the German physicist J. Hans D. Jensen, who shared the 1963 Nobel Prize for their discovery. The quantum mechanical analysis of the structure and properties of nuclei is analogous to that we introduced for atoms in Chapter 5, but the nature of the potential energy function for nucleons was not (and is still not) known, in contrast to the well-known Coulomb potential energy function used in atomic quantum mechanics. These scientists approached the problem by inventing a number of empirical potential functions and by comparing the results of their predictions with experiment, focusing in particular on the magic numbers observed for stable nuclei that were discussed in Section 19.3.

Let's begin by looking at the potential energy function sketched in Figure 19.19. It is a hybrid potential energy function in which the left side represents the potential energy of a neutron approaching an existing nucleus and the right side represents the potential energy of a proton approaching the same nucleus. The potential well represents the attraction due to the strong force; its width is roughly the size of the nucleus (a few fm), and its depth is of the order of the average binding energy of a single nucleon, about 8 MeV. The well is rounded because nuclei are not hard spheres, as shown in Figure 19.2.

A low-energy neutron approaching from the left does not encounter a potential energy barrier; it is attracted by the strong force, and absorbed into the nucleus. The potential well is flat, which means that the binding energy is independent of position within the nucleus, and the neutron is equally likely to be bound at any position in the interior. High-energy neutrons, on the other hand, are very effectively scattered by nuclei. *Neutron scattering* and *neutron diffraction,* based upon this interaction, have been developed into two very high-resolution structural probes that are used to characterize matter, especially materials that contain the lighter elements, which do not interact very strongly with X-rays. The right side of the diagram shows that a proton approaching an existing nucleus must surmount the Coulomb potential energy barrier before it can be captured and absorbed into the interior of the nucleus; protons must have incident kinetic energies on the order of a few MeV to be captured.

We began to describe what is known as the **empirical mass equation** in Section 19.3, where we introduced the idea that the binding energy per nucleon is roughly constant but decreases with decreasing A for the lighter nuclei due to the weaker

binding of surface nucleons compared with those in the interior. We can write an empirical mass equation in the following simplified form

$$E_B(A, Z) = aA - bA^{2/3} - c(Z^2/A^{1/3}) - d[(A - 2Z^2)/A]$$

in which the coefficients are determined by fitting the experimental binding energy data to this equation. The first term represents the constant binding energy per nucleon, and the second term represents the reduction in that binding energy due to the fraction of nucleons that reside on the surface. (It is proportional to the surface area to volume ratio, which decreases slowly with increasing A.) The third term is due to the Coulomb repulsion between protons, which is directly proportional to the product of their charges and inversely proportional to their separation, given by $A^{1/3}$, which has the dimension of length. The fourth term is called the asymmetry term; it is a measure of the relative stability of members of an isobar (nuclides with the same value of A) as a function of Z, as shown in Figure 19.20. The asymmetry term has a parabolic shape, a model which we discuss below, that illustrates the driving force for various decay processes and allows us to predict which processes are likely to dominate in particular cases. The parabola has a well-defined minimum that represents the lowest energy state of the system, by analogy to other potential energy diagrams you have seen. The minimum occurs close to, but not exactly at, $N/Z = 1$. Nuclei with excess protons will spontaneously decay by positron emission or electron capture to produce daughters with configurations near those of the minimum, whereas nuclei that are proton deficient will decay by beta emission to reach the most stable configurations.

Neutrons and protons appear to occupy quantized energy levels in separate potential wells that are superimposed in space. Two lines of evidence support this conclusion. The vast majority (157) of stable nuclei have even numbers of both protons and neutrons, suggesting that the two different kinds of nucleons prefer to be paired separately. Stable nuclei with odd numbers of protons (50 nuclides) have even numbers of neutrons and vice versa (54 nuclides), providing additional support for the preceding conclusion. Finally, there are only four stable nuclides with odd numbers of both protons and neutrons.

Figure 19.21 shows a plot of the neutron separation energy as a function of N for the isotopes of lead. The separation energy for nucleons is analogous to the ionization energy for atoms; it is the energy required to remove a nucleon from the nucleus and separate it to infinity with zero kinetic energy. The pattern in this plot is revealing. Isotopes of a given element (constant Z) with even N are significantly more stable than isotopes with odd N. Analogous plots of the proton separation energy versus Z, holding N constant, reveal the same pattern. Taken together, these

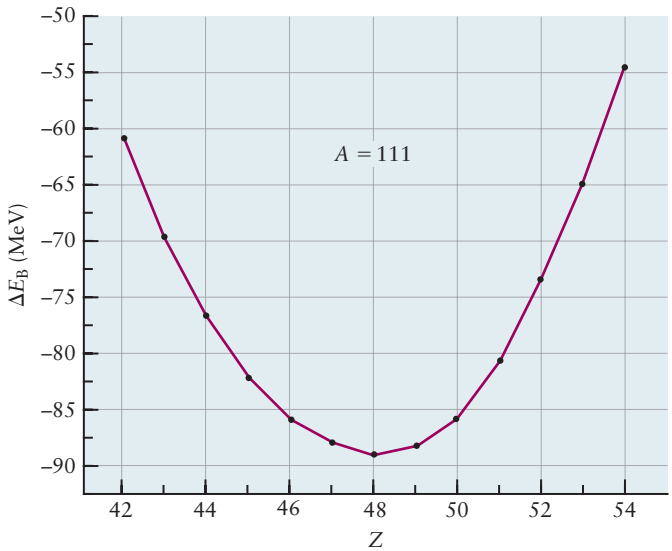

FIGURE 19.20 Asymmetry energy, relative to a standard reference, plotted as a function of Z for nuclides of the $A = 111$ isobar.

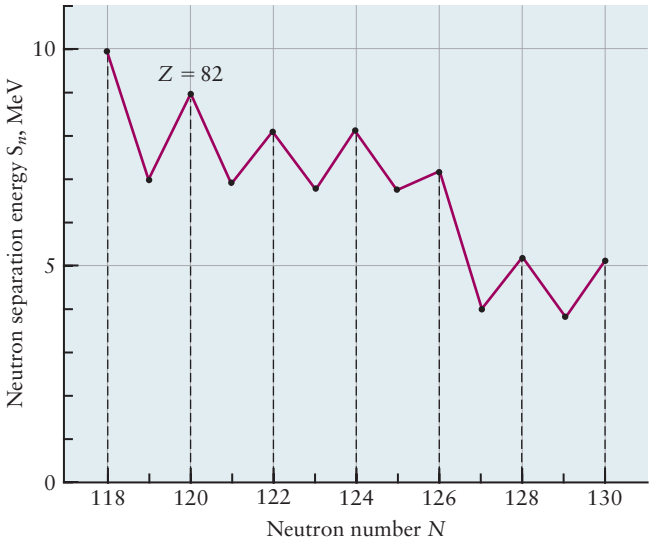

FIGURE 19.21 Neutron separation energy for the isotopes of lead.

pieces of evidence strongly suggest that the energy levels of protons and neutrons are quantized by different potential wells and that there is a strong preference for nucleons of a given type to be paired with one another. Furthermore, we know from experiment that all nucleons are spin-$\frac{1}{2}$ particles, like electrons, that must obey the Pauli principle, which suggests that a quantum mechanical model for nuclear structure will have very similar features to that developed for atomic structure. Let's examine some predictions of such a simple qualitative model before developing it in more detail.

Figure 19.22 shows a schematic of the neutron and proton potential wells, along with a set of occupied energy levels, for members of the $A = 12$ isobar ($^{12}_{5}\text{B}$, $^{12}_{6}\text{C}$, $^{12}_{7}\text{N}$). The doubly occupied levels have paired spins, as required by the Pauli principle. $^{12}_{5}\text{B}$ can be considered a proton-deficient (or neutron-rich) nucleus compared with the stable $^{12}_{6}\text{C}$ isotope, with the extra neutron occupying an orbital at higher energy than the highest occupied, half-filled proton orbital. It is energetically favorable for the neutron to convert into a proton via β^- emission and pair up with the proton in the lower energy proton orbital. Conversely, $^{12}_{7}\text{N}$ can be considered proton-rich (or neutron-poor) with an extra proton occupying an orbital at higher energy than the half-filled neutron orbital. It is energetically favorable for the proton to convert into a neutron by β^+ emission and pair up with the neutron in the lower energy neutron orbital. Diagrams like these can be very helpful in visualizing nuclear decay processes and understanding nuclear stability.

A second example allows us to rationalize the parabolic functional form of the asymmetry term empirical mass equation. Let's consider the creation of neutron-

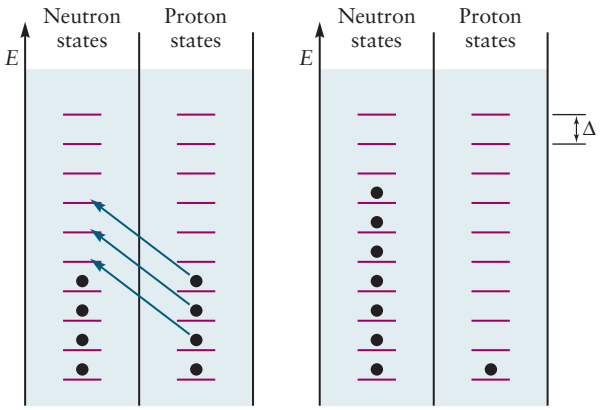

FIGURE 19.23 Schematic showing the energy required to create a nucleus ${}^{A}_{Z-3}A(Z-3)$ from the nucleus ${}^{A}_{Z}Z$ by converting three protons into three neutrons.

rich nuclei and proton-rich nuclei from a stable nucleus with $Z/A = 1$, as suggested by the sketch in Figure 19.23.

We assume, for simplicity, that the energy levels shown represent the energies of discrete quantum states that can be occupied by only one nucleon, that the separations between the proton levels and the neutron levels are all the same (Δ), and that the orbital energy levels are aligned with one another in both wells. We also assume that the energy of the highest filled orbital is the same for all nucleons because the binding energy per nucleon is essentially independent of A. Let's calculate the energy required to convert three protons into three neutrons as sketched in the diagram. The energy of each of the 3 protons must be increased by 3Δ, so the work required to convert 3 protons into 3 neutrons is given by $w = (3)(3\Delta)$. The work required to convert n protons is $w = n^2\Delta$, where $n = (N - Z)/2$, with N and Z being the neutron number and proton number of the newly created nucleus, respectively. The energy level separation Δ is proportional to $1/A$ because the A nucleons fill levels that are uniformly spaced between the bottom of the well and the highest occupied level. Putting this all together we get

$$w \propto (A - 2Z)^2/A$$

where we have made the substitution $N = A - Z$. This simple model rationalizes the parabolic dependence of the asymmetry energy on Z determined experimentally and shown in Figure 19.20.

There are a number of different empirical potential energy functions that describe the attractive potential well shown in Figure 19.20, the simplest of which are the three-dimensional isotropic harmonic oscillator and the three-dimensional rounded square well shown in Figure 19.24. The energy levels of the harmonic oscillator are equally spaced (see Section 20.3), whereas the energy levels of the rounded square well have an irregular spacing, like those of a particle in a cubic box (see Section 4.7). The isotropic harmonic oscillator is the simplest potential energy function that describes the attraction between a neutron and the nucleus as a function of distance.

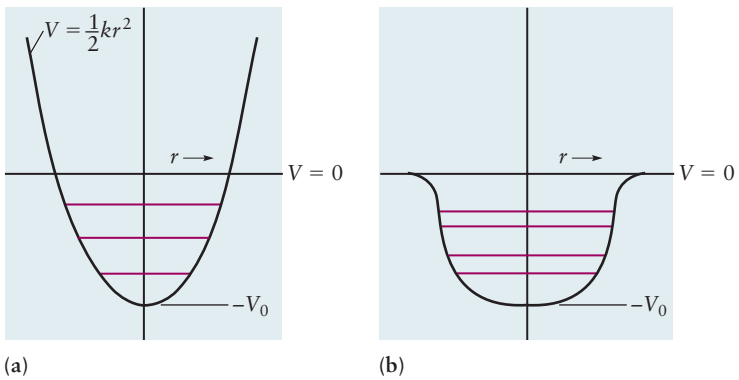

FIGURE 19.24 Sketches of potential energy functions and first few energy levels for neutrons. (a) three-dimensional isotropic harmonic oscillator and (b) rounded square well.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

It is the three-dimensional version of the harmonic oscillator potential energy function (see Section 20.3), which may be written as

$$V(r) = \tfrac{1}{2}\mu(2\pi\nu)^2 r^2 = \tfrac{1}{2}\mu(2\pi\nu)^2(x^2 + y^2 + z^2)$$

because the force constants in all three directions are the same. (It is called the isotropic or spherical harmonic oscillator for this reason.) The potential energy is a function only of r, the distance from the origin, with μ being the reduced mass, and ν being the natural frequency of the oscillator. We have also written the potential energy function in Cartesian coordinates to suggest that the Schrödinger equation for this problem can be solved using the same approach discussed in Section 4.7 for a particle in a three-dimensional cubic box. The wave function for a three-dimensional harmonic oscillator is the product of three one-dimensional harmonic oscillator wave functions; the energy levels are given by

$$E_{n\ell} = (n_x + n_y + n_z + \tfrac{3}{2})h\nu = Nh\nu$$

where ν is the frequency of the oscillator, the quantum numbers n_x, n_y, and n_z are independent of each other, and the constant term $\frac{3}{2}h\nu$ is the zero-point energy. It is customary in nuclear chemistry to refer the energies of the various levels to the energy of the zero-point level, in contrast to the practice in other areas of chemistry in which the zero-point energy $E = \frac{1}{2}h\nu$ is always included explicitly. Each of the n_i can take on the values 0, 1, 2, 3, etc., as can N, which is called the oscillator quantum number. The degeneracy of each level must be worked out by calculation, just as we did for the particle in a cubic box in Section 4.7: There is only one state with $N = 0$, there are three states with $N = 1$, six states with $N = 2$, and so forth. The energy levels are equally spaced by $h\nu$, like those of the one-dimensional harmonic oscillator. Figure 19.25a shows the energy level diagram for the isotropic harmonic oscillator.

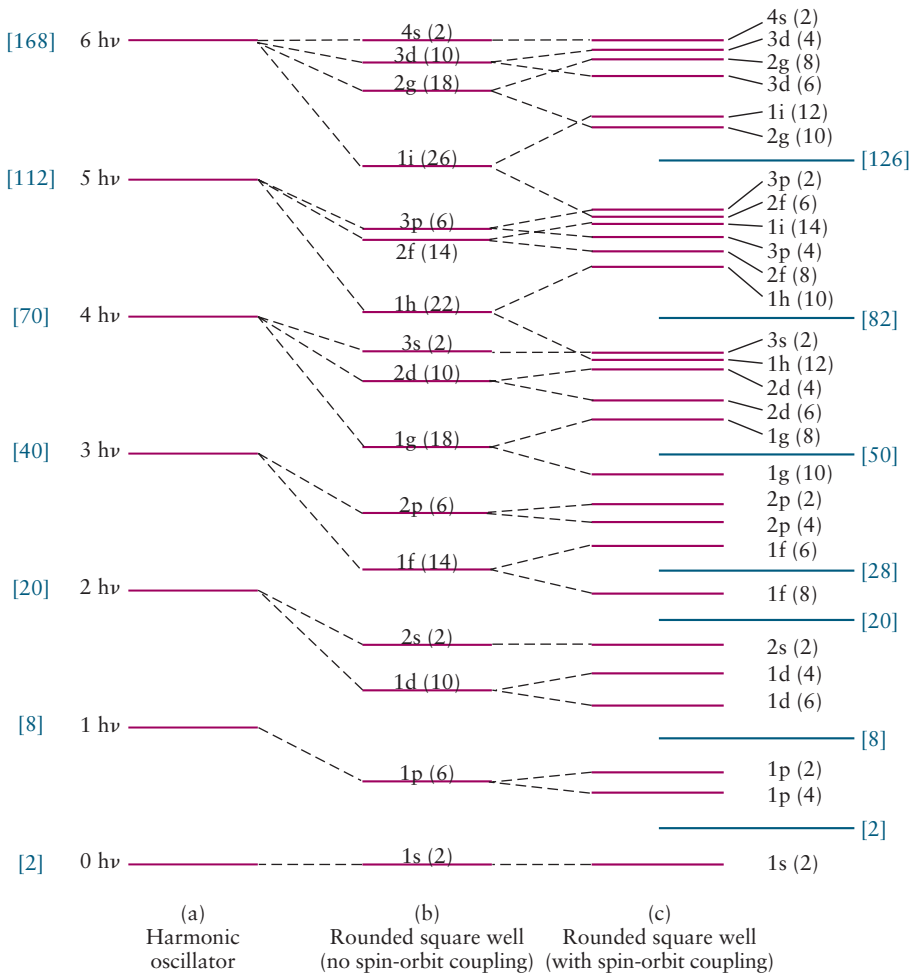

FIGURE 19.25 Energy level diagrams for nucleons: (a) three-dimensional harmonic oscillator potential; (b) rounded square well potential without spin-orbit coupling; (c) rounded square well potential with spin-orbit coupling. The number of nucleons allowed in each level is indicated in parentheses, with the cumulative number of nucleons in filled levels up to each level given in square brackets.

Nuclear configurations are built up using an Aufbau principle that is analogous to that used in building up the electronic configurations of atoms. Remember that neutrons and protons occupy separate potential wells, so we must build up their configurations separately, by adding nucleons to states in order of increasing energy, and remembering that they are spin-$\frac{1}{2}$ particles, like electrons, that must obey the Pauli principle. The lowest-energy nuclear configuration is always the one with the least total spin; a pair of nucleons prefers to occupy the same state rather than occupying two different states. This result is different from the atomic case where the lowest-energy configuration is the one in which single electrons occupy each orbital, with parallel spins, before two electrons occupy the same orbital (Hund's rules). The difference between the filling of nuclear states and electron states is due to the different ranges of the forces responsible. The short range of the attractive strong force favors nuclei occupying the same state, whereas the long range of the repulsive Coulomb force favors electrons occupying different states in many electron atoms.

Let's build up the *neutron* configuration of a nucleus, as a concrete example, by filling the neutron energy levels sequentially. The $N = 0$ level is nondegenerate (accommodating up to 2 neutrons), the $N = 1$ level is threefold degenerate (up to 6 neutrons), the $N = 2$ level is sixfold degenerate (up to 12 neutrons), and the $N = 3$ level is 10-fold degenerate (up to 20 neutrons). The numbers in square brackets to the left of each level are the cumulative numbers of nucleons predicted to occupy filled levels up to and including that level: 2, 8, 20, 40, 70, 112, and 126, respectively. The harmonic oscillator model accounts for the origin of the first few "magic numbers" of neutrons found in especially stable nuclei; the numbers 2, 8, and 20 correspond to the configurations of the filled shells predicted, but the model fails to explain the origin of the next magic number, 28, predicting instead that the next filled shell would accommodate 40 nucleons cumulatively, in contrast to the experimental results. The harmonic oscillator model does provide a reasonable approximation of the nuclear potentials of the lighter elements, however, and it is still used to interpret the results of scattering experiments and nuclear reactions involving those elements.

A number of models have been proposed to better represent the nuclear potential, the simplest of which is the rounded square well shown in Figure 19.24b. Solutions to the Schrödinger equation for all models of this general shape predict a series of energy levels given by $E_{n,\ell} = [(2n - 1) + \ell]h\nu = N_o h\nu$, in which the quantity N_o corresponds to the principal quantum number in atomic systems, and ℓ is an angular momentum quantum number that is exactly analogous to that in atoms. The allowed values for n include 1, 2, 3, . . . , and those for ℓ include 0, 1, 2, 3, ... Nuclear states are labeled by their angular momentum quantum numbers, using the same symbols used for atomic states; $\ell = 0, 1, 2, 3 \ldots$, are labeled *s, p, d, f* . . . , respectively, and the degeneracy of states with the same angular momentum ℓ is $2\ell + 1$. Unlike the atomic case, however, the quantum numbers allowed for ℓ are independent of *n,* which leads to a high level of degeneracy for each level with principal quantum number N_O, like that predicted by the harmonic oscillator model. The degeneracies of the levels are most easily determined by direct calculation, as before. The first two levels, $E_{1,0} = 0$ and $E_{1,1} = 1$ (in units of $h\nu$), are not degenerate, and they are labeled 1*s* and 1*p,* respectively. The 1*s* level can accommodate two nucleons, whereas the 1*p* level can accommodate six nucleons, just like atomic *p* levels. There are two sets of states with $E_{n,\ell} = 2$: $n = 0$, $\ell = 2$, and $n = 2$, $\ell = 0$, which are degenerate for a spherical potential but become nondegenerate in the rounded square well potential. There is a centrifugal term in the potential of the form $\ell(\ell + 1)$, like that for atoms as shown in Equation 5.10, which breaks the degeneracy of sublevels of the same N_o but different ℓ. The different nature of the forces involved leads to a different relative ordering of the sublevels; the energy of the nuclear sublevels increases with decreasing ℓ, as shown in Figure 19.25b. The $N_o = 2$ level splits into a 1*d* level that can accommodate 10 nucleons (like *d* orbitals) that lies at lower energy than the 2*s* level that can accommodate 2 nucleons. The rounded square well potential (and all related

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

models) breaks the degeneracy predicted by the isotropic harmonic model but still fails to account for the magic numbers observed. The energy level diagram predicts that filling the $1f$ sublevel of $N_o = 3$ would produce a cumulative total of 34 nucleons, not the magic number 28 that is observed.

Nuclear shell models only began to explain the experimental magic numbers when they included the coupling between the spin and orbital angular momenta of individual nucleons. Nucleons are characterized by a spin quantum number $s = \frac{1}{2}$ and an angular momentum quantum number ℓ, just like electrons. These angular momentum components can be aligned parallel to one another, giving a total angular momentum $j = \ell + \frac{1}{2}$ or antiparallel to one another, with $j = \ell - \frac{1}{2}$. It turns out that the parallel arrangement lies lower in energy than the antiparallel arrangement, so levels of a given ℓ are split into a pair of states separated by the spin-orbit coupling energy. This splitting is proportional to $2\ell + 1$, which accounts for the increase in the splittings observed for larger values of ℓ in Figure 19.25b. The energy level diagram shown was generated by adding the spin-orbit coupling term to the rounded square well potential energy function and solving the resulting Schrödinger equation. The magnitude of the spin-orbit coupling constants was adjusted to bring the energy levels into agreement with experiment. The 1963 Nobel Prize in Physics was awarded for this achievement. The number of nucleons that occupy each level is shown in parentheses, and the total number of nucleons in filled levels up to the energy represented by the horizontal line is shown in square brackets. The sequence 2, 8, 29, 28, 50, 82, 126 is in perfect agreement with the experimental magic numbers observed, and the general model has been very successful in explaining a wide variety of other nuclear properties and reactions as well. Maria Goeppert Mayer, who shared the Nobel Prize for her part in this discovery, described the idea to her daughter, which we paraphrase as follows: "Imagine that an energy level of a given angular momentum is represented by a circle of dancers waltzing counterclockwise, with the z component of the orbital angular momentum pointing up. Now imagine that the dancers are twirling as well as circling, with some twirling counterclockwise and others twirling clockwise, the twirling corresponding to the projections of the spin angular momentum. Most dancers would agree that it is easier to twirl in the same direction as they circle, the energy required being less for this arrangement than for the opposite one. And so it is for nucleons, the lower energy state being the one with paired angular momenta."

The shell model of nuclear structure was developed using a similar approach to that which led to the shell model of the atom. The important differences between the models include the existence of separate wells for protons and neutrons, the extremely short range and great depth of the potential energy function for the strong force, and the central role of spin-orbit coupling, which is present in atoms but not as dominant as in nuclei. The model successfully explains the greater relative abundances of nuclides with even numbers of nucleons, the existence of only one stable isotope for nuclei with odd mass numbers but several stable isotopes for nuclei with even mass numbers, and the driving force and decay mechanisms responsible for converting unstable members of an isobar to the stable isotopes.

CHAPTER SUMMARY

The identities of the elements are not preserved in nuclear reactions—elements decay into lighter daughter elements in fission reactions, and heavier elements are synthesized from lighter elements in fusion reactions. Mass changes in nuclear reactions are relatively small, but the accompanying energy changes are enormous; they are related by Einstein's famous formula $E = mc^2$. The isotopes of the lighter elements ($Z < 40$ or so) are stable when the ratio of the number of neutrons to the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

number of protons (N/Z) is approximately equal to 1. Isotopes with $N/Z < 1$ will decay via positron emission or electron capture to increase the number of protons in the nucleus, whereas those with $N/Z > 1$ will decay via beta emission to decrease the number of protons in the nucleus. A fourth decay channel, alpha particle emission, becomes important for heavier nuclei. Radioactive decay follows first order kinetics, and the half-life $t_{1/2}$ is a convenient measure of the timescale of the reaction. Half-lives range from 10^{-16} s to 10^{20} years, which is an incredibly wide range of timescales. The half-life of ^{238}U has been used to calibrate geological timescales, and ^{14}C dating is a well-established method for dating human artifacts in anthropology. X-rays, gamma rays, electrons, positrons, and alpha particles are all used in medical diagnostics and therapy with increasing efficacy and fewer side effects. Nuclear fusion, which led to the formation of the heavier elements from hydrogen in the process called nucleosynthesis, continues to hold promise as a source of clean power for the future.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 19.1 – Radioactivity

Summarize the characteristics of the three kinds of ionizing radiation identified by Rutherford.

- α particles are $^4_2$He nuclei that are the least penetrating form of ionizing radiation, β rays are electrons that penetrate a few millimeters into matter, and γ rays are very high energy electromagnetic radiation that penetrate deeply.

Describe the various kinds of radiation detectors.

- Photographic film darkens when exposed to radiation, the degree of darkening being proportional to the dose. Geiger counters are gas-filled tubes across which a large voltage is applied. Radiation ionizes gas molecules, and the high-energy primary electrons produced are converted into a large number of low-energy secondary electrons. Geiger counters count the resulting large current pulses. Proportional counters are gas-filled tubes, the gases being ionized by radiation. Proportional counters measure the activity by counting the number of pulses per second, and they measure the energy of the emitted particles or rays by measuring the pulse height (voltage).

Section 19.2 – Nuclear Structure and Nuclear Decay Processes

Identify the characteristic features of nuclear structure and nuclear forces.

- Nuclei are closely packed arrangements of nucleons, protons, and neutrons, whose radii are of the order of 10^{-15} m = 1 fm; nuclear radii can be calculated using $R = 1.2 \times 10^{-15} A^{1/3}$ m, where A is the mass number. The densities of all nuclei are large and approximately the same.
- Nucleons are bound together by the strong force, an attractive force that is stronger than the Coulomb force at short distances (fm). Typical nuclear binding energies are of the order of 8 MeV, about 10^6 times larger than chemical bond energies.
- Nucleons are built from quarks, which have fractional charges. The proton comprises two up quarks and a down quark, and the neutron comprises two down quarks and an up quark.

Identify and characterize patterns of nuclear stability and the nuclear decay processes.

- Stable nuclei are those for which $N/Z = 1$ for $Z < 40$ and $N/Z \approx 1.5$ for $Z > 40$.
- Alpha decay is the spontaneous emission of α particles ($^4_2$He nuclei) from heavy nuclei ($Z > 83$) that reduces the Coulomb repulsion between protons; the parent nucleus loses two protons and two neutrons.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- There are three different modes of β decay: β^- (electron) emission; β^+ (positron) emission, and EC (electron capture). These processes convert protons into neutrons (and vice versa) to bring the N/Z ratio closer to the line of stability.
- γ-ray emission occurs when nuclei in excited states decay to states of lower energy, by analogy to the emission of electromagnetic radiation by atoms and molecules in electronically excited states.

Write balanced nuclear equations for beta decay, positron emission, electron capture, and alpha decay, and calculate the maximum kinetic energies of the particles emitted (Problems 1–12).

- Charge, mass number, and atomic number are conserved in a balanced nuclear reaction.

Section 19.3 – Mass–Energy Relationships

Describe mass energy relationships in nuclear reactions (Problems 13–18).

- Einstein's relation $E = mc^2$ establishes the relationship between mass and energy in nuclear reactions; the conversion of very small quantities of mass produces tremendous quantities of energy. Spontaneous nuclear reactions are those for which $\Delta m < 0$.

Section 19.4 – Kinetics of Radioactive Decay

Solve problems involving the half-life or decay constant of a radioactive sample and its activity (Problems 19–24).

- Nuclear decay follows first-order kinetics characterized by a half-life $t_{1/2} = \ln 2/k = 0.693/k$ where k is the first-order rate constant.

Apply the kinetics of nuclear decay to the dating of rocks or artifacts (Problems 25–30).

- The ages of rocks are determined by comparing the ratio of the numbers of daughter to parent nuclei. Radiocarbon dating using ^{14}C assumes that living things have $^{14}C/^{12}C$ ratios that are in equilibrium with the atmosphere that persists until death, after which time the ^{14}C decays with its characteristic 5430-year half-life.

Section 19.5 – Radiation in Biology and Medicine

Discuss the interactions of radiation with various kinds of matter and the measurement of radiation dosage (Problems 31–36).

- The radiation dose is the energy deposited per kg of tissue; it is measured in rads or grays (SI unit). The relative biological damage is given by the dose multiplied by a factor that takes into account the damage caused by different kinds of radiation. Alpha particles and high-energy neutrons cause about 20 times as much damage as β or γ rays.

Section 19.6 – Nuclear Fission

Describe the processes of nuclear fission and fusion, and calculate the amounts of energy released when they occur (Problems 37–41).

- Nuclear fission is the spontaneous splitting of a nucleus into two smaller fragments, whereas nuclear fusion is the synthesis of a heavier nucleus from a pair of lighter nuclei.
- Nuclear chain reactions occur when more than one neutron is produced per fission event, allowing self-propagating reactions to occur.

Explain the benefits and risks associated with nuclear power.

- Nuclear power has the potential to provide essentially unlimited energy without contributing to global climate change. The major risks include high-level waste disposal and the possibility of diverting nuclear fuel to make nuclear weapons.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

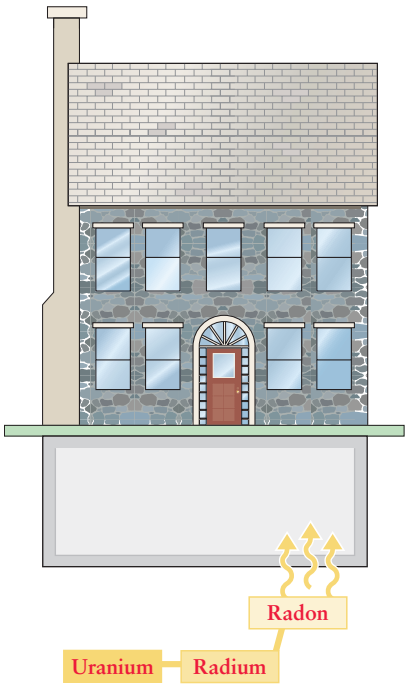
Section 19.7 – Nuclear Fusion and Nucleosynthesis

Explain the potential benefits of nuclear fusion.

- Fusion of hydrogen isotopes in normal stars produces He, which reacts further to produce all of the heavier elements in a series of fusion reactions called nucleosynthesis.

Section 19.8 – A Deeper Look . . . The Shell Model of the Nucleus

Describe the evidence that led to the development of the shell model of the nucleus.



- Key pieces of evidence include: the existence of magic numbers of protons and neutrons in particularly stable nuclei and the patterns observed in nuclear separation energies.

Describe the shell model of the nucleus.

- Neutrons and protons occupy separate potential wells with quantized energy levels; up to two nucleons can occupy each quantum state because of the Pauli principle. Nucleons tend to pair in states before occupying higher energy states, in contrast to atoms, because of the strength and range of the strong nuclear force.
- The harmonic oscillator potential and any number of square well potentials without spin-orbit coupling fail to account for the magic numbers observed. Coupling the spin and orbital angular momentum of each nucleon satisfactorily accounts for the pattern of magic numbers observed.

CUMULATIVE EXERCISE

Radon in the Environment

Radon most commonly enters houses through the foundation or basement walls.

Radioactive ^{222}Rn and ^{220}Rn form constantly from the decay of uranium and thorium in rocks and soil and, being gaseous, seep out of the ground. The radon isotopes decay fairly quickly, but their products, which are also radioactive, are then in the air and attach themselves to dust particles. Thus, airborne radioactivity can accumulate to worrisome levels in poorly ventilated basements in ground that is rich in uranium and thorium.

(a) Describe the composition of an atom of ^{222}Rn and compare it with that of an atom of ^{220}Rn.

(b) Although ^{222}Rn is a decay product of ^{238}U, ^{220}Rn comes from ^{232}Th. How many alpha particles are emitted in the formation of these radon isotopes from their uranium or thorium starting points? (*Hint:* Alpha decay changes the mass number *A*, but other decay processes do not.)

(c) Can alpha decay alone explain the formation of these radon isotopes from ^{238}U and ^{232}Th? If not, state what other types of decay must occur.

(d) Can $^{222}_{86}$Rn and $^{220}_{86}$Rn decay by alpha particle emission? Write balanced nuclear equations for these two decay processes, and calculate the changes in mass that would result. The masses of ^{222}Rn and ^{220}Rn atoms are 222.01757 and 220.01140 u, respectively; those of ^{218}Po and ^{216}Po are 218.0089 and 216.00192 u, respectively.

(e) Calculate the energy change in the alpha decay of one ^{220}Rn nucleus, in million electron volts and in joules.

(f) The half-life of ^{222}Rn is 3.82 days. Calculate the initial activity of 2.00×10^{-8} g of ^{222}Rn, in disintegrations per second.

(g) What will be the activity of the ^{222}Rn from part (f) after 14 days?

(h) The half-life of ^{220}Rn is 54 s. Are the health risks of exposure to a given amount of radon for a given short length of time greater or smaller for ^{220}Rn than for ^{222}Rn?

Answers

(a) An atom of ^{222}Rn has 86 electrons outside the nucleus. Inside the nucleus are 86 protons and 222 − 86 = 136 neutrons. An atom of ^{220}Rn has the same number of electrons and protons, but only 134 neutrons in its nucleus.

(b) Four alpha particles are produced to make ^{222}Rn from ^{238}U; three are produced to make ^{220}Rn from ^{232}Th.

(c) If $^{238}_{92}\text{U}$ were to lose four alpha particles, $^{222}_{84}\text{Po}$ would result instead of $^{222}_{84}\text{Rn}$. Two $^{0}_{-1}e^{-}$ beta particles must be ejected from the nucleus along the way to raise the atomic number to $Z = 86$. The same is true of the production of ^{220}Rn from ^{232}Th.

(d) $^{222}_{86}\text{Rn} \longrightarrow {}^{218}_{84}\text{Po} + {}^{4}_{2}\text{He}$; $\Delta m = -0.00617$ u < 0; allowed
$^{220}_{86}\text{Rn} \longrightarrow {}^{216}_{84}\text{Po} + {}^{4}_{2}\text{He}$; $\Delta m = -0.0069$ u < 0; allowed

(e) $\Delta E = -6.4 \text{ MeV} = -1.03 \times 10^{-12}$ J

(f) $A = 1.14 \times 10^{8}\ \text{s}^{-1}$

(g) $A = 9.0 \times 10^{6}\ \text{s}^{-1}$

(h) Greater

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

Nuclear Structure and Nuclear Decay Processes

1. The nuclide $^{8}_{5}\text{B}$ decays by positron emission to $^{8}_{4}\text{Be}$. What is the energy released (in MeV)?

2. The nuclide $^{10}_{4}\text{Be}$ undergoes spontaneous radioactive decay to $^{10}_{5}\text{B}$ with emission of a beta particle. Calculate the maximum kinetic energy of the emitted beta particle.

3. Write balanced equations that represent the following nuclear reactions.
   (a) Beta emission by $^{39}_{17}\text{Cl}$
   (b) Positron emission by $^{22}_{11}\text{Na}$
   (c) Alpha emission by $^{224}_{88}\text{Ra}$
   (d) Electron capture by $^{82}_{38}\text{Sr}$

4. Write balanced equations that represent the following nuclear reactions.
   (a) Alpha emission by $^{155}_{70}\text{Yb}$
   (b) Positron emission by $^{26}_{14}\text{Si}$
   (c) Electron capture by $^{65}_{30}\text{Zn}$
   (d) Beta emission by $^{100}_{41}\text{Nb}$

5. The stable isotopes of neon are ^{20}Ne, ^{21}Ne, and ^{22}Ne. Predict the nuclides formed when ^{19}Ne and ^{23}Ne decay.

6. The two stable isotopes of carbon are ^{12}C and ^{13}C. Predict the nuclides formed when ^{11}C and ^{14}C decay. Is alpha emission by ^{14}C possible?

7. The free neutron is an unstable particle that decays into a proton. What other particle is formed in neutron decay, and what is the maximum kinetic energy (in MeV) that it can possess?

8. The radionuclide $^{210}_{84}\text{Po}$ decays by alpha emission to a daughter nuclide. The atomic mass of $^{210}_{84}\text{Po}$ is 209.9829 u, and that of its daughter is 205.9745 u.
   (a) Identify the daughter, and write the nuclear equation for the radioactive decay process.
   (b) Calculate the total energy released per disintegration (in MeV).
   (c) Calculate the kinetic energy of the emitted alpha particle.

9. The natural abundance of ^{30}Si is 3.1%. Upon irradiation with neutrons, this isotope is converted to ^{31}Si, which decays to the stable isotope ^{31}P. This provides a way of introducing trace amounts of phosphorus into silicon in a much more uniform fashion than is possible by ordinary mixing of silicon and phosphorus and gives semiconductor devices the capability of handling much higher levels of power. Write balanced nuclear equations for the two steps in the preparation of ^{31}P from ^{30}Si.

10. The most convenient way to prepare the element polonium is to expose bismuth (which is 100% ^{209}Bi) to neutrons. Write balanced nuclear equations for the two steps in the preparation of polonium.

11. One convenient source of neutrons is the reaction of an alpha particle from an emitter such as polonium (^{210}Po) with an atom of beryllium (^{9}Be). Write nuclear equations for the reactions that occur.

12. Three atoms of element 111 were produced in 1994 by bombarding ^{209}Bi with ^{64}Ni.
   (a) Write a balanced equation for this nuclear reaction. What other species is produced?
   (b) Write a balanced equation for the alpha decay process of this nuclide of element 111.

Mass–Energy Relationships

13. Complete and balance the following equations for nuclear reactions that are thought to take place in stars:
   (a) $2\ {}^{12}_{6}\text{C} \longrightarrow\ ? + {}^{1}_{0}n$
   (b) $? + {}^{1}_{1}\text{H} \longrightarrow {}^{12}_{6}\text{C} + {}^{4}_{2}\text{He}$
   (c) $2\ {}^{3}_{2}\text{He} \longrightarrow\ ? + 2\ {}^{1}_{1}\text{H}$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

14. Complete and balance the following equations for nuclear reactions that are used in particle accelerators to make elements beyond uranium:
(a) $^{4}_{2}\text{He} + {}^{253}_{99}\text{Es} \longrightarrow ? + 2{}^{1}_{0}n$
(b) $^{249}_{98}\text{Cf} + ? \longrightarrow {}^{257}_{103}\text{Lr} + 2{}^{1}_{0}n$
(c) $^{238}_{92}\text{U} + {}^{12}_{6}\text{C} \longrightarrow {}^{244}_{98}\text{Cf} + ?$

15. Calculate the total binding energy, in both kJ per mole and MeV per atom, and the binding energy per nucleon of the following nuclides, using the data from Table 19.1.
(a) $^{40}_{20}\text{Ca}$ (b) $^{87}_{37}\text{Rb}$ (c) $^{238}_{92}\text{U}$

16. Calculate the total binding energy, in both kilojoules per mole and MeV per atom, and the binding energy per nucleon of the following nuclides, using the data from Table 19.1.
(a) $^{10}_{4}\text{Be}$ (b) $^{35}_{17}\text{Cl}$ (c) $^{49}_{22}\text{Ti}$

17. Use the data from Table 19.1 to predict which is more stable: four protons, four neutrons, and four electrons organized as two ^{4}He atoms or as one ^{8}Be atom. What is the mass difference?

18. Use the data from Table 19.1 to predict which is more stable: 16 protons, 16 neutrons, and 16 electrons organized as two ^{16}O atoms or as one ^{32}S atom. What is the mass difference?

Kinetics of Radioactive Decay

19. How many radioactive disintegrations occur per minute in a 0.0010-g sample of ^{209}Po that has been freshly separated from its decay products? The half-life of ^{209}Po is 103 years.

20. How many alpha particles are emitted per minute by a 0.0010-g sample of ^{238}U that has been freshly separated from its decay products? Assume that each decay emits one alpha particle. The half-life of ^{238}U is 4.47×10^{9} years.

21. The nuclide ^{19}O, prepared by neutron irradiation of ^{19}F, has a half-life of 29 s.
(a) How many ^{19}O atoms are in a freshly prepared sample if its decay rate is $2.5 \times 10^{4}\ \text{s}^{-1}$?
(b) After 2.00 min, how many ^{19}O atoms remain?

22. The nuclide ^{35}S decays by beta emission with a half-life of 87.1 days.
(a) How many grams of ^{35}S are in a sample that has a decay rate from that nuclide of $3.70 \times 10^{2}\ \text{s}^{-1}$?
(b) After 365 days, how many grams of ^{35}S remain?

23. Astatine is the rarest naturally occurring element, with ^{219}At appearing as the product of a very minor side branch in the decay of ^{235}U (itself not a very abundant isotope). It is estimated that the mass of all the naturally occurring ^{219}At in the upper kilometer of the earth's surface has a steady-state value of only 44 mg. Calculate the total activity (in disintegrations per second) caused by all the naturally occurring astatine in this part of the earth. The half-life of ^{219}At is 54 s, and its atomic mass is 219.01 u.

24. Technetium has not been found in nature. It can be obtained readily as a product of uranium fission in nuclear power plants, however, and is now produced in quantities of many kilograms per year. One medical use relies on the tendency of ^{99m}Tc (an excited nuclear state of ^{99}Tc) to concentrate in abnormal heart tissue. Calculate the total activity (in disintegrations per second) caused by the decay of 1.0 μg of ^{99m}Tc, which has a half-life of 6.0 hours.

25. The specific activity of ^{14}C in the biosphere is $0.255\ \text{Bq g}^{-1}$. What is the age of a piece of papyrus from an Egyptian tomb if its beta counting rate is $0.153\ \text{Bq g}^{-1}$? The half-life of ^{14}C is 5730 years.

26. The specific activity of an article found in the Lascaux Caves in France is $0.0375\ \text{Bq g}^{-1}$. Calculate the age of the article.

27. Over geological time, an atom of ^{238}U decays to a stable ^{206}Pb atom in a series of eight alpha emissions, each of which leads to the formation of one helium atom. A geochemist analyzes a rock and finds that it contains $9.0 \times 10^{-5}\ \text{cm}^3$ of helium (at 0°C and atmospheric pressure) per gram and 2.0×10^{-7} g of ^{238}U per gram. Estimate the age of the mineral, given that $t_{1/2}$ of ^{238}U is 4.47×10^{9} years.

28. The isotope ^{232}Th decays to ^{208}Pb by the emission of six alpha particles, with a half-life of 1.39×10^{10} years. Analysis of 1.00 kg of ocean sediment shows it to contain 7.4 mg of ^{232}Th and $4.9 \times 10^{-3}\ \text{cm}^3$ of gaseous helium at 0°C and atmospheric pressure. Estimate the age of the sediment, assuming no loss or gain of thorium or helium from the sediment since its formation and assuming that the helium arose entirely from the decay of thorium.

29. The half-lives of ^{235}U and ^{238}U are 7.04×10^{8} years and 4.47×10^{9} years, respectively, and the present abundance ratio is $^{238}\text{U}/^{235}\text{U} = 137.7$. It is thought that their abundance ratio was 1 at some time *before* our earth and solar system were formed about 4.5×10^{9} years ago. Estimate how long ago the supernova occurred that supposedly produced all the uranium isotopes in equal abundance, including the two longest lived isotopes, ^{238}U and ^{235}U.

30. Using the result of problem 29 and the accepted age of the earth, 4.5×10^{9} yr, calculate the $^{238}\text{U}/^{235}\text{U}$ ratio at the time the earth was formed.

Radiation in Biology and Medicine

31. Write balanced equations for the decays of ^{11}C and ^{15}O, both of which are used in positron emission tomography to scan the uptake of glucose in the body.

32. Write balanced equations for the decays of ^{13}N and ^{18}F, two other radioisotopes that are used in positron emission tomography. What is the ultimate fate of the positrons?

33. The positrons emitted by ^{11}C have a maximum kinetic energy of 0.99 MeV, and those emitted by ^{15}O have a maximum kinetic energy of 1.72 MeV. Calculate the ratio of the number of millisieverts of radiation exposure caused by ingesting a given fixed chemical amount (equal numbers of atoms) of each of these radioisotopes.

34. Compare the relative health risks of contact with a given amount of ^{226}Ra, which has a half-life of 1622 years and emits 4.78-MeV alpha particles, with contact with the same chemical amount of ^{14}C, which has a half-life of 5730 years and emits beta particles with energies of up to 0.155 MeV.

35. The nuclide ^{131}I undergoes beta decay with a half-life of 8.041 days. Large quantities of this nuclide were released into the environment in the Chernobyl accident. A victim of radiation poisoning has absorbed 5.0×10^{-6} g (5.0 μg) of ^{131}I.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) Compute the activity, in becquerels, of the ^{131}I in this person, taking the atomic mass of the nuclide to equal 131 g mol^{-1}.
(b) Compute the radiation absorbed dose, in milligrays, caused by this nuclide during the first *second* after its ingestion. Assume that beta particles emitted by ^{131}I have an average kinetic energy of 0.40 MeV, that all of this energy is deposited within the victim's body, and that the victim weighs 60 kg.
(c) Is this dose likely to be lethal? Remember that the activity of the ^{131}I diminishes as it decays.

36. The nuclide ^{239}Pu undergoes alpha decay with a half-life of 2.411×10^4 years. An atomic energy worker breathes in 5.0×10^{-6} g (5.0 μg) of ^{239}Pu, which lodges permanently in a lung.
(a) Compute the activity, in becquerels, of the ^{239}Pu ingested, taking the atomic mass of the nuclide to be 239 g mol^{-1}.
(b) Determine the radiation absorbed dose, in milligrays, during the first *year* after its ingestion. Assume that alpha particles emitted by ^{239}Pu have an average kinetic energy of 5.24 MeV, that all of this energy is deposited within the worker's body, and that the worker weighs 60 kg.
(c) Is this dose likely to be lethal?

Nuclear Fission

37. Strontium-90 is one of the most hazardous products of atomic weapons testing because of its long half-life ($t_{1/2}$ = 28.1 years) and its tendency to accumulate in bone.
(a) Write nuclear equations for the decay of ^{90}Sr via the successive emission of two beta particles.
(b) The atomic mass of ^{90}Sr is 89.9073 u and that of ^{90}Zr is 89.9043 u. Calculate the energy released per ^{90}Sr atom, in MeV, in decaying to ^{90}Zr.
(c) What will be the initial activity of 1.00 g of ^{90}Sr released into the environment, in disintegrations per second?
(d) What activity will the material from part (c) show after 100 years?

38. Plutonium-239 is the fissionable isotope produced in breeder reactors; it is also produced in ordinary nuclear plants and in weapons tests. It is an extremely poisonous substance with a half-life of 24,100 years.
(a) Write an equation for the decay of ^{239}Pu via alpha emission.
(b) The atomic mass of ^{239}Pu is 239.05216 u and that of ^{235}U is 235.04393 u. Calculate the energy released per ^{239}Pu atom, in MeV, in decaying via alpha emission.
(c) What will be the initial activity, in disintegrations per second, of 1.00 g of ^{239}Pu buried in a disposal site for radioactive wastes?
(d) What activity will the material from part (c) show after 100,000 years?

39. The three naturally occurring isotopes of uranium are ^{234}U (half-life 2.5×10^5 years), ^{235}U (half-life 7.0×10^8 years), and ^{238}U (half-life 4.5×10^9 years). As time passes, will the average atomic mass of the uranium in a sample taken from nature increase, decrease, or remain constant?

40. Natural lithium consists of 7.42% ^6Li and 92.58% ^7Li. Much of the tritium (^3_1H) used in experiments with fusion reactions is made by the capture of neutrons by ^6Li atoms.
(a) Write a balanced nuclear equation for the process. What is the other particle produced?
(b) After ^6Li is removed from natural lithium, the remainder is sold for other uses. Is the molar mass of the leftover lithium greater or smaller than that of natural lithium?

41. Calculate the amount of energy released, in kilojoules per *gram* of uranium, in the fission reaction

$$^{235}_{92}U + {}^{1}_{0}n \longrightarrow {}^{94}_{36}Kr + {}^{130}_{56}Ba + 3\ {}^{1}_{0}n$$

Use the atomic masses in Table 19.1. The atomic mass of ^{94}Kr is 93.919 u and that of ^{139}Ba is 138.909 u.

Nuclear Fusion and Nucleosynthesis

42. Calculate the amount of energy released, in kilojoules per *gram* of deuterium (^2H), for the fusion reaction

$$^{2}_{1}H + {}^{2}_{1}H \longrightarrow + {}^{4}_{2}He$$

Use the atomic masses in Table 19.1. Compare your answer with that from the preceding problem.

ADDITIONAL PROBLEMS

43. When an electron and a positron meet, they are replaced by two gamma rays, called the "annihilation radiation." Calculate the energies of these radiations, assuming that the kinetic energies of the incoming particles are 0.

44. The nuclide $^{231}_{92}U$ converts spontaneously to $^{231}_{91}Pa$.
(a) Write two balanced nuclear equations for this conversion, one if it proceeds by electron capture and the other if it proceeds by positron emission.
(b) Using the nuclidic masses in Table 19.1, calculate the change in mass for each process. Explain why electron capture can occur spontaneously in this case but positron emission cannot.

45. The radioactive nuclide $^{64}_{29}Cu$ decays by beta emission to $^{64}_{30}Zn$ or by positron emission to $^{64}_{28}Ni$. The maximum kinetic energy of the beta particles is 0.58 MeV, and that of the positrons is 0.65 MeV. The mass of the neutral $^{64}_{29}Cu$ atom is 63.92976 u.
(a) Calculate the mass, in atomic mass units, of the neutral $^{64}_{30}Zn$ atom.
(b) Calculate the mass, in atomic mass units, of the neutral $^{64}_{28}Ni$ atom.

46. A puzzling observation that led to the discovery of isotopes was the fact that lead obtained from uranium-containing ores had an atomic mass lower by two full atomic mass units than lead obtained from thorium-containing ores. Explain this result, using the fact that decay of radioactive uranium and thorium to stable lead occurs via alpha and beta emission.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

47. By 1913, the elements radium, actinium, thorium, and uranium had all been discovered, but element 91, between thorium and uranium in the periodic table, was not yet known. The approach used by Meitner and Hahn was to look for the parent that decays to form actinium. Alpha and beta emission are the most important decay pathways among the heavy radioactive elements. What elements would decay to actinium by each of these two pathways? If radium salts show no sign of actinium, what does this suggest about the parent of actinium? What is the origin of the name of element 91, discovered by Meitner and Hahn in 1918?

48. Working in Rutherford's laboratory in 1932, Cockcroft and Walton bombarded a lithium target with 700-keV protons and found that the following reaction occurred:

$$^{7}_{3}\text{Li} + {}^{1}_{1}\text{H} \longrightarrow +2\ {}^{4}_{2}\text{He}$$

Each of the alpha particles was found to have a kinetic energy of 8.5 MeV. This research provided the first experimental test of Einstein's $\Delta E = c^2\Delta m$ relationship. Discuss. Using the atomic masses from Table 19.1, calculate the value of c needed to account for this result.

49. (a) Calculate the binding energy per nucleon in $^{30}_{15}\text{P}$.
(b) The radioactive decay of the $^{30}_{15}\text{P}$ occurs through positron emission. Calculate the maximum kinetic energy carried off by the positron.
(c) The half-life for this decay is 150 s. Calculate the rate constant k and the fraction remaining after 450 s.

50. Selenium-82 undergoes *double* beta decay:

$$^{82}_{34}\text{Se} \longrightarrow {}^{82}_{36}\text{Kr} + 2\ {}^{0}_{-1}e^{-} + 2\tilde{\nu}$$

This low-probability process occurs with a half-life of 3.5×10^{27} s, one of the longest half-lives ever measured. Estimate the activity in an 82.0-g (1.00 mol) sample of this isotope. How many ^{82}Se nuclei decay in a day?

51. Gallium citrate, which contains the radioactive nuclide ^{67}Ga, is used in medicine as a tumor-seeking agent. Gallium-67 decays with a half-life of 77.9 hours. How much time is required for it to decay to 5.0% of its initial activity?

52. The nuclide ^{241}Am is used in smoke detectors. As it decays (with a half-life of 458 years), the emitted alpha particles ionize the air. When combustion products enter the detector, the number of ions changes and with it the conductivity of the air, setting off an alarm. If the activity of ^{241}Am in the detector is 3×10^4 Bq, calculate the mass of ^{241}Am present.

53. The half-life of ^{14}C is $t_{1/2} = 5730$ years, and 1.00 g of modern wood charcoal has an activity of 0.255 Bq.
(a) Calculate the number of ^{14}C atoms per gram of carbon in modern wood charcoal.
(b) Calculate the fraction of carbon atoms in the biosphere that are ^{14}C.

54. Carbon-14 is produced in the upper atmosphere by the reaction

$$^{14}_{7}\text{N} + {}^{1}_{0}n \longrightarrow {}^{14}_{6}\text{C} + {}^{1}_{1}\text{H}$$

where the neutrons come from nuclear processes induced by cosmic rays. It is estimated that the steady-state ^{14}C activity in the biosphere is 1.1×10^{19} Bq.
(a) Estimate the total mass of carbon in the biosphere, using the data in problem 53.
(b) The earth's crust has an average carbon content of 250 parts per million by mass, and the total crustal mass is 2.9×10^{25} g. Estimate the fraction of the carbon in the earth's crust that is part of the biosphere. Speculate on the whereabouts of the rest of the carbon in the earth's crust.

55. Analysis of a rock sample shows that it contains 0.42 mg of ^{40}Ar for every 1.00 mg of ^{40}K. Assuming that all the argon resulted from decay of the potassium and that neither element has left or entered the rock since its formation, estimate the age of the rock. (*Hint:* Use data from Table 19.2.) Note that not all the ^{40}K decays to ^{40}Ar.

* 56. Cobalt-60 and iodine-131 are used in treatments for some types of cancer. Cobalt-60 decays with a half-life of 5.27 years, emitting beta particles with a maximum energy of 0.32 MeV. Iodine-131 decays with a half-life of 8.04 days, emitting beta particles with a maximum energy of 0.60 MeV.
(a) Suppose a fixed small number of moles of each of these isotopes were to be ingested and remain in the body indefinitely. What is the *ratio* of the number of millisieverts of total lifetime radiation exposure that would be caused by the two radioisotopes?
(b) Now suppose that the contact with each of these isotopes is for a fixed short period, such as 1 hour. What is the ratio of millisieverts of radiation exposure for the two in this case?

57. Boron is used in control rods in nuclear power reactors because it is a good neutron absorber. When the isotope ^{10}B captures a neutron, an alpha particle (helium nucleus) is emitted. What other atom is formed? Write a balanced equation.

* 58. The average energy released in the fission of a ^{235}U nucleus is about 200 MeV. Suppose the conversion of this energy to electrical energy is 40% efficient. What mass of ^{235}U is converted to its fission products in a year's operation of a 1000-megawatt nuclear power station? Recall that 1 W is 1 J s^{-1}.

59. The energy released by a bomb is sometimes expressed in tons of TNT (trinitrotoluene). When one ton of TNT explodes, 4×10^9 J of energy is released. The fission of 1 mol of uranium releases approximately 2×10^{13} J of energy. Calculate the energy released by the fission of 1.2 kg of uranium in a small atomic bomb. Express your answer in tons of TNT.

60. The solar system abundances of the elements Li, Be, and B are four to seven orders of magnitude lower than those of the elements that immediately follow them: C, N, and O. Explain.

* 61. The sun's distance from earth is approximately 1.50×10^8 km, and the earth's radius is 6371 km. The earth receives radiant energy from hydrogen burning in the sun at a rate of 0.135 J s^{-1} cm^{-2}. Using the data of Table 19.1, calculate the mass of hydrogen converted per second in the sun.

CUMULATIVE PROBLEMS

62. In 1951 wood from two sequoia trees was dated by the ^{14}C method. In one tree, clean borings located between the growth rings associated with the years A.D. 1057 and 1087 (that is, wood known to have grown 880 ± 15 years prior to the date of measurement) had a ^{14}C activity about 0.892 of that of wood growing in 1951. A sample from a second tree had an activity about 0.838 of that of new wood, and its age was established as 1377 ± 4 years by tree-ring counting.
    (a) What ages does carbon dating associate with the wood samples?
    (b) What values of $t_{1/2}$ can be deduced if the tree-ring dates given are used as the starting point?
    (c) Discuss assumptions underlying the calculations in (a) and (b), and indicate in what direction failures of these assumptions might affect the calculations.

63. A typical electrical generating plant has a capacity of 500 megawatts (MW; 1 MW = 10^6 J s^{-1}) and an overall efficiency of about 25%. (a) The combustion of 1 kg of bituminous coal releases about 3.2×10^4 kJ and leaves an ash residue of 100 g. What weight of coal must be used to operate a 500-MW generating plant for 1 year, and what weight of ash must be disposed of? (b) Enriched fuel for nuclear reactors contains about 4% ^{235}U, fission of which gives 1.9×10^{10} kJ per mole ^{235}U. What weight of ^{235}U is needed to operate a 500-MW power plant, assumed to have 25% efficiency, for 1 year, and what weight of fuel must be reprocessed to remove radioactive wastes? (c) The radiation from the sun striking the earth's surface on a sunny day corresponds to a power of 1.5 kW m^{-2}. How large must the collection surface be for a 500-MW solar-generating plant? (Assume that there are 6 hours of bright sun each day and that storage facilities continue to produce power at other times. The efficiency for solar-power generation would be about 25%.)

64. Examine the ratio of atomic mass to atomic number for the elements with *even* atomic number through calcium. This ratio is approximately the ratio of the average mass number to the atomic number.
    (a) Which two elements stand out as different in this set of ten?
    (b) What would be the "expected" atomic mass of argon, based on the correlation considered here?
    (c) Show how the anomaly in the ordering of natural atomic masses of argon and potassium can be accounted for by the formation of "extra" ^{40}Ar via decay of ^{40}K atoms.

65. Hydrazine, $N_2H_4(\ell)$, reacts with oxygen in a rocket engine to form nitrogen and water vapor:

$$N_2H_4(\ell) + O_2(g) \longrightarrow N_2(g) + 2\ H_2O(g)$$

    (a) Calculate $\Delta H°$ for this highly exothermic reaction at 25°C, using data from Appendix D.
    (b) Calculate $\Delta U°$ of this reaction at 25°C.
    (c) Calculate the total change in mass, in grams, during the reaction of 1.00 mol of hydrazine.

66. The long-lived isotope of radium, ^{226}Ra, decays by alpha particle emission to its daughter radon, ^{222}Rn, with a half-life of 1622 years. The energy of the alpha particle is 4.79 MeV. Suppose 1.00 g of ^{226}Ra, freed of all its radioactive progeny, were placed in a calorimeter that contained 10.0 g of water, initially at 25°C. Neglecting the heat capacity of the calorimeter and heat loss to the surroundings, calculate the temperature the water would reach after 1.00 hour. Take the specific heat of water to be 4.18 J K^{-1} g^{-1}.

67. The radioactive nuclide $^{232}_{90}Th$ has a half-life of 1.39×10^{10} years. It decays by a series of consecutive steps, the first two of which involve $^{228}_{88}Ra$ (half-life 6.7 years) and $^{228}_{89}Ac$ (half-life 6.13 hours).
    (a) Write balanced equations for the first two steps in the decay of ^{232}Th, indicating all decay products. Calculate the total kinetic energy carried off by the decay products.
    (b) After a short initial time, the rate of formation of ^{228}Ra becomes equal to its rate of decay. Express the number of ^{228}Ra nuclei in terms of the number of ^{232}Th nuclei, using the steady-state approximation from Section 18.4.

68. Zirconium is used in the fuel rods of most nuclear power plants. The following half-cell reduction potential applies to aqueous acidic solution:

$$ZrO_2(s) + 4\ H_3O^+(aq) + 4e^- \longrightarrow Zr(s) + 6H_2O(\ell) \qquad E° = -1.43\ V$$

    (a) Predict whether zirconium can reduce water to hydrogen. Write a balanced equation for the overall reaction.
    (b) Calculate $E°$ and K for the reaction in part (a).
    (c) Can your answer to part (b) explain the release of hydrogen in the Three Mile Island accident and the much greater release of hydrogen (which subsequently exploded) at Chernobyl?

Spectroscopy, broadly defined, refers to the field of science that is devoted to understanding the interactions between electromagnetic radiation and matter, and exploiting that understanding to develop and apply new experimental techniques to probe the structures and dynamics of material systems. The line spectra of atoms and the blackbody radiation spectrum played central roles in the development of quantum mechanics, and spectroscopic measurements have either stimulated or confirmed many of the key developments in theoretical physics of the 20th century. Molecular spectroscopy enables us to determine the three-dimensional structures of molecules, to detect and identify single molecules, and to measure the rates and mechanisms of physical processes and chemical reactions on the femtosecond (10^{-15} s) timescale. Spectroscopic imaging techniques have given us unprecedented insight into biological structure and function, and the development of

medical imaging techniques over the past 40 years has revolutionized the practice of medicine. Our goal for this chapter is to introduce you to the basic concepts and methods of molecular spectroscopy and photochemistry to give you an appreciation for how they have contributed to our understanding of the nature of the chemical bond and to the development the bonding theories discussed in Chapter 6. We also provide an introduction to the analytical applications of these methods that you will encounter in more advanced chemistry courses. Finally, we introduce you to molecular photophysics and photochemistry and illustrate the importance of these processes with examples drawn from atmospheric photochemistry and photosynthesis.

20.1 INTRODUCTION TO MOLECULAR SPECTROSCOPY

Molecular spectroscopy experiments measure the intensity of radiation absorbed, emitted, or scattered by molecules as a function of frequency. Examples of atomic absorption and emission spectra are shown and discussed in Section 4.2. Peaks or bands (broad peaks) appear in molecular absorption and emission spectra at frequencies that satisfy the resonance condition, $\Delta E = h\nu$, where ΔE is the energy difference between two levels and ν is the frequency of the radiation. Transitions between molecular energy levels can also be caused by **Raman scattering,** a form of inelastic light scattering. Photons can either gain or lose energy in *inelastic* collisions with molecules; energy conservation requires that $\Delta E = h\nu_i - h\nu_s$, where ν_i and ν_s are the frequencies of the incident and scattered radiation, respectively.

The Born-Oppenheimer approximation allows us to calculate the electronic wave functions for molecules as a function of the positions of the nuclei, and to generate a potential energy function for each electronic state, which governs the nuclear motion for that electronic state (see Section 6.1). Figure 20.1a shows the

potential energy function for the lowest energy (ground) electronic state of HCl as well as that of the first excited state. The shapes of these potential energy functions for diatomic molecules should be familiar to you. The minimum occurs at the equilibrium internuclear separation for each state, which for the ground state is R_e, the equilibrium bond length. A few vibrational levels of each electronic state are shown; the arrow shown in Figure 20.1a represents a transition between the ground vibrational level in the ground electronic state to an excited vibrational level in the excited electronic state. These transitions occur as a result of absorption of ultraviolet and visible radiation and are discussed in more detail in Section 20.5. Figure 20.1b is an expanded view of the potential energy function of the ground electronic state, showing transitions that correspond to the excitation of rotational levels in the ground vibrational state (lower part of the figure) or the simultaneous excitation of rotation and vibration, which is represented by the longer arrow.

We showed in Section 12.5 that molecular motions can be separated classically into translations, rotations, and vibrations (see Figure 12.11 in particular). The energies of these motions are sufficiently different that we can approximate the total energy as the sum of these independent contributions. The energies associated with each kind of motion are measured using a variety of spectroscopic methods, one of which is illustrated in Figure 20.2, which shows the vibration–rotation spectrum of carbon monoxide as measured using infrared absorption spectroscopy. We discuss how we extract information from spectra like this one later but use this example to illustrate in general the kinds of information available from spectra. The spectrum arises from the simultaneous excitation of vibrational and rotational motion. The energy difference between adjacent lines is due to transitions between adjacent rotational energy levels, from which we deduce the bond length. The frequency that corresponds to the midpoint between the transitions labelled 1–0 and 0–1 is the frequency of the CO stretching vibration, from which we deduce the bond force constant and bond strength. This vibration-rotation spectrum provides justification for the energy level diagrams shown in Figure 20.1 and for our assertion that we can treat various classes of molecular motions independently of each other.

The spectrum also demonstrates the importance of two conservation laws that are strictly observed: conservation of energy and conservation of angular momentum. The Bohr frequency rule $\Delta E = h\nu$ is a consequence of the conservation of energy, in addition to expressing the resonance condition required for transitions between discrete states that is responsible for the line structure of the spectrum. Conservation of angular momentum manifests itself as a rigorous "selection rule" that determines whether particular transitions can be induced by absorption, emission or scattering. You are familiar with the quantization of angular momentum and its spatial components in atoms and molecules, *s*-orbitals having the angular momentum quantum number $\ell = 0$ and *p*-orbitals having the angular momentum quantum number $\ell = 1$ for example. The spin angular momentum of photons is also quantized, as is its projection along the direction of propagation; photons

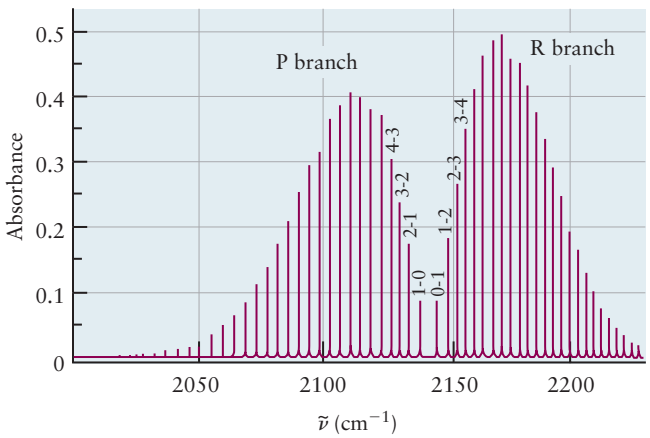

FIGURE 20.2 Vibration-rotation spectrum of carbon monoxide in the gas phase, measured using infrared absorption spectroscopy. Absorbance (see Section 20.5) is plotted as a function of frequency in wave numbers (see discussion preceding Table 20.1). Courtesy of Husheng Yang, Department of Chemistry, University of Idaho.

carry one unit of angular momentum, $h/2\pi$, with the allowed projections being $\pm h/2\pi$. The selection rule based upon conservation of angular momentum is quite powerful. Adjacent lines in the vibration–rotation spectrum of CO arise from transitions in which the rotational angular momentum of the molecule changes by one unit. The Q branch is absent in this spectrum because there is no change in the rotational angular momentum of the molecule for this transition, which would leave the angular momentum of the photon unaccounted for if absorbed.

In the sections that follow we discuss how we measure the following properties of molecules using the various spectroscopic techniques described:

1. Bond lengths and bond angles, from microwave, infrared, and Raman spectroscopy
2. Bond force constants and effective reduced masses (treating several atoms in a function group as a single mass) from vibrational spectroscopy
3. Identification of functional groups and their relative locations in molecules, from vibrational spectroscopy and nuclear magnetic resonance spectroscopy

Spectroscopic techniques have historically been classified in terms of the relevant frequencies of the electromagnetic radiation involved. Table 20.1 shows a number of important spectroscopic techniques, the relevant region of the electromagnetic spectrum, the nature of the energy levels involved and the kinds of information obtained about the properties of molecules. We list frequencies, wavelengths and energies in several sets of units that are used in practice, for convenience. Radiofrequency and microwave spectra are generally reported as a function of frequency (Hz), infrared and visible spectra in terms of frequency or wavelength, and ultraviolet and X-ray spectra in terms of wavelength, or energy in eV, for example.

Frequencies are often reported in units of wave numbers where $\tilde{\nu} = (1/\lambda)$ where λ is measured in cm. This is a convenient unit that is proportional to energy because $E = h\nu = hc/\lambda = (hc)(1/\lambda)$. Microwave spectra, for example, are presented either as a function of frequency (GHz) or energy (cm^{-1}), infrared and Raman spectra most often use wave numbers, and ultraviolet and visible spectra are presented as functions of wavelength (nm) or energy (eV).

Intensities of Spectral Transitions

The relative intensities of spectral lines depend upon the nature of the transition and the population differences between the two levels involved. Many of the experiments we discuss present spectra only in terms of relative intensities, so we need not be overly precise in our definition, but it is useful to have a general idea of what we mean by the intensities of spectral lines. Let's begin by considering an absorp-

TABLE 20.1

Spectroscopic Methods

Spectral Region	Frequency	Wavelength	Transition Energies	Excitations	Information Obtained
Radio waves	10^7–10^9 Hz	30–0.3 m	0.0033–0.033 cm^{-1}	Nuclear spin	Bonding environment, molecular structure
Microwave, far infrared	10^9–10^{12} Hz	0.3 m–300 μm	0.033–33 cm^{-1}	Rotational	Bond lengths and bond angles
Near infrared	10^{12}–10^{14} Hz	300 μm–3 μm	33–3300 cm^{-1}	Vibrational	Bond force constants and effective reduced mass
Visible, ultraviolet	10^{14}–10^{17} Hz	3000 nm–3 nm	3300–330,000 cm^{-1}	Valence electrons	Electronic energy levels and molecular environment
X-ray	10^{17}–10^{19} Hz	3 nm–0.3 Å	413–41,300 eV	Core electrons	Ionization energies and atomic environment

tion experiment in which we measure the attenuation of a beam of radiation as it passes through an absorbing sample. The intensity of the transmitted beam is given by the Beer–Lambert law $I_t = I_0 e^{-\alpha \ell}$ where I_0 is the intensity of the incident beam, I_t is the intensity of the transmitted beam, ℓ is the path length and α is the absorption coefficient for the sample. Intensity is defined as the amount of energy crossing a surface per unit time, or power; alternatively it may be viewed in terms of the number of photons passing through a surface per unit time. The Beer–Lambert law has the same form as that for first order kinetics; a constant fraction of the light is absorbed per unit path length and that fraction is independent of the intensity of the incident radiation. We can also think of absorption and scattering in terms of collisions between photons and molecules, using the same ideas developed for the collision theory of gases in Section 9.5. The Beer–Lambert law becomes $I_t = I_0 \exp[-(N/V)\sigma\ell]$ where σ (πd^2) is the cross-section for the process of interest. The intensity of the radiation that is absorbed or scattered is then given by $I_{a,s} = I_0 - I_t = I_0[1 - \exp[-(N/V)\sigma\ell]]$. Expressing absorption, emission, and scattering intensities in terms of cross sections allows us to compare the results of these different kinds of experiments from a common point of view. Chemists generally use a different form of the Beer–Lambert law in which concentrations are expressed in molarity, not as number densities; we introduce you to Beer's law in Section 20.5.

EXAMPLE 20.1

Benzene has several absorption bands in the ultraviolet region of the electromagnetic spectrum, the weakest of which appears at 260 nm with an absorption cross section of 2.15×10^{-18} cm^2 molecule^{-1}. Calculate the fraction of the incident radiation absorbed by a sample of benzene confined in a cell with a 1 cm path length at 0.001 atm and 300K. The Raman scattering cross section for the "ring-breathing" vibrational mode of benzene is 3.3×10^{-29} cm^2 molecule^{-1}. Calculate the fraction of incident photons that undergo Raman scattering under the same conditions.

Solution

Use the Beer-Lambert law in the form $I/I_0 = \exp[-(N/V)\sigma\ell]$ and calculate N/V using the ideal gas law. Substituting the number density, cross section, and path length into the Beer-Lambert law gives

$$I/I_0 = \exp[-(2.45 \times 10^{16} \text{ molecules cm}^{-3})(2.15 \times 10^{-18} \text{ cm}^{-2} \text{ molecule}^{-1})(1 \text{ cm})]$$
$$= 0.95$$

Only about 5% of the incident radiation is absorbed under these conditions.

Substituting the Raman cross section into the Beer-Lambert law and subtracting from 1 gives $I_s = 1 - (I/I_0) \approx 10^{-12}$. Only about 1 out of a trillion photons undergoes Raman scattering from benzene under these conditions.

Related Problems: 1, 2

The intensities of spectral transitions depend not only on the strength of the transition (see Sections 20.5 and 20.8) but also on the differences in the populations of the initial and final states. The fraction of the total number of molecules in a particular level with energy E_i is given by the **Boltzmann distribution**

$$N_i/N \approx g_i \exp(-\varepsilon_i/k_B T) \qquad [20.1]$$

where N_i is the number of molecules in level *i*, N is the total number of molecules in the system, g_i is the degeneracy of level *i*, and k_B is Boltzmann's constant (1.38×10^{-23} J K^{-1}), which was introduced in Section 9.5. (See Section 12.8 for an introduction to the Boltzmann distribution and its application to vibrational energy

levels of diatomic molecules.) The difference in populations between two levels is given by

$$N_i - N_f = N[g_i \exp(-\varepsilon_i/k_BT) - g_f \exp(-\varepsilon_f/k_BT)] \quad [20.2]$$

where N_i and N_f are the populations of the initial and final levels respectively. It is convenient to represent the population difference in terms of the relative populations by dividing both sides of Equation 20.2 by N_i to get

$$\Delta N/N = N_i - N_f = [1 - (N_f/N_i)] = [1 - (g_f/g_i)\exp[-(\varepsilon_f - \varepsilon_i)/k_BT]]$$
$$= [1 - (g_f/g_i)\exp(-\Delta\varepsilon/k_BT)] \quad [20.3]$$

Let's calculate the population differences for a few different kinds of experiments to get a feel for the numbers involved. $\Delta\varepsilon = 4 \times 10^{-19}$ J for an electronic absorption in the green region of the visible spectrum ($\lambda = 500$ nm) and $\Delta\varepsilon \gg k_BT$ so that the second term in Equation 20.3 can be ignored and we need only consider the population of the ground state. A similar calculation reveals that only about 3% of molecules with vibrational energy level separations of 1000 cm^{-1} are in the first excited state. We can safely ignore these for most applications of vibrational spectroscopy but point out that the populations of these levels are important when we consider the emission of infrared radiation relevant to climate change in Section 20.6.The separation between adjacent rotational energy levels is generally much smaller than k_BT, and many rotational levels are populated at room temperature. The population differences depend upon both the relative degeneracy of the levels and their energy level spacing, both of which depend upon the rotational quantum number J (see Section 20.3). Example 20.2 shows that the population of the first excited rotational level of CO actually exceeds that of the ground state, illustrating the importance of degeneracy. The overall shapes of the envelopes shown in the figure arise because the population difference depends upon the product of two factors, the degeneracy increasing with increasing J (see Equation 20.46) and the probability of a given level being populated being given by the Boltzmann distribution. Finally, we consider the population differences between nuclear spin states for which the energy level separation is 300 MHz; the populations are nearly equal with an excess in the lower level of only some 50 parts per million.

EXAMPLE 20.2

Calculate the ratio of the populations in the first two rotational energy levels of carbon monoxide at 300 K if the energy difference between the levels is 3.8 cm^{-1} and the degeneracies of the two levels are $g_0 = 1$ and $g_1 = 3$, respectively.

Solution

Equation 20.3 is

$$\Delta N/N = [1 - (g_1/g_0)\exp(-\Delta\varepsilon/k_BT)]$$

Substituting the values provided into the above equation and expressing k_B in wave numbers ($k_B = 0.695$ cm^{-1} K^{-1}) gives

$$N_1/N_0 = (g_1/g_0)\exp[(-3.8\ cm^{-1})/(0.695\ cm^{-1}\ K^{-1})(300K)]$$
$$= (3/1)\exp(-0.0182)$$
$$= 2.95$$

The rotational level spacings are so much smaller than k_BT, and the degeneracy of the upper level so much greater than that of the lower level, that there are more molecules in the $J = 1$ level than in the $J = 0$ level.

20.2 EXPERIMENTAL METHODS IN MOLECULAR SPECTROSCOPY

Molecular spectroscopy experiments measure the intensity of the radiation absorbed, emitted, or scattered by a sample as a function of frequency. Absorption experiments measure the decrease in the intensity of the incident radiation, whereas emission and scattering experiments measure the intensity of the emitted or scattered radiation. All of these experiments have three elements in common, a source of electromagnetic radiation, an element that either disperses the different wavelengths or modulates the frequencies in some way, and a detector.

You were introduced to atomic absorption and emission spectroscopy in Section 4.2 and reviewing Figure 4.10 should help you visualize other kinds of spectroscopy experiments. The light sources in those experiments were gas discharge lamps for the emission experiments illustrated in part (a) and a white light source (a light bulb) for the absorption experiments illustrated in part (b). The dispersing element was a glass prism, which separated the different wavelengths in space, and the detector was a strip of photographic film. The emission spectrum appears as a series of colored lines on a dark background while the absorption spectrum appears as a series of dark lines across the visible spectrum. You will very likely measure absorption and emission spectra in one of your laboratory courses, using a more modern spectrograph than the one discussed earlier, or a monochromator. Modern versions of these instruments use diffraction gratings instead of prisms to disperse the radiation. A diffraction grating consists of a series of closely spaced metal lines fabricated on a glass substrate that diffract light of different colors into different directions, by the same mechanism as that discussed for X-ray diffraction in Section 21.1. Monochromators are instruments that use an entrance slit to define an image, like that shown in Figure 4.9, and an exit slit that passes only a narrow range of wavelengths at a time. Spectra are acquired by scanning the grating and measuring the intensity of the light transmitted through the exit slit as a function of the grating position. A schematic of a dual beam spectrometer used primarily for absorption experiments in the ultraviolet and visible regions of the spectrum is shown in Figure 20.3. Radiation from a white light or UV source is split into two beams that are alternately passed through the sample cell, which contains the sample dissolved in solution, and a reference cell, which contains only the solvent. The beams are recombined and sent through a monochromator that disperses the radiation and sends the transmitted radiation to a detector. The intensity of the reference beam is subtracted from that of the sample beam to account for fluctuations in light intensity, and for reflections and absorption by the sample cells and solvent. Modern instruments often use spectrographs, analogous to those illustrated in Figure 4.10 with

a charge-coupled device (CCD) detector, like that in your cell phone camera, replacing the photographic film. This kind of detection scheme is much faster than scanning because the intensity at all wavelengths of interest is measured simultaneously.

A schematic of an emission or Raman scattering experiment is shown in Figure 20.4. Samples are illuminated by radiation from various sources, which are usually monochromatic (light passed through a monochromator or lasers), and the intensity of the emitted or Raman scattered radiation collected at right angles to the incident beam is measured as a function of frequency, using the same techniques described above.

Fourier transform (FT) methods have largely replaced scanning methods in infrared (FTIR) and nuclear magnetic resonance (FT-NMR) spectroscopy. The samples are irradiated over a range of frequencies simultaneously in both cases, and the spectra are extracted from the raw data by a mathematical algorithm called a Fourier transform. The way in which FTIR and FT-NMR work in practice are sufficiently different from scanning methods that we discuss them separately in the sections on IR and NMR spectroscopy.

20.3 ROTATIONAL AND VIBRATIONAL SPECTROSCOPY

We introduced you to the properties of the chemical bond and to the shapes of molecules in Chapter 3, and showed how molecular orbital theory explained the trends in bond order, bond lengths, bond dissociation energies, and bond force constants observed for homonuclear diatomic molecules and ions (see Fig. 6.18). Where did these data come from? How do we measure bond lengths and force constants and how can we use these data to estimate bond dissociation energies? We begin this section with a discussion of the spectroscopy of diatomic molecules to show how the properties of individual bonds are measured and then proceed to discuss the spectroscopy of polyatomic molecules from which we learn much about their three-dimensional structures.

Diatomic Molecules

The Born-Oppenheimer approximation, introduced in Section 6.1, allows us to find the electronic wave functions for diatomic molecules with the nuclei at fixed positions. The variation in the electronic energy with internuclear separation is added to the nuclear–nuclear repulsion to generate the potential energy function that governs nuclear motion. We can write the Schrödinger equation to solve for the nuclear wave functions and energy levels if we know the form of this potential energy function. The nuclear Schrödinger equation can be solved exactly for several model potential energy functions to get wave functions and energy levels associated with rotational and vibrational motion. These include: 1) The rigid rotor model, in which the bond length is fixed and the potential energy term is constant, used to interpret rotational spectroscopy experiments; 2) The harmonic oscillator model, which represents the chemical bond as a spring with a potential given by Hooke's law, used to interpret vibrational spectroscopy experiments and 3) The Morse potential, which is used to interpret the vibrational spectra of molecules in which the potential energy function is not harmonic, as well as to provide a method for estimating bond dissociation energies from these spectra. These methods are used for polyatomic molecules as well but we discuss them in detail only for diatomic molecules to illustrate their important general characteristics.

Rotational Spectroscopy

We treat the rotations of diatomic molecules using the quantum mechanical linear rigid rotor model, in which the bond length is fixed and the molecule rotates about an axis that is perpendicular to the internuclear axis and passes through its center of mass, as illustrated in Figure 20.5. The rotational motion is described by a single moment of inertia, which is defined as

$$I = \mu R_e^2$$

where R_e is the equilibrium bond length and $\mu = m_1 m_2/(m_1 + m_2)$ is the reduced mass.

The wave functions for the rigid rotor are identical to the angular parts of the hydrogen atom wave functions, and the angular momentum is quantized in the same way. The square of the angular momentum and its projection along the laboratory z-axis can only take on the following values:

$$J^2 = J(J+1)(h/2\pi)^2 \qquad J = 0, 1, 2, 3... \qquad [20.4a]$$

$$J_z = M_J(h/2\pi) \qquad M_J = -J, -J+1, ...0..., J-1, J \qquad [20.4b]$$

Equation 20.4b shows that the degeneracy of each level is given by $g_J = 2J + 1$. Note that rotational states with $J = 0$ are allowed, which implies complete certainty about the angular momentum. The uncertainty principle is not violated in this case because the variable that corresponds to the position in linear momentum is the angular coordinate ϕ, which runs from $0 \longrightarrow 2\pi$. While we may know the angular momentum with certainty, we have no knowledge whatsoever about the angular coordinate, which can be anywhere on a circle. The shapes of the wave functions for this problem are also interesting; they correspond to the angular parts of the hydrogen wave functions, as mentioned above. States for which $J = 0$ correspond to s-orbitals, those for which $J = 1$ correspond to p-orbitals, and so forth. Molecules in $J = 0$ states are spherical; they have no rotational angular momentum and they pack like spheres, perhaps the most famous example being *para*-H_2 with paired nuclear spins (see Sec. 20.4).

The energy levels for the linear rigid rotor are given by

$$E_J = hBJ(J+1) \qquad [20.5a]$$

or

$$E_J = hc\tilde{B}J(J+1) \qquad [20.5b]$$

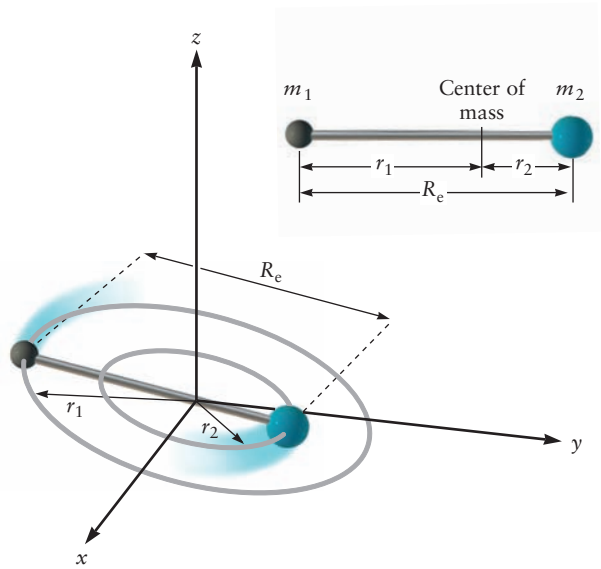

FIGURE 20.5 A diatomic molecule rotates about its center of mass, which is located by the coordinates $r_1 = \left(\frac{m_1}{m_1 + m_2}\right) R_e$ and $r_2 = \left(\frac{m_2}{m_1 + m_2}\right) R_e$

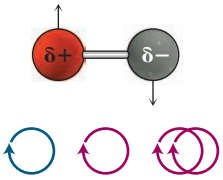

FIGURE 20.7 The angular momentum of a photon (blue circular arrow) is transferred to a molecule (red circular arrows) upon absorption. Peter Atkins, Julio de Paula. Physical Chemistry, W. H. Freeman and Company, New York 2010 p. 457.

where $B = (h/8\pi^2 I)$ and $\tilde{B} = (h/8\pi^2 cI)$ are rotational constants, the former measured in Hz and the latter measured in cm^{-1}. Both units are widely used in rotational spectroscopy, and conversion between them is straightforward: $1\ cm^{-1} = 30 \times 10^9$ Hz (30 GHz).

Microwave absorption spectroscopy has historically been one of our most important experimental methods for accurately measuring bond lengths in heteronuclear diatomic molecules. Microwave emission spectra are used to identify molecules in interstellar space as well as to monitor the concentrations of gases of importance in the atmospheric chemistry of the Earth. Absorption and emission of microwave radiation can be interpreted classically by considering the oscillating dipole moment of a heteronuclear diatomic molecule as it rotates, as shown in Figure 20.6.

Oscillating electromagnetic fields exert torques on polar diatomic molecules, causing them to rotate. Conversely, a rotating molecular dipole emits electromagnetic radiation. Molecules must have permanent dipole moments in order to absorb or emit microwave or far infrared radiation as a result of rotational motion. Quantum mechanics imposes two additional requirements: conservation of energy and conservation of angular momentum. Conservation of energy is enforced by the familiar Bohr frequency rule $\Delta E = h\nu$ that relates the photon frequency to the energy difference between the levels. Conservation of angular momentum (introduced in Section 20.1) requires that $\Delta J = \pm 1$ for microwave absorption and emission, respectively. Figure 20.7 shows one unit of angular momentum being transferred to a molecule upon absorption. The angular momentum of a molecule decreases by one unit when a photon is emitted, the angular momentum being carried away by the photon. This **selection rule,** based upon the conservation of angular momentum, is rigorous. There are other kinds of useful selection rules in spectroscopy that are somewhat weaker because they are based upon approximations, such as the harmonic oscillator approximation introduced later.

We can use Equation 20.5b to calculate the frequencies of the allowed transitions for microwave absorption in wave numbers, by letting J_i and J_f represent the rotational quantum numbers of the initial and final states and imposing the selection rule.

$$\begin{aligned}\Delta\tilde{\nu} &= \tilde{B}[J_f(J_f+1) - J_i(J_i+1)] \\ &= \tilde{B}[(J_i+1)(J_i+2) - J_i(J_i+1)] \\ &= 2\tilde{B}(J+1)\end{aligned} \qquad [20.6]$$

Equation 20.6 predicts that the microwave absorption spectrum of a heteronuclear diatomic molecule consists of a series of equally spaced lines separated by $2\tilde{B}$. Figure 20.8 shows the energy level diagram for a rigid rotor, with the allowed transitions represented by vertical arrows and the spectrum represented schematically by the stick diagram at the bottom of the figure. The microwave absorption spectrum of carbon monoxide is shown in Figure 20.9. The separation between each pair of lines is 3.8 cm^{-1} from which we determine the rotational constant $\tilde{B} = 1.9\ cm^{-1}$. The relative intensities of the lines observed in the experimental spectrum reflects both the increasing degeneracy of each level with increasing J as well as the exponentially decreasing populations of the levels as determined by the Boltzmann distribution.

Bond lengths of heteronuclear diatomic molecules are simply calculated from the experimentally measured rotational constants and the atomic masses, as illustrated in Example 20.3.

EXAMPLE 20.3

The microwave absorption spectrum of gaseous NaH (isotope: $^{23}Na^{1}H$) has been measured experimentally; microwaves with wavelengths of 1.02 mm excite the transition from $J = 0$ to $J = 1$. Calculate the bond length of the NaH molecule. Use isotopic masses provided in Table 19.1.

Solution

The reduced mass is

$$\mu = \frac{m_{Na}m_H}{m_{Na} + m_H} = \frac{(22.9898\ \text{u})(1.0078\ \text{u})}{22.9898 + 1.0078\ \text{u}}$$
$$= 0.9655\ \text{u} = 1.603 \times 10^{-27}\ \text{kg}$$

The energy change is

$$\Delta E = h\nu = \frac{hc}{\lambda}$$

which in this case is

$$\Delta E_{rot} = \frac{(6.626 \times 10^{-34}\ \text{J s})(2.998 \times 10^{8}\ \text{m s}^{-1})}{1.02 \times 10^{-3}\ \text{m}} = 1.95 \times 10^{-22}\ \text{J}$$
$$= \frac{h^2}{8\pi^2 I}[(1)(2) - (0)(1)] = \frac{h^2}{4\pi^2 I}$$

Solving for the moment of inertia I gives

$$I = \frac{h^2}{4\pi^2 \Delta E_{rot}} = \frac{(6.626 \times 10^{-34}\ \text{J s})^2}{4\pi^2(1.95 \times 10^{-22}\ \text{J})} = 5.70 \times 10^{-47}\ \text{kg m}^2$$

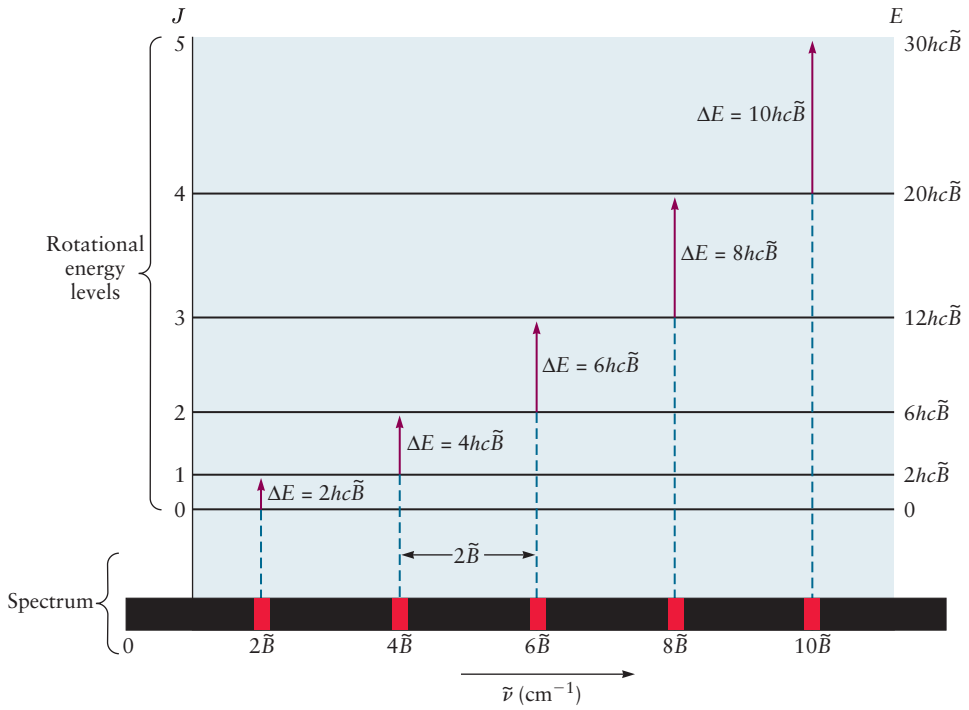

FIGURE 20.8 Rotational energy levels and allowed transitions for a heteronuclear diatomic molecule predicted by the rigid rotor model. The energy levels are given by $E_J = \tilde{B}J(J+1)$ and the selection rule $\Delta J = +1$ for absorption predicts a series of lines equally spaced by $2\tilde{B}$, where $\tilde{B}$ is the rotational constant in cm^{-1}.

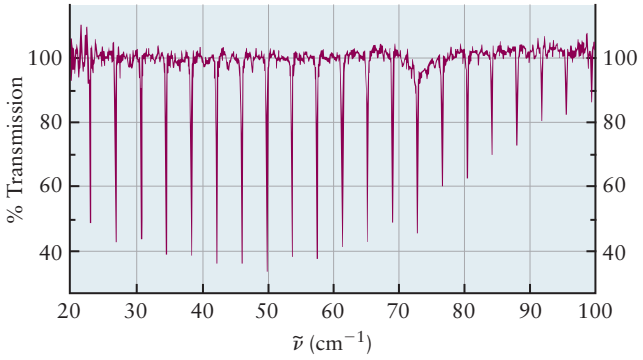

FIGURE 20.9 Microwave absorption spectrum of gas-phase carbon monoxide. The spacing between adjacent lines is 3.8 cm^{-1}, from which the rotational constant $\tilde{B} = 1.9\ \text{cm}^{-1}$ is determined. The pure rotational spectrum shown here is analogous to the R-branch spectrum shown in Figure 20.2. Each line in both spectra results from a rotational transition with $\Delta J = +1$. There has been no vibrational excitation in the spectrum shown here whereas the spectrum shown in Figure 20.2 results from the simultaneous excitation of vibrational and rotational motion.

The moment of inertia I is related to the bond length R_e by $I = mR_e^2$ so

$$R_e^2 = \frac{I}{\mu} = \frac{5.70 \times 10^{-47}\ \text{kg m}^2}{1.603 \times 10^{-27}\ \text{kg}} = 3.56 \times 10^{-20}\ \text{m}^2$$

$$R_e = 1.89 \times 10^{-10}\ \text{m} = 1.89\ \text{Å}$$

Related Problems: 5, 6, 7, 8

Microwave absorption cannot be used to measure bond lengths in homonuclear diatomic molecules because they have no permanent dipole moments. Rotational Raman spectroscopy, however, can be used to measure bond lengths in both heteronuclear and homonuclear diatomic molecules because it depends upon a different kind of interaction. Electromagnetic radiation induces dipole moments in molecules by displacing their electron densities; the induced dipole moment is proportional to the component of the molecular **polarizability** that is oriented parallel to the electric field of the radiation. Polarizability (see Section 10.2) is a measure of the degree to which the electron distributions of atoms and molecules distort in the presence of electric fields; larger atoms, with more loosely bound electrons, have larger polarizabilities than smaller atoms, and molecules with delocalized electrons have larger polarizabilities than those that don't. Figure 20.10 shows that the polarizability of a diatomic molecule is generally larger when the molecule is aligned with the electric field than when it is oriented perpendicular to the field. The polarizability of a homonuclear diatomic molecule oscillates at twice the rotational frequency, producing an oscillating dipole moment that emits radiation at a frequency shifted from that of the incident radiation by that amount. We interpret Raman scattering using quantum mechanics as arising from the absorption of radiation from rotational levels of the ground electronic state to a set of "virtual" electronic states followed by emission to different rotational (or vibrational) levels of the ground electronic state, as shown in Figure 20.11.

We calculate the rotational frequencies by measuring the differences in frequencies of the incident and scattered radiation. $\tilde{\nu} = \tilde{\nu}_i - \tilde{\nu}_s$ where $\tilde{\nu}$ is the frequency of the transition and $\tilde{\nu}_i$ and $\tilde{\nu}_s$ are the frequencies of the incident and scattered radiation, respectively. The scattered radiation may appear either at higher or lower frequencies than the incident radiation, depending upon whether the final rotational level lies lower or higher in energy than the initial rotational level. The selection rule for rotational Raman spectroscopy is $\Delta J = 0 \pm 2$; transitions for which $\Delta J = 0$ produce Raman scattered radiation at the incident frequency, those

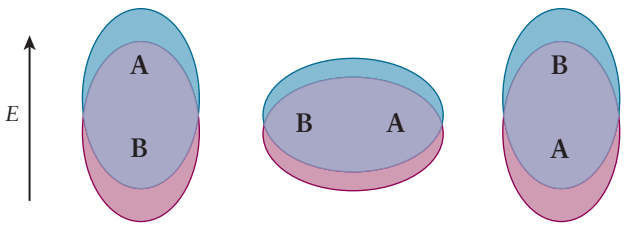

FIGURE 20.10 Schematic of the polarization induced in a diatomic molecule by the electric field component of electromagnetic radiation. The component of the polarizability along the bond axis is, in general, larger than that perpendicular to the axis so the dipole moment that results oscillates at twice the rotational frequency. (We have chosen to represent the polarizability by an ellipse in which the magnitude is proportional to the lengths of the major and minor axes, which is more intuitive than the conventional representation.)

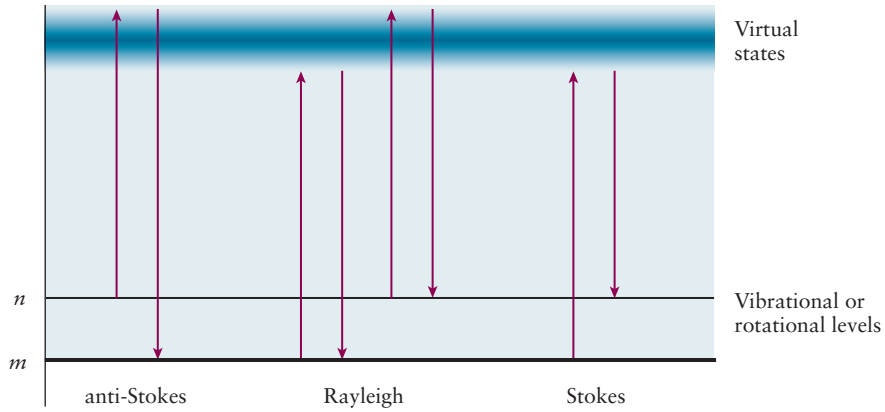

FIGURE 20.11 Quantum mechanical picture of Raman scattering arising from absorption and emission by virtual electronic states.

for which $\Delta J = +2$ produce Raman scattered radiation at lower frequencies (Stokes lines), and transitions for which $\Delta J = -2$ produce Raman scattered radiation at higher frequencies (anti-Stokes lines). The selection rule for rotational Raman scattering is most easily understood by enforcing the conservation of angular momentum. Unlike absorption and emission, with only one photon involved, Raman scattering is a two-photon process that allows for several different combinations of the spin angular momenta of the incident and scattered photons. The projection of the spin angular momentum along the propagation direction can have one of two values, $+1$ or -1 (in units of $h/2\pi$), which we refer to simply as the spin, for simplicity. If the incident and scattered photons have the same spin then the change in the angular momentum is zero, leading to the $\Delta J = 0$ selection rule. If the incident photon has a spin of $+1$ and the scattered photon has a spin of -1, then two units of angular momentum must have been transferred to the molecule, leading to the $\Delta J = +2$ selection rule; the opposite situation leads to the $\Delta J = -2$ selection rule.

Figure 20.12 is a figure of some historical significance. The rotational Raman spectrum of O_2 is shown on the left and that of N_2 is shown on the right. These spectra were taken in 1929, just a year after the discovery of the Raman effect by the Indian physicist Sir C. V. Raman, for which he was awarded the Nobel Prize. The spectra consist of a series of lines, analogous to those in the microwave spectrum of CO, from which the rotational constants, moments of inertia, and bond lengths of these molecules were determined. The rotational Raman spectrum of N_2

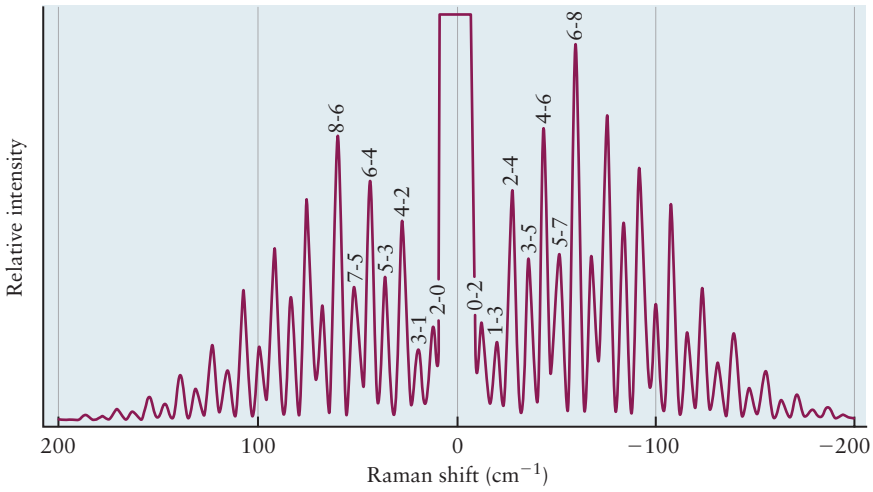

FIGURE 20.13 The pure rotational Raman spectrum of N_2. Courtesy of Bryan Broocks, Department of Chemistry, University of Idaho.

provided the very first measurement of the equilibrium bond length (R_e) of that molecule. Rotational Raman spectroscopy provided much, if not most, of the spectroscopic data shown in Figure 6.18 for the second period homonuclear diatomic molecules, which was of pivotal importance in developing an understanding of the nature of the chemical bond.

Figure 20.13 shows the pure rotational Raman spectrum of N_2 recorded using a modern spectrometer. The Stokes lines appear as the envelope on the right, with negative Raman shifts, and the anti-Stokes lines appear as the envelope on the left, with positive Raman shifts. The overall shape of the envelopes is determined by the same factors as those for microwave absorption spectra, the degeneracy of the levels, and the Boltzmann factor. Notice the interesting alternating intensities of the lines in the spectrum, which results from the effects of nuclear spin (see Section 20.4) on the effective symmetry of the molecule. Different patterns are observed for different nuclear spins: the pattern seen in the figure arises because ^{14}N has a nuclear spin of one, a different pattern appears for H_2 with a nuclear spin of $\frac{1}{2}$, and if you look closely at the spectrum of O_2 shown in Figure 20.12 you will see that every other line is missing, because the spin of ^{16}O is zero.

EXAMPLE 20.4

The rotational constant $\tilde{B}$ for H_2 is 60.86 cm^{-1}. Predict the rotational Raman spectrum of H_2 and calculate the bond length of the molecule.

Solution

The rotational Raman spectrum of H_2 consists of two envelopes of lines, a series of Stokes lines at lower frequencies than that of the excitation source and a series of anti-Stokes lines at higher frequencies. The separation between adjacent lines is $4\tilde{B} = 243.4$ cm^{-1}, from which the rotational constant was determined. The intensity of the lines in each of the envelopes peaks at low values of J, because the rotational energies of H_2 are comparable to thermal energies at 300 K and only the first few vibrational levels are populated to a significant extent. The bond length is calculated from the moment of inertia, determined from the rotational constant, and the reduced mass by rearranging Equation 20.6b to get

$$I = (h/8\pi^2 c\tilde{B}) = 4.6 \times 10^{-46} \text{ kg m}^2$$

The reduced mass of H_2 is $\mu = 8.3 \times 10^{-28}$ kg from which we calculate the bond length using $I = \mu R_e^2$ to get $R_e = 0.74$ Å.

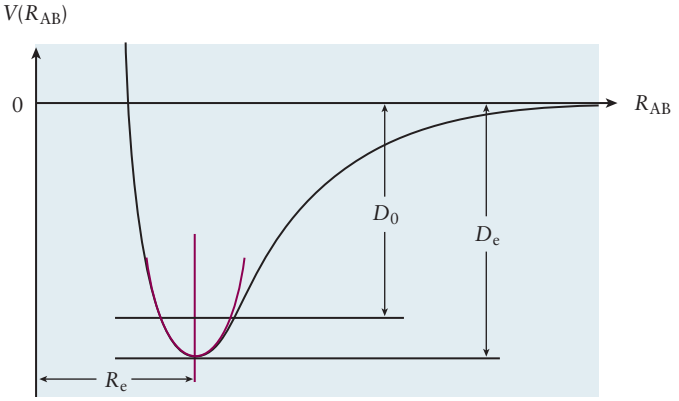
Vibrational Spectroscopy

The vibrational motions of diatomic molecules are analogous to those of a pair of masses connected by a spring and they are analyzed using two simple mechanical potential energy functions, the harmonic oscillator and the Morse potential. The atoms oscillate about the equilibrium bond length at frequencies that depend upon the "stiffness" of the spring as well as the masses of the two atoms. Molecules are always vibrating, even at absolute zero, but transitions between quantized vibrational states can be induced by absorption, emission, or scattering of electromagnetic radiation. The frequencies observed in the vibrational spectra of diatomic molecules, along with the known reduced masses, are used to calculate force constants such as those plotted in Figure 6.18, which correlate strongly with bond order and bond strength, as determined by bond dissociation energies. The importance of vibrational spectroscopy in developing an understanding of chemical bonding can hardly be overstated.

Figure 20.14 shows the potential energy function for a diatomic molecule along with the potential energy function for the harmonic oscillator model. Let's review the characteristics of potential energy functions before introducing the harmonic oscillator model. The potential energy of the atoms separated at infinity is taken to be zero, by convention. The potential energy decreases as the bond is formed, reaching its minimum value D_e at the equilibrium bond length, R_e. Recall that the force between the nuclei is equal to the negative slope of the potential energy function; the force always acts in the direction that lowers the potential energy. The nuclei are attracted to one another in the region where the slope is positive, which is called the attractive region, and they are repelled from one another in the region where the slope is negative, which is called the repulsive region. The nuclei are pulled together by the attractive electrostatic forces exerted on them by the electrons, as suggested by the simple classical model shown in Figure 3.15, the electrostatic nuclear–nuclear repulsion is responsible for the repulsive region of the intermolecular potential energy curve.

The potential energy curve near the minimum closely resembles a parabola, which is the potential energy function for the harmonic oscillator model, one of the most important mechanical models in physics. We discuss the classical and quantum harmonic oscillator models to provide a basis for interpreting the vibrational spectra of molecules. We introduced you to the harmonic oscillator model (without calling it that) in our discussion of blackbody radiation in Section 4.2. Our model for that problem was a mass connected to a wall by a spring. Hooke's law, which is empirical, states that the restoring force acting on that mass is directly proportional to the displacement of the mass from its equilibrium position but acting in the opposite direction. Let's now consider two masses connected by a spring, the masses representing the atoms of a diatomic molecule and the spring representing the chemical bond. For the case of two masses connected by a spring we simply



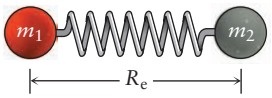


FIGURE 20.14 Potential energy curves for a diatomic molecule (black) and a harmonic oscillator (red) that have the same equilibrium bond length R_e, bond dissociation energy D_e, and similar curvature near the minimum.

Diatomic molecule represented by a ball and spring model.

replace the single mass used in our first model by the reduced mass of the system, which is given by

$$\mu = m_1 m_2/(m_1 + m_2)$$

Let's apply Hooke's law to a diatomic molecule with reduced mass μ and equilibrium bond length R_e. The restoring force is directly proportional to the change in bond length for small displacements

$$F(R - R_e) = -k(R - R_e) \qquad [20.7]$$

where the **force constant** k is a measure of the stiffness of the bond, expressed in N m^{-1} and $(R - R_e)$ is the displacement from the equilibrium bond length. The potential energy function that results from this restoring force is obtained by integrating Equation 20.7 to get

$$V(R - R_e) = \tfrac{1}{2} k(R - R_e)^2 \qquad [20.8]$$

which is shown as the red parabolic curve in Figure 20.14. Note how well the harmonic oscillator potential approximates the real potential energy function in the region around the minimum. This close agreement justifies the use of the harmonic oscillator approximation in vibrational spectroscopy. If the two masses in the system just described are displaced from their equilibrium separation, they will begin to oscillate back and forth about that position with a characteristic frequency given by

$$\nu = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}} \qquad [20.9]$$

in which μ is the reduced mass and k is the force constant of the harmonic oscillator. Classical harmonic oscillators (Fig. 4.9) vibrate at a natural frequency that is determined by Equation 20.9; they can vibrate with any amplitude (and energy, therefore) but the energies of quantum harmonic oscillators are restricted to fixed values as we now show.

The energies and wave functions for the quantum harmonic oscillator model are obtained by solving the one-dimensional Schrödinger equation with the harmonic oscillator potential energy term added to the kinetic energy term.

$$-\frac{h^2}{8\pi^2 m}\frac{d^2\psi(x)}{dx^2} + \frac{1}{2}kx^2\psi(x) = E\psi(x) \qquad [20.10]$$

The method by which this equation is solved is beyond the scope of this textbook, but the wave functions and energy levels are easy to write down, graph, and interpret. You may verify the solutions by substituting them into the Schrödinger equation above. The first four wave functions for the quantum harmonic oscillator are listed in Table 20.2 and plotted in Figure 20.15.

The frequency of a quantum harmonic oscillator is calculated using the same formula as that for the classical harmonic oscillator, Equation 20.9. The quantized energy levels of the harmonic oscillator are given by

$$E_v = (v + \tfrac{1}{2})\, h\nu \qquad [20.11]$$

where ν is its fundamental vibrational frequency and v is a quantum number that can have the values 0, 1, 2, . . . The energy levels are equally spaced, like the steps of a ladder, with adjacent levels being separated by $\Delta E = h\nu$. The higher energy vibrations may be thought of as harmonics of the fundamental, by analogy to the one-dimensional particle-in-a-box model, discussed in Section 4.6. Unlike the particle-in-a-box, however, the $v = 0$ state of the harmonic oscillator is allowed because the term $E = \frac{1}{2} h\nu$ ensures that the energy of the oscillator never equals zero, which would violate the uncertainty principle. In the ground state all mole-

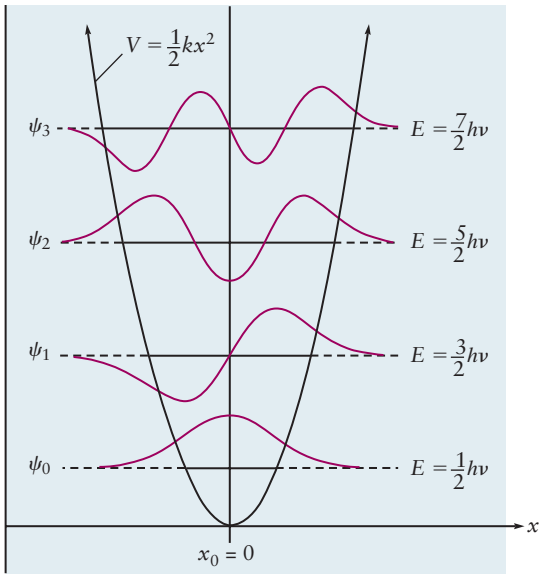

FIGURE 20.15 Energy levels and wave functions for the lower energy states of the harmonic oscillator.

TABLE 20.2

The First Four Harmonic Oscillator Wave Functions

$$\alpha = \frac{2\pi}{h}(k\mu)^{1/2}$$

$$\psi_0(x) = \left(\frac{\alpha}{\pi}\right)^{1/4} e^{-\alpha x^2/2}$$

$$\psi_1(x) = \left(\frac{4\alpha^3}{\pi}\right)^{1/4} xe^{-\alpha x^2/2}$$

$$\psi_2(x) = \left(\frac{\alpha}{4\pi}\right)^{1/4} (2\alpha x^2 - 1)e^{-\alpha x^2/2}$$

$$\psi_3(x) = \left(\frac{\alpha^3}{9\pi}\right)^{1/4} (2\alpha x^3 - 3x)e^{-\alpha x^2/2}$$

cules have $\frac{1}{2}h\nu$ of vibrational energy in each vibrational mode, even at 0 K; this motion is called **zero-point motion** and the energy is called the **zero-point energy.** Differences in zero-point energy account for very important isotope effects on reaction rates in chemical kinetics, as discussed in Section 18.6. Vibrational spectra are usually presented as a function of frequency expressed in wave numbers; the highest-frequency molecular vibration is that of H_2, at 4400 cm^{-1}, and the low-frequency end of the vibrational spectral region for molecules is generally around 100 cm^{-1}, frequencies that are characteristic of metal–metal stretching vibrations, for example.

Transitions between vibrational energy levels can occur by absorption or emission of infrared radiation, or by Raman scattering. Molecules must have dipole moments that change as they vibrate in order for them to absorb or emit infrared radiation, by the same classical argument presented for rotation earlier. Vibrational Raman scattering, on the other hand, requires a change in the molecular polarizability during vibration. The angular momentum selection rule introduced in Section 20.1 applies rigorously to vibrational spectroscopy as well, but it is a little harder to visualize than for rotational spectroscopy. The harmonic oscillator approximation introduces an additional, but weaker, quantum mechanical selection rule $\Delta v = \pm 1$ for both infrared absorption and emission and for Raman scattering. That selection rule is relaxed for anharmonic potential energy functions, like the Morse potential, which is introduced in the discussion that follows Example 20.6. It is appropriate, however, to describe briefly the experimental method by which infrared spectra are obtained before continuing our discussion of their interpretation.

Fourier Transform Infrared spectroscopy (FTIR) is by far the most widely used technique for acquiring infrared spectra because it is very rapid; the intensities at all wavelengths are measured simultaneously, instead of sequentially as done by scanning the prism or grating in a monochromator. An FTIR spectrometer consists of an infrared source, the sample compartment, an interferometer and a detector. Figure 20.16 is a schematic of a Michelson interferometer, which is the key component of an FTIR spectrometer. The source is typically a heated element that emits blackbody radiation over the entire range of wavelengths of interest. The radiation passes through the sample and enters the interferometer where it is split into two beams oriented perpendicular to one another. The beams are sent to two mirrors, one fixed and one that is scanned back and forth to provide a variable path length for one arm of the interferometer. The beams are recombined at the beam splitter and sent to a detector where an interference pattern (an interferogram) is recorded and subsequently transformed into a spectrum by a mathematical algorithm called a Fourier transform, as illustrated by analogy in Figure 20.17. Example 20.5 shows how to calculate force constants for a diatomic molecule from vibrational frequencies measured using infrared absorption spectroscopy.

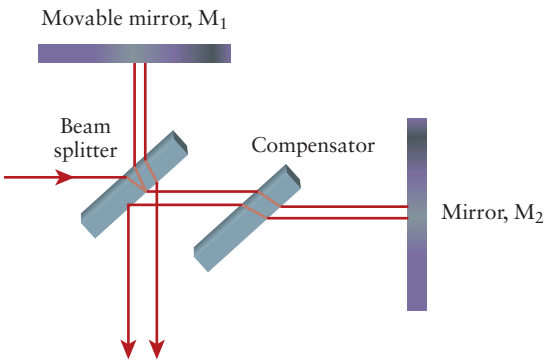

FIGURE 20.16 Schematic of an interferometer. The movable mirror is scanned back and forth, which causes a periodic modulation in the detected signal due to interference between the two beams. EXAMPLE 20.5

The infrared spectrum of gaseous NaH (isotope: $^{23}Na^{1}H$) was determined via absorption spectroscopy. A single absorption band was observed at $\lambda = 8.53\ \mu m$. Calculate the vibrational force constant of the NaH molecule using the harmonic oscillator model using the masses of the isotopes provided in Table 19.1.

Solution

The vibrational frequency is

$$\nu = \frac{c}{\lambda} = \frac{2.998 \times 10^{8}\ \text{m s}^{-1}}{8.53 \times 10^{-6}} = 3.515 \times 10^{13}\ \text{s}^{-1} = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}}$$

Solving for the constant k (using the reduced mass from Example 20.1) gives

$$k = \mu(2\pi\nu)^2 = (1.603 \times 10^{-27}\ \text{kg})(2\pi)^2(3.515 \times 10^{13}\ \text{s}^{-1})^2$$

$$= 78.2\ \text{kg s}^{-2} = 78.2\ \text{J m}^{-2}$$

Related Problems: 13, 14, 15, 16

Force constants are a measure of the "stiffness" of chemical bonds. Figure 6.18 shows a strong correlation between force constants and other properties such as bond lengths and bond dissociation energies. It is not obvious from inspection of potential energy functions why this should be the case. The force constant is equal to the second derivative of the potential energy, which would appear to be independent of the depth of the well or the equilibrium bond length. But there is a very good empirical relationship, called Badger's rule, which states that vibrational frequencies and bond lengths are strongly correlated in a series of related compounds. In fact, Badger's rule is often used to estimate bond lengths from vibrational spectra for molecules, as an alternative to X-ray diffraction. We can rationalize this correlation by the following simple argument. Chemical bond lengths and bond dissociation energies fall within very narrow ranges, with potential energy functions that are well-described by a number of simple two-parameter empirical potentials like the Morse potential. The bond length is determined by the balance between the steep repulsive force and the more slowly varying attractive force, with the latter becoming steeper as R_e decreases, making the potential well more narrow for shorter bonds. The curvature of more narrow wells is greater than that of more shallow wells, accounting for the correlation between force constants and bond lengths. The correlation between bond length and bond dissociation energy is also accounted for by the different range dependences of the attractive and repulsive parts of the potential energy function. Imagine that the repulsive part of the potential energy function is represented by a vertical wall that intercepts the x-axis at R_e and that the attractive part of the potential energy function is the same for a series of related molecules. The repulsive wall moves to the left as the bond length decreases, intersecting the attractive part of the potential energy function at lower energies, which accounts for the inverse correlation between bond length and bond dissociation energy. Example 20.6 shows how the force constants plotted in Figure 6.18 were determined from vibrational spectra.

EXAMPLE 20.6

Homonuclear diatomic molecules do not absorb infrared radiation but their vibrational spectra are readily obtained using Raman spectroscopy, as shown for H_2, N_2 and O_2 in the *Connection to Instrumental Analysis* in Chapter 3. The measured vibrational frequencies for the second period diatomic molecules are: $^{7}Li_2$ (351 cm^{-1}); $^{11}B_2$ (1051 cm^{-1});

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

$^{12}C_2$ (1855 cm^{-1}); $^{14}N_2$ (2358 cm^{-1}); $^{16}O_2$ (1580 cm^{-1}); $^{19}F_2$ (919 cm^{-1}). Calculate the force constants for each molecule, using the vibrational frequencies given and the atomic masses provided in Table 19.1. Compare the values you obtain with those in the figure in the Chapter 3 *Connection* and comment on the utility of vibrational spectroscopy for determining force constants.

Solution

Let's calculate the force constant for N_2 as an example, leaving the rest of the molecules for you to work out on your own. We modify the formula given in Example 20.5 to account for frequencies expressed in wave numbers and substitute the experimental values and the reduced mass for N_2 to solve for the force constant.

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{2\pi c}\sqrt{\frac{k}{\mu}}$$

$$k = \mu(2\pi c\tilde{\nu})^2$$

$$= [1.16 \times 10^{-26}][(2\pi)(3 \times 10^{10}\ \text{cm s}^{-1})(2358\ \text{cm}^{-1})]^2$$

$$= 2292\ \text{N m}^{-1}$$

which is in good agreement with the value plotted in Figure 6.18. The values calculated for all of these molecules agrees with the values plotted in the figure and shows that vibrational spectroscopy is a reliable and straightforward way to measure bond force constants.

Related Problems: 13, 14, 15, 16

The differences in the vibrational frequencies observed for the series C_2—F_2 are dominated by the differences in force constants, the reduced masses varying by less than a factor of two. This allows us to determine the bond orders of individual bonds in polyatomic molecules simply by inspection; single bonds between the second period elements give rise to bands in the 1000 cm^{-1} region of the spectrum, double bonds around 1600 cm^{-1}, and triple bonds around 2300 cm^{-1}. These characteristic frequencies are very helpful in the analysis of the vibrational spectra of polyatomic molecules, as we show later. Examining trends in the vibrational frequencies of a series of diatomic hydrides reveals the importance of the reduced mass in determining vibrational frequencies and also allows us to establish the range over which they occur, again to assist in the interpretation of the spectra of polyatomic molecules. The vibrational frequencies of the hydrogen halides are: $^1H^{19}F$ (4139 cm^{-1}); $^1H^{35}Cl$ (2991 cm^{-1}); $^1H^{81}Br$ (2449 cm^{-1}); and $^1H^{127}I$ (2308 cm^{-1}). The reduced masses in each of these cases is essentially the mass of the hydrogen atom, which is why the vibrational frequencies are so high. The motion is that of the hydrogen atom vibrating against the more massive halogen atoms, which can be thought of as stationary. The vibrational frequencies of the gas-phase diatomic hydrides $^{12}C^1H$ (2859 cm^{-1}) and $^{16}O^1H$ (3765 cm^{-1}) are also typical for these bonds in polyatomic molecules; frequencies that are characteristic of particular bonds are extremely useful in the analysis of the vibrational spectra of polyatomic molecules. The harmonic oscillator model does not describe the motions of the nuclei very well for higher vibrational levels. These motions are governed by an anharmonic potential energy function like the **Morse potential** energy function shown in Figure 20.18. The Morse potential (as it is often called) is a simple analytical expression that is widely used to describe the anharmonic potential energy function of a diatomic molecule. It is

$$V(R - R_e) = D_e[1 - \exp(-a(R - R_e)]^2 \qquad [20.12]$$

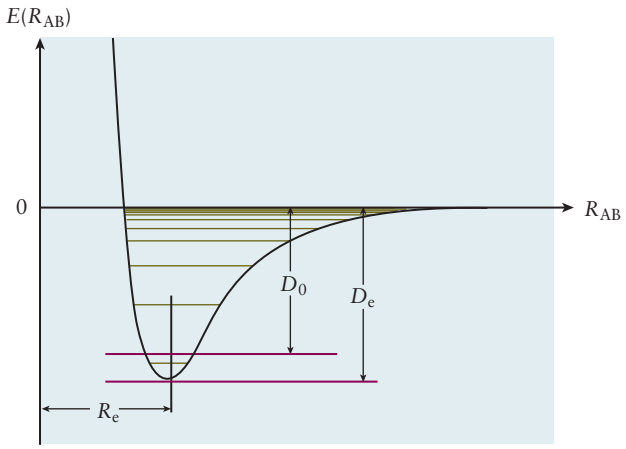

FIGURE 20.18 Morse potential energy function and associated vibrational energy levels.

where V is the potential energy, R is the distance between the nuclei, R_e is the equilibrium bond length, D_e is the "depth" of the potential energy well, and a is a constant that determines the "width" of the potential energy well. The Morse potential is a particularly convenient choice for a potential energy function because the resulting Schrödinger equation can be solved analytically. The solutions for the energy add an anharmonic correction term to the equation for the oscillator energy levels. In addition, the harmonic oscillator selection rule is relaxed for anharmonic oscillators and overtones, with $\Delta v > 1$, are observed. The energy levels are no longer uniformly spaced, as shown schematically in Figure 20.18, and the experimental spectrum shows a progression of frequencies corresponding to these smaller energy gaps. The decrease in frequencies observed between successive levels is proportional to the vibrational quantum number v; summing these differences provides a very good estimation of the dissociation energy of the molecule, an important quantity that may be very difficult to obtain by other methods for some molecules. The use of this method is illustrated in Figure 20.19 and discussed in Example 20.7.

EXAMPLE 20.7

Estimate the bond dissociation energy for H_2^+ using Birge-Sponer extrapolation. The differences in frequencies between successive transitions ($0 \longrightarrow 1, 1 \longrightarrow 2$, etc.) in cm^{-1} are 2191, 2064, 1941, 1821, 1705, 1591, 1479, 1368, 1257, 1145, 1033, 918, 800, 677, 548, and 411.

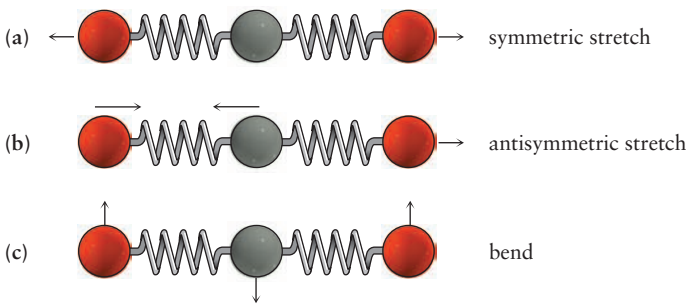
Solution

Plot the frequency differences versus the lower quantum number of each pair, as illustrated in Figure 20.19. Fit to a straight line using the linear least squares function on your calculator or a computer and calculate the area of the triangle formed by the origin and the *x* and *y* intercepts. You may also plot the points and determine the area graphically. Adapted from Physical Chemistry 9th Edition, Peter Atkins and Julio De Paula W. H Freeman, New York 2010.

Polyatomic Molecules

Rotational Spectroscopy

Pure rotational spectra of polyatomic molecules are considerably more complicated than those of diatomic molecules because they may have up to three different moments of inertia that result from rotations about three different molecular axes (see Section 12.5 and Figure 12.11). The symmetry of the molecule determines the number of distinct values for the moments of inertia. Linear molecules have one unique axis and a single moment of inertia for rotation about any axis perpendicular to that axis. The analysis of pure rotational spectra for *linear* triatomic molecules is only slightly more complicated than that for diatomic molecules because there are two bond lengths and only one rotational constant. We can determine both bond lengths by measuring the rotational constants of at least two molecules in which one or more isotopic substitutions have been made and solving two equations for the two unknowns. The calculation is straightforward, but tedious, and examples can be found in standard physical chemistry textbooks. All axes are equivalent for spherically symmetric molecules such as CH_4 and SF_6, with tetrahedral and octahedral symmetry, respectively; these spherical rotors have three moments of inertia that are equal to one another. Molecules such as NH_3 and CH_3Cl have one unique axis and two different moments of inertia, one for rotation about the unique axis and one for rotations about any axis perpendicular to that axis. These molecules are called symmetric rotors. Finally, molecules with three different moments of inertia, such as H_2O, are called asymmetric rotors. The analysis of rotational spectra for nonlinear polyatomic molecules is significantly more complex than that for linear triatomic molecules, but it is carried out in the same way, and has enabled scientists to determine the geometries of many small polyatomic molecules, like those shown in Chapters 3, 6, 7 and 8, very accurately.



Vibrational Spectroscopy

The number and frequencies of the bands observed in vibrational spectra are used to identify molecules, to characterize bonding, and to probe their local environments in complex systems such as those found in biology, geology, or materials science, for example. Molecules containing N atoms have $3N$ degrees of freedom in total, corresponding to the three translational degrees of freedom for each atom if they were not bound together. Three of these degrees of freedom correspond to translations of a molecule through space, and there are either 2 (linear molecule) or 3 (nonlinear molecule) rotational degrees of freedom. Subtracting these external motions from the total leaves $3N - 5$ vibrational degrees of freedom for linear molecules and $3N - 6$ vibrational degrees of freedom for nonlinear molecules. The vibrational motions of relatively small molecules, especially rather symmetric ones, can be represented as a superposition of a number of "normal modes" in which the

motions of the atoms are arranged in uniquely different ways. The normal modes of water include a symmetric H—O—H stretch (both bonds stretching and compressing in phase), an antisymmetric H—O—H stretch (both bonds stretching and compressing out of phase) and an H—O—H bending motion, for example. It is instructive to examine the vibrations of a small polyatomic molecule, CO_2, to get a feel for some characteristic vibrational motions, their frequencies, and their spectroscopic activity before turning our attention to the spectroscopy of more complicated polyatomic molecules.

CO_2 is a linear triatomic molecule with $3N - 5 = 4$ different "normal" modes of vibration, as shown in the adjacent figure.

CO_2 vibrations

There are two stretching modes and two bending modes: stretching modes are those in which the bond length changes without changing the bond angles, and bending modes are those in which the bond angles change without changing the bond lengths. The two oxygen atoms move in different directions (along the bond axis) during one cycle of the symmetric stretching vibration (a) whereas they move in the same direction during one cycle of the antisymmetric stretch (b). The bond angle changes during the two bending vibrations (c), which are degenerate. The bending modes are considered to be distinct because the motions occur in two mutually perpendicular planes. Let's examine how the dipole moment and polarizability of the molecule changes during each of these vibrations to determine their infrared and Raman activity.

Let's examine how the dipole moment changes during each of the vibrations, beginning with the degenerate bending modes. The permanent dipole moment of CO_2 is zero by symmetry, but there is clearly an oscillating dipole moment associated with the bending mode so this mode is infrared active. The dipole moment of CO_2 does not change during the symmetric stretching motion, so that mode cannot be excited by infrared absorption. The dipole moment of the molecule clearly changes during the antisymmetric stretching vibration, so that mode can be excited by infrared absorption. The infrared spectrum of CO_2 consists of two bands, one at 673 cm^{-1}, which is assigned to the doubly degenerate bending mode and one at 2396 cm^{-1}, which is assigned to the antisymmetric stretch.

Visualizing the change in polarizability during the vibrations is a little more difficult than visualizing the change in dipole moment. It is helpful to think about the polarizability of each of the bonds separately to see how the polarizability of the molecule changes during vibrations. We need to consider only the component of the polarizability that is parallel to the bond axis to understand the stretching modes. The polarizability increases as the bonds stretch and decreases as the bonds are compressed. The two C—O bonds oscillate in phase during the symmetric stretch, so the changes in the bond polarizability are additive. The bond polarizabilities oscillate out of phase during the antisymmetric stretch, and there is no change in the overall polarizability during that vibration. The symmetric stretch is Raman-active and the antisymmetric stretch is not. Understanding the Raman activity of the bending mode is not so easy to explain visually, so we just state the

TABLE 20.3

CO_2 Vibrational Modes, Frequencies, and Spectroscopic Activity

Mode	Frequency	Activity
Symmetric stretch	1354 cm^{-1}	Raman
Bend (doubly degenerate)	673 cm^{-1}	IR
Antisymmetric stretch	2396 cm^{-1}	IR

result; that mode is not Raman-active. The frequencies and IR or Raman activities of the three modes are summarized in Table 20.3. Notice that none of the vibrational modes of CO_2 is both infrared active and Raman active; this is a consequence of inversion symmetry (see Section 6.1).There is a mutual exclusion rule for all centrosymmetric molecules: Modes that are infrared-active are not Raman-active, and vice versa.

Infrared and Raman spectroscopy tend to be complementary methods even for molecules that lack inversion symmetry, because the nature of the interactions between the molecules and electromagnetic radiation are different in the two cases. IR spectroscopy tends to emphasize vibrations involving polar bonds and is less sensitive to vibrations involving largely covalent bonds. Raman spectroscopy, on the other hand, is more sensitive to the motions of highly polarizable covalent bonds, such as those involving π bonds or conjugated systems, and rather less sensitive to the vibrations of very polar or ionic bonds, especially those involving the less polarizable lighter elements. The complementarity of the methods is illustrated by comparing the IR and Raman spectra of the amino acid cystine, as shown in Figure 20.20. Cystine is a dimer of the amino acid cysteine; the disulfide bond formed between two cysteine residues located in different regions of a protein cross-links the polymer chains and is a contributing factor to their tertiary structures. The S—S stretch observed near 500 cm^{-1} is barely visible in the infrared spectrum whereas it dominates the Raman spectrum.

Vibrational spectra of polyatomic molecules with more than three atoms are considerably more complex than those of diatomic molecules or CO_2. Fortunately, the vibrational modes of functional groups containing a few atoms are often independent of the rest of the molecule to which they are bound, in the same way that their chemical properties are quite similar in different molecules, as discussed in Section 7.6. Even the simplest amino acid glycine (H_2NCH_2COOH), for example, has 20 normal modes, but its spectrum can be analyzed by looking for vibrations that are characteristic of the carboxylic acid (—COOH) and amino ($—NH_2$) groups. These complex spectra provide "fingerprints" that are used to identify and characterize molecules. The vibrational spectra of larger molecules are generally analyzed by looking for characteristic frequencies of functional groups, which are largely independent of other features of the molecule of which they are a part. The characteristic frequencies of these functional groups can be interpreted as a set of "normal" or "local" modes that involve only the atoms of a particular group. The stretching vibrations of methyl ($—CH_3$) or methylene ($—CH_2$) groups can be thought of as "normal" modes of those groups, comprising symmetric and antisymmetric combinations of the individual C—H bond stretches. C—X stretching vibrations, where X is a halogen, the O—H stretch of an alcohol or the C≡N stretch of the nitrile functional group, on the other hand, can be thought of as "local" modes. Table 20.4 is an abbreviated version of a table of characteristic frequencies used to analyze infrared and Raman spectra and Example 20.8 shows how to use these characteristic group frequencies to analyze the infrared spectrum of a polyatomic molecule.

EXAMPLE 20.8

Identify some characteristic group frequencies in the spectrum of an organic molecule shown and identify the class of molecules to which it belongs. Propose a structure if you can.

Solution

The highest frequency mode shown appears around 3350 cm^{-1}, a region characteristic of N—H stretching vibrations, the stronger absorption appearing around 2850 cm^{-1} is characteristic of C—H stretching vibrations in alkanes, and the very strong mode appearing near 1650 cm^{-1} is characteristic of the carbonyl (C=O) stretching vibration. The absorption near 1450 cm^{-1} is associated with a C—N stretching vibration and the one near 1175 cm^{-1} is characteristic of a C—C single bond stretch. Taken together these observations suggest that the molecule is an amide, with the R(CO)N— functional group. The presence of the C—H stretching vibrations characteristic of an alkane as well as the C—C single bond stretch suggest that it is an alkyl amide. The molecule is $H_3CCH_2(CO)NHCH_3$.

Related Problems: 25, 26

20.4 NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

Nuclear magnetic resonance (NMR) spectroscopy measures the energies and intensities of transitions between quantized nuclear spin states of ^{1}H, ^{13}C, and a few other nuclei. The energies of these states are degenerate in the absence of a magnetic field, but separate from each other (split) when an external field is applied; transitions between the split levels are induced by interactions with electromagnetic radiation in the radiofrequency region of the spectrum (typically 300–600 MHz). The resonance frequencies observed for a particular nucleus of a given type provide chemists with a great deal of information about the functional group to which the atom belongs (through chemical shifts), as well as the identities of adjacent functional groups (through spin–spin splitting). The rich information content provided makes NMR spectroscopy undoubtedly among the most important techniques available for investigating structure and dynamics in many areas of chemistry, biology, and medicine. Synthetic chemists use NMR, along with mass spectrometry, to verify the identities of new products as well as those of intermediates formed in complex multistep reactions to ensure that their synthetic strategies are on track. Biologists use NMR to study the three-dimensional structures and reactions of proteins, enzymes, and nucleic acids (DNA and RNA). The method is complementary to X-ray diffraction (see Section 21.1); it does not require crystals

to be grown, the molecules are studied in their native environments, it is reasonably quick, and it enables binding and other reactions to be studied that would be very difficult to accomplish using X-ray diffraction. The importance of magnetic resonance imaging (MRI) in modern medicine can hardly be overstated. Images are obtained with millimeter spatial resolution, and specialized techniques have been developed for different applications that include imaging the major organs for function, identifying tumors, and monitoring blood flow to look for evidence of possible cardiovascular disease, for example.

The Stern–Gerlach experiment (see Section 5.1) demonstrated the existence of an intrinsic "spin" angular momentum associated with the electron that is characterized by the spin quantum number $s = \frac{1}{2}$. The magnitude of the spin angular momentum is quantized, as is its projection along the laboratory z-axis, the allowed values being given by appropriate substitutions into Equations 5.2a and 5.2b.

$$|s| = \sqrt{s(s+1)}(h/2\pi) \quad \text{and}$$
$$s_z = m_s(h/2\pi)$$

where $m_s = \pm\frac{1}{2}$, with $m_s = +\frac{1}{2}$ being spin "up" and $m_s = -\frac{1}{2}$ being spin "down." The magnetic dipole moment of the electron is oriented antiparallel to the spin because the charge on the electron is negative.

Most nuclei also have intrinsic spin angular momenta and magnetic dipole moments that arise from the rotating charge distribution of the nucleus. Nuclear spin levels are identified by a quantum number I, and the same quantization conditions as those for the electron spin apply.

$$|I| = \sqrt{I(I+1)}(h/2\pi) \quad \text{and} \qquad [20.13a]$$
$$I_z = m_I(h/2\pi) \qquad [20.13b]$$

^{1}H and ^{13}C are both spin $\frac{1}{2}$ nuclei, as are most of the others used in NMR spectroscopy for specialized purposes: ^{15}N, ^{19}F, ^{29}Si, and ^{31}P. The nuclear spins of ^{12}C and ^{16}O are both zero. The energy of a magnetic dipole in an external magnetic field oriented along the positive z-axis is given by $E = -\mu_z B_0$, where μ_z is the projection of μ along the z-axis and B_0 is the strength of the magnetic field. The lower energy configuration is the one in which the magnetic dipole is aligned with the magnetic field; the "south" end of the dipole points toward the "north" end of the field. The magnetic dipole moments of various nuclei are related to their spin by $\mu_i = g_i\mu_N I_i$, where $\mu_N = eh/4\pi m_P = 5.051 \times 10^{-27}$ J T^{-1} is the **nuclear magneton,** a quantity that is independent of any particular nucleus. The SI unit for magnetic field strength (more formally the magnetic flux density) is the **tesla (T).** A particle carrying one coulomb of charge, traveling at one meter per second through a one-tesla field experiences a force of one newton. Nuclear g factors are simply proportionality constants that allow us to express the magnetic moments of various nuclei in terms of the nuclear magneton. The g factors for most nuclei are positive, which means that the magnetic dipole moment is aligned parallel with the spin, in contrast to the electron. The g factor for the proton is 5.586, whereas that of the ^{13}C nucleus is only 1.405.

Figure 20.21 shows a schematic of an NMR spectrometer. The sample is contained in a small (5 mm diameter) tube that is placed in a magnetic field created by a superconducting magnet. Radiofrequency radiation is transmitted to the sample by a set of coils placed around the sample, and a second set of coils detects the signal. NMR spectrometers are traditionally operated by setting the frequency and scanning the magnetic field until the sample comes into "resonance," hence the name. Figure 20.22a shows the splitting of the proton energy levels as a function of magnetic field strength and the field strength at which the energy-level splitting comes into resonance with the radiofrequency radiation, causing absorption. Figure 20.22b shows the resulting NMR spectrum of a single proton.

Virtually all contemporary NMR spectrometers are Fourier transform instruments, (FT-NMR) in which the spins, initially in thermal equilibrium, are excited by a short burst of broad band radiofrequency radiation. They emit radiation as they return to thermal equilibrium, and the transient decay of this emission is recorded. The transient is then analyzed using a Fourier transform algorithm, which produces a spectrum that shows the resonance frequencies of the nuclei, which differ due to shielding and spin–spin splitting. Figure 20.23 illustrates the process, using a piano string as an analogy.

Figure 20.23a shows a pure sine wave oscillating at 440 Hz (left); its Fourier transform is the single line at 440 Hz (right). Figure 20.23b shows the response of a piano string being struck (left) and its Fourier transform (right). The frequencies observed are the fundamental and its harmonics and the relative intensities of the harmonics give the note its character. The transient decay of the NMR signal looks similar to that of the piano, with the different frequencies "beating" against each other and the spectrum being obtained by Fourier transformation of the transient.

The intensities of NMR spectra depend upon the population differences between the spin states, which are determined by the nuclear magnetic moment, the magnetic field strength, and the temperature. NMR spectrometers are identified by proton resonance frequencies; 300 MHz instruments that are now common in university teaching laboratories have 7.05 T magnets. The signal is proportional to the population difference $\Delta N = N_{\text{down}} - N_{\text{up}}$. We showed in Section 20.1 that the population difference can be written in terms of the ratios of the populations as

$$\Delta N/N = [1 - \exp(-\Delta\varepsilon/k_B T)]$$

which, for NMR, becomes

$$\Delta N/N = [1 - \exp(-g\mu_N B_0/k_B T)] \qquad [20.14]$$

Inserting the values of the nuclear g factors for the proton and for ^{13}C, we get $\Delta N/N = 4.8 \times 10^{-5}$ for the proton and $\Delta N/N = 1.2 \times 10^{-6}$ for ^{13}C, for a 7.05 T magnet at 300 K.

NMR is a valuable tool for elucidating molecular structure because the local magnetic field felt by each nucleus depends upon two kinds of interactions, both of which are sensitive to the local chemical environment: (1) The external magnetic field induces currents that shield the nucleus, producing **chemical shifts** that are very sensitive to the nature of the bonds it forms with its neighbors and (2) **spin–spin splitting,** which is fine structure observed for a particular resonance due to the magnetic fields of neighboring nuclei. We discuss each of these effects in turn.

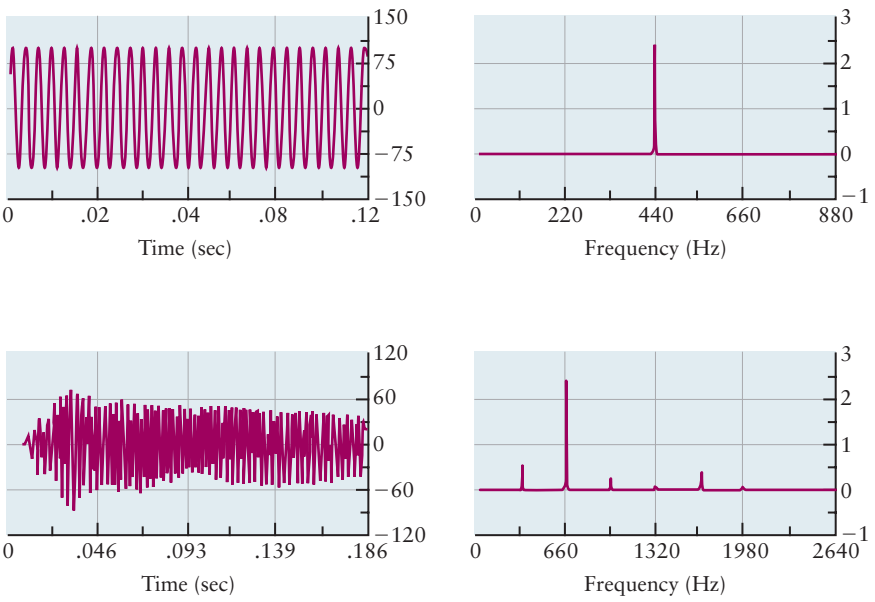

FIGURE 20.23 (a) a pure sine wave oscillating at 440 Hz (concert A) and its Fourier transform. (b) a struck piano string (concert E = 330 Hz), its transient decay and Fourier transform showing the relative intensities of the harmonics.

The local magnetic field felt by a particular nucleus is slightly different from the external field because of shielding effects. (Recall how shielding of the nuclear charge by electrons in inner shells reduces the effective nuclear charge felt by electrons in outer shells as discussed in Section 5.2). In the case of NMR the magnetic shielding arises from local magnetic fields that are set up by little electrical currents induced in molecules by the external magnetic field. The local field may be expressed phenomenologically using $B_{loc} = (1 - \sigma)B_0$ where σ is a shielding constant; we discuss several different contributions to the shielding constant later. Differences in local magnetic fields manifest themselves in different resonance frequencies for each nucleus, because the resonant frequency is directly proportional to the local field strength. Chemical shifts are small; they range between a few hundred Hz and a few thousand Hz in a 300 MHz spectrometer. Because the shifts are so small, it is customary to report them on a scale that is based on the differences between the resonance frequencies of the sample of interest and that of a standard reference compound, (tetramethylsilane, TMS, for proton NMR). The dimensionless chemical shift δ is defined as

$$\delta = \frac{\nu_s - \nu_r}{\nu_r} \times 10^6 \qquad [20.15]$$

where ν_s is the resonance frequency of a sample peak and ν_r is the resonance frequency of the reference standard. We relate the chemical shift to the shielding constants using.

$$\delta = \frac{(1 - \sigma_s) - (1 - \sigma_r)}{(1 - \sigma_r)} \times 10^6 \approx (\sigma_r - \sigma_s) \times 10^6$$

where we have set the denominator equal to 1 because chemical shifts are so small. Figure 20.24 shows the ^{1}H NMR spectrum of methyl acetate with two resonances of equal intensity along with the resonance of the TMS reference. The protons in TMS are very well shielded, which is one reason it was chosen as a reference compound. The magnetic field required to bring the TMS protons into resonance is higher than for most other compounds, so that region of the spectrum is called **upfield.** Protons with less shielding than those of TMS are called **deshielded,** and their resonances are shifted **downfield.** Let's analyze the spectrum of methyl acetate to help you learn to interpret NMR spectra.

Notice that there are only two resonances, one at $\delta = 2$ and one at $\delta = 3.6$. This observation tells us that the hydrogen atoms in each of the two methyl groups are magnetically equivalent and shielded to the same extent. Protons are equivalent when they are part of a functional group that is free to rotate, like the methyl group, or where they are related by a plane of symmetry, like the protons in ethylene. That there are two different resonance frequencies tells us that the degree of shielding of the protons in the two methyl groups is different. Finally, that the peak heights (and areas, not shown) are identical tells us that there are the same numbers of hydrogen atoms in each group. Figure 20.25 shows a range of chemical shifts for protons in different functional groups, which makes it clear why NMR is such a

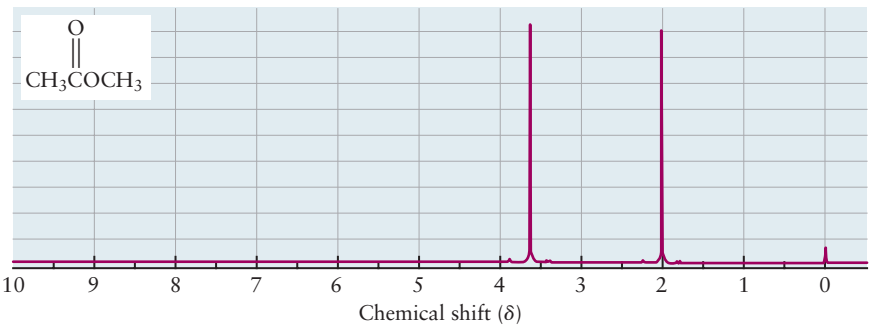

FIGURE 20.24 NMR spectrum of methyl acetate showing resonances from two different methyl groups, one attached to the carbonyl carbon atom and one attached to the oxygen atom of the ester group.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

powerful technique for identifying functional groups. We can rationalize a few of the trends, but the quantum mechanical explanations of the origins of the chemical shift are beyond the scope of this textbook, so you may also interpret the data shown as empirical. The **diamagnetic shielding** results from induced currents around each proton, which are proportional to the electron density around the proton. Electronegative elements bonded to adjacent carbon atoms withdraw electron density, which deshields protons bonded to those carbon atoms. The chemical shifts for a series of methane derivatives shows a clear correlation with electronegativity; $\delta = 4.26$ for CH_3F, and it decreases smoothly through the series —OH, —Cl, Br, and I. The series of compounds RCH_2X, where X is a halogen atom, shown in the figure, also shows that deshielding increases with the electronegativity of the halogen. The TMS protons are so well shielded because carbon is more electronegative than silicon, which increases the electron density on the methyl protons. Ring currents induced in benzene rings establish magnetic fields that reinforce the external field at protons bound to the carbon atoms of the ring but oppose the external field for protons in side groups that may lie above or below the plane of the ring. The ring protons are deshielded, their resonances appearing downfield.

Important additional information about molecular structure is provided when peaks are split into multiplets, due to **spin–spin coupling,** as seen in the spectrum of 1,1-dichloroethane shown in Figure 20.26. These patterns allow chemists to determine how different functional groups are connected to each other in molecules. The local field experienced by a group of equivalent protons may be split by the spins of a group of neighboring protons in the following way. Let's first consider how the spin of the single (methine) proton in 1,1-dichloroethane affects the local magnetic field felt by the methyl group protons. The spin of the methine proton can be oriented either parallel to the external magnetic field (up) or antiparallel (down) with equal probability. The effective field is stronger for the spin-up configuration, moving the resonance upfield, and weaker for the spin-down configuration, moving the resonance downfield, producing two resonances of equal intensity, as observed. The difference in chemical shifts is called the spin–spin splitting constant

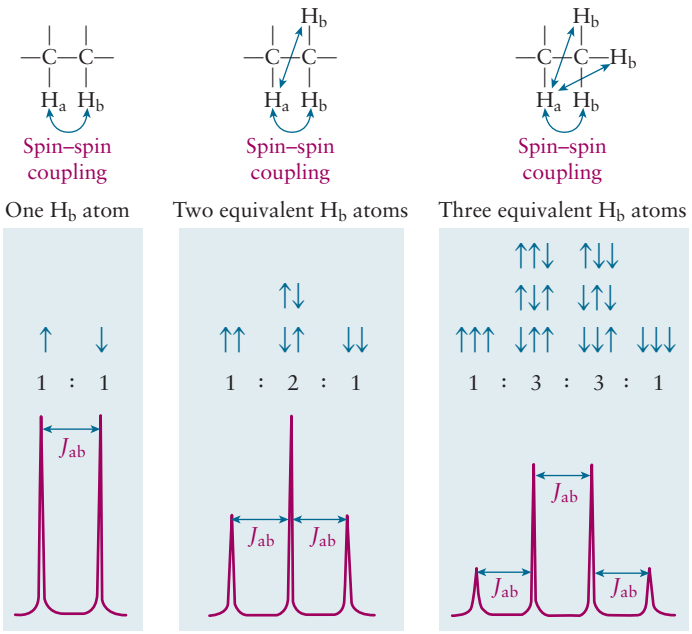

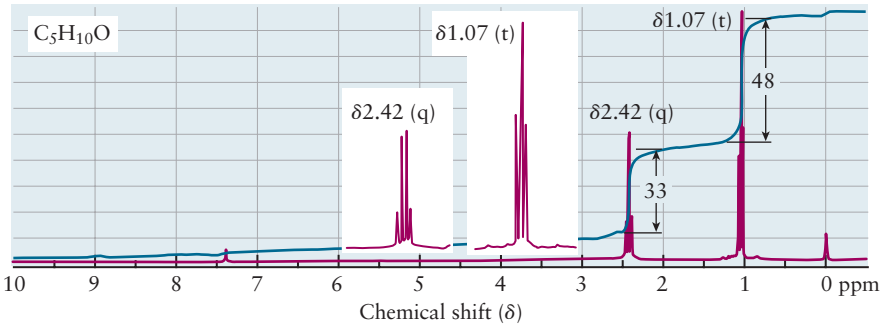

FIGURE 20.27 Spin–spin coupling between a single proton H_a and groups of one, two and three equivalent protons H_b on the adjacent carbon atom.

J_{ab}. Let's now consider the effect of the methyl protons on the methine resonance frequency. Each of the three methyl spins can be oriented up or down, independently, and with equal probability, so we simply have to count all of the possible ways these orientations can combine to determine what local fields will result. There is only one arrangement with all three spins up and only one arrangement with all three spins down, but there are three ways to have one spin up with two spins down and three ways to have one spin down with two spins up, resulting in the quartet with relative intensities in the ratio 1:3:3:1 as shown in Figure 20.26. These two splitting patterns, along with a triplet pattern observed when the resonance of one proton is split by a pair of adjacent protons, are shown in Figure 20.27. More complex splitting patterns can be worked out systematically by applying these ideas in sequence. Suppose, for example, that proton H_a was interacting with two inequivalent protons, H_b and H_c, on neighboring groups. The resonance would be split into one doublet separated by J_{ab} and a second doublet separated by J_{ac} to produce a quartet of peaks with two different sets of spacings, in contrast to the three peaks observed when a proton interacts with a pair of equivalent protons.

Solution
There are two sets of peaks, a triplet at $\delta = 1.07$ and a quartet at $\delta = 2.42$, that arise from two sets of equivalent protons. The chemical shift of the triplet is in a region that suggests it is an alkyl group and the triplet splitting pattern suggests that it is adjacent to a methylene (CH_2) group. The quartet arises from a functional group adjacent to a methyl group and the chemical shift suggests that it is located adjacent to a carbonyl functional group. Subtracting CO from the molecular formula leaves C_4H_{10} for the rest of the molecule. The combination of a triplet and a quartet is characteristic of an ethyl group ($-C_2H_5$) so it appears that there are two equivalent ethyl groups bonded to the carbonyl carbon. The molecule is diethyl ketone.

20.5 ELECTRONIC SPECTROSCOPY AND EXCITED STATE RELAXATION PROCESSES

Electronic spectroscopy is used to probe the electronic energy level structures of molecules and to follow the fates of electronically excited states created by absorption or by other means, such as electron or ion impact, energy or electron transfer or from energy released in chemical reactions, for example. The energy level separations between electronic states are relatively large (a few eV) so transitions between these states occur as a result of absorption or emission of electromagnetic radiation in the ultraviolet and visible regions of the spectrum. Electronic absorption spectroscopy is also widely used as an analytical method to measure the concentrations of species in solution because the measurements are easily quantified. Electronic emission spectroscopy, fluorescence in particular, is a very sensitive analytical technique (detection limit − 1 molecule), used for biological imaging, and to follow the dynamics of energy and electron transfer processes on timescales as short as a few femtoseconds (1 fs = 10^{-15} s).

Excited electronic states relax by a number of processes that are illustrated schematically in Figure 20.28. They may return to the ground electronic state by emitting fluorescence or phosphorescence, or through several nonradiative processes that dissipate the energy as heat. Energy and electron transfer to neighboring molecules are important processes that play central roles in a variety of natural phenomena and underlie a number of important technologies; examples of the former include photosynthesis (see Section 20.7) and examples of the latter include artificial photosynthesis (see Section 17.6 and the accompanying *Connection to Energy*). Understanding the factors that govern the rates of radiative and nonradiative processes is essential for the design and operation of lasers (see Section 20.8). Photoexcitation may also lead to photochemical reactions such as *cis–trans* isomerization, the first step in the vision process.

Molecular orbital (MO) theory, introduced in Chapter 6, provides the framework for understanding the electronic states of molecules and the nature of the transitions among them. We restrict our discussion in this section to the spectroscopy and photochemistry of organic molecules, having introduced you to the spectroscopy of inorganic compounds in Chapter 8. Our goal is to help you develop your intuition for the energies, length scales, and time scales of these important physical and chemical processes.

We begin by considering the molecular orbitals, energy level diagrams, and electronic transitions of a series of molecules that have been chosen to illustrate, in a systematic way, the characteristic features of organic **chromophores,** the functional groups in molecules that absorb light. We restrict our discussion to molecules with closed shells (no unpaired electrons) and begin by considering only those excited states in which the spins of the electrons are paired. These states are called

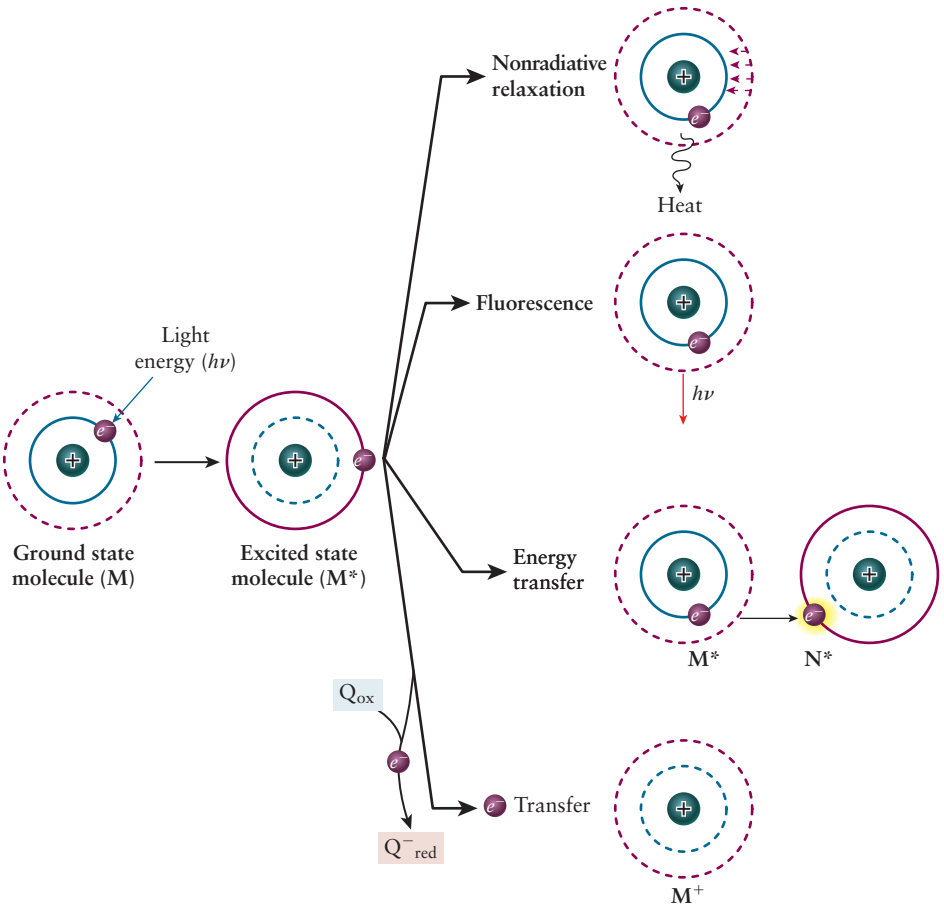

FIGURE 20.28 Radiative and nonradiative photophysical processes, and energy and electron transfer from electronically excited states to nearby molecules.

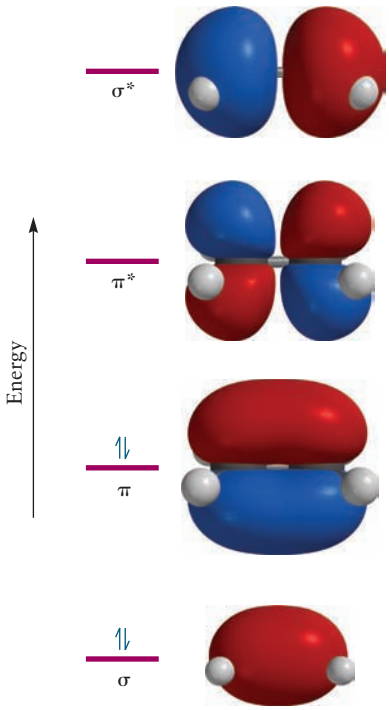

FIGURE 20.29 π molecular orbitals and energy level diagram for ethylene. The bonding and antibonding orbitals constructed from the carbon 2*s* orbitals are not shown.

singlet states, for reasons provided later in our discussion of excited state relaxation processes. We use the combined LCAO and VB method introduced in Section 6.12, in which the σ framework is constructed by overlap of C and O sp^2 hybrid orbitals and H 1*s* orbitals using the VB approach and the π bonds are constructed using the LCAO MO method. We follow the procedures developed in Section 6.5 and label the orbitals using the same notation that we use for diatomic molecules, even though these molecules are not cylindrically symmetric; we have σ, σ^*, π, π^*, and n (nonbonding) orbitals to use in our discussion. The nonbonding orbitals are occupied by lone pairs on **heteroatoms** such as oxygen, nitrogen, and sulfur, which play important roles in spectroscopy and photochemistry.

The Lewis dot model for ethylene shows that it has 12 valence electrons, 8 of which are in the four localized C—H σ orbitals, the remaining four being associated with the C=C bond. The C—H σ orbitals lie too low in energy to play any significant role in the spectroscopy and photochemistry of ethylene so we consider only those MOs associated with the C=C bond. These include the σ and σ^* and the π and π^* orbitals that are derived from the carbon $2p_z$ and $2p_x$ (or $2p_y$) orbitals, respectively, as shown in Figure 20.29. The energy level separation (splitting) between the σ and σ^* orbitals is greater than that between the π and π^* orbitals because "end-to-end" overlap of the p_z orbitals to form σ bonds is greater than the "side-to-side" overlap of the p_x (or p_y) orbitals that form π bonds, as discussed in Section 6.5. The lowest energy configuration is $(\sigma)^2(\pi)^2$, in the notation used by spectroscopists and photochemists, a shorthand version of the notation we introduced in Section 6.5. Ethylene has a double bond, with two electrons occupying each of the two bonding MOs. The **highest occupied molecular orbital (HOMO)** is the bonding π orbital, and the **lowest unoccupied molecular orbital (LUMO)** is the antibonding π^* orbital. These **frontier orbitals** are of central importance in spectroscopy, photochemistry, and in many organic chemical reaction mechanisms because changes in the occupancy of these orbitals affect bond order and reactivity.

The lowest energy electronic transition between the singlet states of ethylene is one in which an electron in the bonding π orbital (the HOMO) is excited to the antibonding π^* orbital (the LUMO), giving an excited-state configuration written as $(\sigma)^2(\pi)^1(\pi^*)^1$. Excited state configurations are often labeled using only the names of the partially filled orbitals; the lowest-energy excited state of ethylene is called a π, π^* state, for example. The electronic transitions are identified in the same way, by naming only those orbitals whose occupancy changes as a result of the transition. This lowest-energy transition in ethylene, therefore, is called a $\pi \longrightarrow \pi^*$ transition and it is responsible for an absorption band in the vacuum ultraviolet at 162 nm. The simple MO diagram shown for ethylene suggests the possibility of other transitions at higher energies, for example a $\sigma \longrightarrow \sigma^*$ transition at very high energies, some of which have been observed experimentally.

Chemists are most often concerned with determining the spectroscopic properties of molecules in solution so they have modified the Beer–Lambert law, which was introduced in Section 20.1, to convert number densities to molarity. They have also chosen to use common logarithms instead of natural logarithms. The integrated form of **Beer's law** is

$$I = I_0 10^{-\varepsilon c \ell}$$

by analogy to the Beer–Lambert law, but it is usually expressed in its logarithmic form as

$$A = \log\left(\frac{I_0}{I}\right) = \varepsilon c \ell \qquad [20.16]$$

where A is the **absorbance** (sometimes called the optical density), c is the concentration in mol L^{-1}, ε is the **molar absorption coefficient** (molar extinction coefficient in some older textbooks) expressed in units M^{-1} cm^{-1}, and ℓ is the path length in cm, as before. Chemists chose these units for convenience because they generally measure concentrations in mol L^{-1} and because 1 cm path lengths are convenient for handling solutions. The intensity of both the incident and the transmitted light is measured experimentally and the results reported either in absorbance or transmittance units, which are related as follows

$$A = \log\left(\frac{I_0}{I}\right) = -\log\left(\frac{I}{I_0}\right) = -\log T$$

where $T = (I/I_0)$ is the transmittance. The transmittance is often converted to percent transmission by multiplying T by 100, as shown in Figure 20.9, for example. Ultraviolet and visible absorption spectra generally graph absorbance as a function of wavelength or wave number, whereas infrared and microwave spectra generally graph percent transmission as a function of wave number.

Molar absorption coefficients can be related to absorption cross sections by comparing the integrated form of Beer's law to a form of the Beer-Lambert law introduced in Section 20.1 as follows, where N_A is Avogadro's number.

$$I/I_0 = 10^{-\varepsilon c \ell} = e^{-(N_A/V)\sigma\ell}$$

Taking natural logarithms and rearranging gives

$$(\ln 10)(-\varepsilon c \ell) = -(N_A/V)\sigma$$

which can be solved to get

$$\varepsilon = (N_A/V)\sigma/2.303c = N_A\sigma/(2.303)(10^3) = 2.6 \times 10^{20}\sigma$$

where the factor of 10^3 arises because the cross section σ and the path length ℓ have units of cm^2 and cm, respectively, and molarity is expressed in mol L^{-1}. Only about 1/3 of the molecules in solution have favorable orientations to absorb radiation from an unpolarized source, so it is customary to make the approximation that

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

$\varepsilon \approx 10^{20}\sigma$. This is a very useful result that allows us to calculate absorption cross sections from extinction coefficients measured experimentally and to get a feel for the "size" of a molecule that is effective in absorbing photons. Molar absorption coefficients for strongly absorbing organic molecules are as large as 10^5 M^{-1} cm^{-1}, from which we calculate a cross section of about 10 $Å^2$, which is roughly the geometric cross section of an organic chromophore such as benzene. Electronic transitions with molar absorption coefficients of the order of 10^2 are considered to be "weak" with the effective absorption cross section being a thousand times smaller than the geometric cross section.

The molar absorption coefficient for the strongest absorption band in ethylene, which appears at $\lambda_{max} = 163$ nm is $= 1.5 \times 10^4$ L mol^{-1} cm^{-1}; this value is characteristic of strong $\pi \longrightarrow \pi^*$ transitions. To give you a feeling for what strong absorption means let's calculate what fraction of a beam of 163 nm radiation is absorbed by ethylene gas contained in a 1 cm path length cell at 0.001 atm and 300 K. Converting to molarity and using Beer's law we find that $A = 0.61$, and that this dilute, but strongly absorbing, sample transmits only about 25% of the incident radiation.

Let's continue to focus on the π electrons and examine the energy level diagrams and transitions between singlet states in some conjugated polyenes and aromatic hydrocarbons to which you were introduced in Sections 7.3 and 7.4. Conjugated polyenes are hydrocarbon chains with alternating single and double bonds. Resonance structures suggest, and simple MO theory confirms, that the π electrons in these systems are delocalized over the entire molecule. Figure 20.30 shows the four π orbitals of *trans*-1,3-butadiene, the simplest conjugated polyene, which are

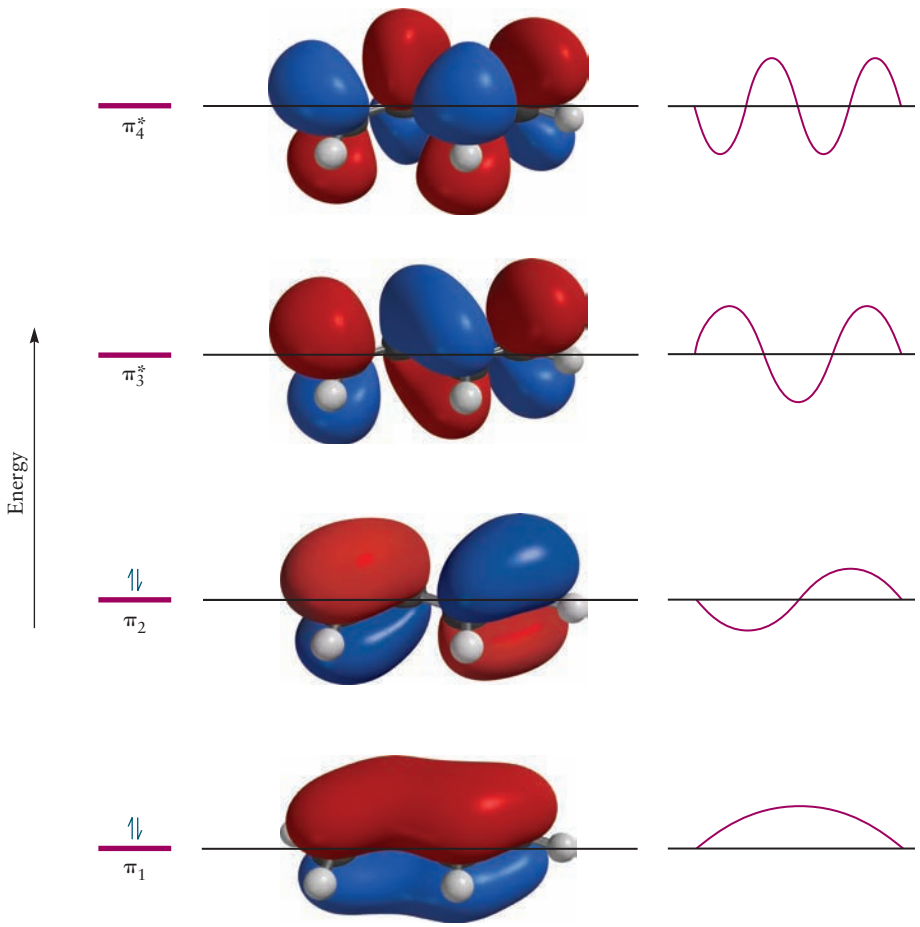

FIGURE 20.30 π molecular orbitals and energy level diagram for 1,3-butadiene.

constructed from the four carbon $2p_z$ orbitals. A ball-and-stick model for the molecule is also shown in the figure.

The orbitals of linear conjugated polyenes resemble the particle-in-a-box wave functions, as shown in the figure, and that model provides considerable insight into the electronic structures of these molecules. The energy of the levels increases with the number of nodes in the corresponding wave functions. The model can be used to estimate the energies of the transitions in butadiene and longer polyenes by choosing a value for L, the length of the box, filling the orbitals using an aufbau principle, and calculating the energy difference between the HOMO and the LUMO. The four π electrons in *trans*-1,3-butadiene occupy the two bonding π orbitals giving the configuration $(\pi_1)^2(\pi_2)^2$. The lowest energy absorption band arising from the $\pi_2 \longrightarrow \pi_3^*$ transition appears at 217 nm. Transitions at higher energies are possible, a $\pi_2 \longrightarrow \pi_4^*$ transition from the HOMO to the higher-energy antibonding orbital shown in the figure, for example. A simple formula was derived in the Chapter 4 *Cumulative Exercise* to predict the wavelengths of the lowest energy absorption bands in a series of conjugated linear polyenes. Without reproducing the derivation in detail, the model assumes: 1) that the length of the box is equal to the number of carbon atoms in the chain times the average of the C—C single and C=C double bond lengths; and 2) that n for the HOMO is equal to N/2, where N is the number of π electrons (aufbau and Pauli principles). The energy of the HOMO–LUMO transition is given approximately by $\Delta\varepsilon \approx h^2/(8md^2N)$ where d is the average of the carbon–carbon single and double bond lengths. This simple model accounts for the increase in the wavelength of longest absorption observed for the series of conjugated linear polyenes shown in Table 20.5, as well as for the molecules vitamin A and β-carotene included in the Chapter 4 *Cumulative Exercise*.

The longest wavelength absorption bands of conjugated polyenes with eight or more double bonds appear in the visible region of the spectrum and solutions of these compounds are colored. The color we perceive is related to the absorption spectrum of the material, but only indirectly. What we see is the light transmitted through or reflected from the material, not the light absorbed. So, the color perceived is **complementary** to the color most strongly absorbed by the molecule, as shown in Figure 20.31. The color wheel shows the three primary colors, red, green, and blue (RGB), and their complementary colors, cyan, magenta, and yellow (CMY). The RGB system is used in computer displays and in television, and the CMYK system (K is black) is used in color printing, like that in this textbook. Figure 20.31b shows the spectrum of the transmitted light and the perceived color (blue) for indigo, which absorbs in the yellow–orange region, and Figure 20.31c shows the spectrum of the transmitted light and the perceived color for carotene that absorbs in the blue–violet region of the spectrum. Indigo is used to dye blue jeans; beta-carotene is responsible for the orange color of carrots, the colors of some processed foods, and the yellow and orange in certain bird feathers. The absorption spectra of these two compounds are shown in Figure 20.32.

TABLE 20.5

Absorption of Light by Molecules with Conjugated π Electron Systems

EXAMPLE 20.10

Suppose you set out to design a new green dye. Over what range of wavelengths would you want your trial compound to absorb light?

Solution

A good green dye must transmit green light and absorb all of the other colors to a significant extent so you should select a dye that absorbs in the violet–blue *and* orange–red regions of the spectrum (see Fig. 20.31).

The naturally occurring substance chlorophyll, which is responsible for the green colors of grass and leaves, absorbs light over just these wavelength ranges, converting solar energy to chemical energy stored as carbohydrates in plants. Chlorophyll is also used commercially as a green dye.

Related Problems: 37, 38

Aromatic hydrocarbons have alternating single and double bonds like the linear polyenes but they are arranged in two dimensions with the π electrons delocalized over the molecular planes. Let's consider benzene as our exemplar for discussing $\pi \longrightarrow \pi^*$ transitions in aromatic hydrocarbons. The MOs and energy level diagram for benzene are shown in Figure 20.33. The energy level diagram for benzene is different from those of the linear conjugated polyenes; it has a pair of degenerate π orbitals and a pair of degenerate π^* orbitals because of its highly symmetrical structure. Two of the six π electrons occupy the lowest-energy orbital, while the other four π electrons doubly occupy each of the degenerate higher-lying bonding MOs. The electron configuration of the ground state is $(\pi_1)^2(\pi_2)^2(\pi_3)^2$. The stron-

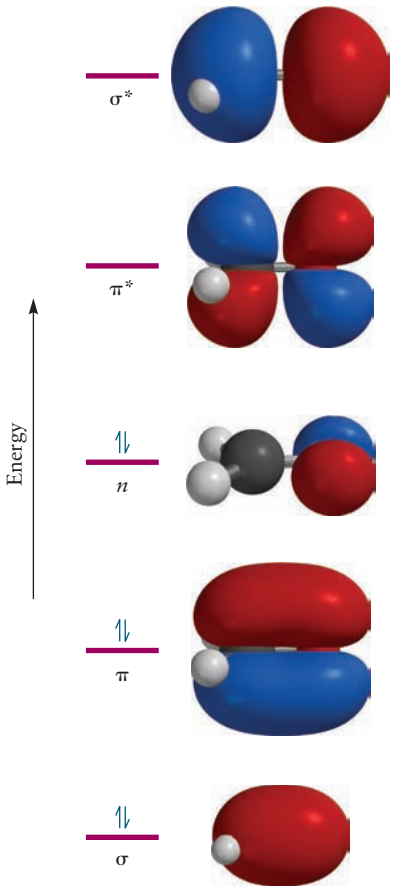

FIGURE 20.34 Approximate molecular orbitals and energy level diagram for formaldehyde.

gest UV absorption band for benzene ($\lambda_{max} \approx 180$ nm, $\varepsilon_{max} = 6 \times 10^4$) results from a $\pi \longrightarrow \pi^*$ transition in which one electron is excited from the HOMO to the LUMO. (There are absorption bands that appear at lower energies [260 nm, for example], which arise from mixing of the sets of degenerate orbitals, but a discussion of that issue is beyond the scope of this textbook.) The electronic states of benzene and related aromatic compounds can also be understood qualitatively using the 2-D particle-in-a-box models discussed in Section 4.7, or a "particle-on-a-ring" model that is closely related to the rigid rotor model introduced in Section 20.3. The spectra of condensed aromatic hydrocarbons (those with joined rings) show shifts in the onset of absorbance to longer wavelengths as the number of rings and the size of the "box" increases, by analogy to the behavior observed for the linear polyenes.

We now consider the electronic structure and spectra of formaldehyde, a prototype for molecules in which transitions involving nonbonding electrons are important. The Lewis dot model for formaldehyde shows 12 valence electrons, two C—H bonding pairs that we do not consider, for the same reasons given for ethylene, two C=O bonding pairs and two lone pairs on the oxygen atom. One of the oxygen lone pairs resides in the O 2*s* orbital, which is at sufficiently low energy that we do not consider it when forming the MOs that are relevant to the spectroscopy and photochemistry of formaldehyde. The second lone pair on the oxygen atom resides in an O $2p_y$ orbital that is oriented perpendicular to both the internuclear axis and the O $2p_z$ orbital that we use to form π orbitals. The frontier orbitals and associated energy level diagram for formaldehyde are shown in Figure 20.34.

The MOs shown are labeled using the same notation we introduced earlier in this chapter for the unsaturated hydrocarbons. They comprise a bonding and antibonding pair of σ orbitals, a bonding and antibonding pair of π orbitals, and a nonbonding n orbital localized on the oxygen atom. The energies of the bonding and antibonding pairs of orbitals of each type are symmetrically arranged about the energy of the nonbonding orbital in our simplified picture. The ground state electron configuration, considering only these frontier orbitals, is $(\sigma)^2(\pi)^2(n)^2$, and there is now a greater variety in the types of possible transitions than for the other molecules we have discussed. The HOMO of formaldehyde is the nonbonding n orbital, and the LUMO is the π^* orbital, so the lowest energy transition is now an $n \longrightarrow \pi^*$ transition. The energy difference between the n and the π^* orbitals is not very large, however, so that $n \longrightarrow \pi^*$ and $\pi \longrightarrow \pi^*$ transitions are both important in the spectroscopy and photochemistry of formaldehyde. These transitions lead to $(\sigma)^2(\pi)^2(n)^1(\pi^*)^1$ and $(\sigma)^2(\pi)^1(n)^2(\pi^*)^1$ excited state configurations, respectively. The excited state configuration that results from an $n \longrightarrow \pi^*$ transition is labeled simply the n, π^* configuration and that resulting from an $\pi \longrightarrow \pi^*$ transition is labeled the π, π^* configuration.

Photoelectron spectroscopy, discussed for atoms in Chapter 5 and for diatomic molecules in Chapter 6, provides important clues about the nature of these molecular orbitals; the photoelectron spectrum of formaldehyde is shown in Figure 20.35. The three sets of peaks observed arise from photoionization from three distinct molecular orbitals. The **vibrational fine structure** observed as a series of closely spaced lines in each band allows us to identify the orbitals involved and to confirm the validity of our energy level diagram. Energy in excess of the minimum necessary to ionize a molecule can excite vibrations in the positive ion left behind, and the nature of those excitations can be used to identify the orbital from which the electron was removed. Removing an electron from bonding MOs weakens bonds and lowers the vibrational frequencies of the ion from those in the parent molecule. Removing an electron from an antibonding orbital strengthens bonds and increases vibrational frequencies. Photoemission from nonbonding orbitals does not affect bonding very much; very little vibrational fine structure is observed and the frequencies are very close to those in the parent molecule. These general characteristics are summarized in the *Connection to Instrumental Analysis* in Chapter 6. Let's use this approach to interpret the photoelectron spectrum of formaldehyde and

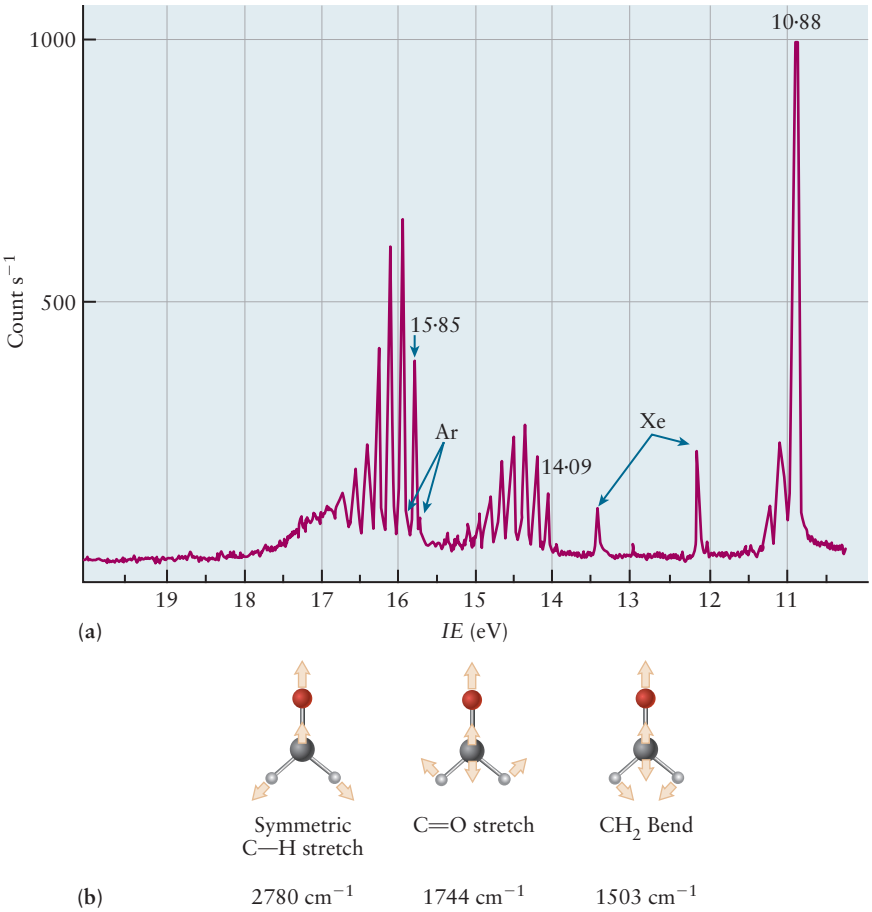

FIGURE 20.35 (a) Photoelectron spectrum of formaldehyde. The lines labeled Ar and Xe are due to photoemission from residual rare gases in the sample chamber. (b) Formaldehyde vibrational modes and frequencies in the ground electronic state. D. W. Turner, C. Baker, A. D. Baker, C. R. Brundle. Molecular Photoelectron Spectroscopy. John Wiley & Sons, London 1970 p. 141.

identify the orbitals associated with each set of bands. The peak that appears at 10.88 eV arises from electrons that have the lowest binding energies and it is assigned, therefore, to the HOMO. There is very little vibrational fine structure, with most of the intensity appearing in the 10.88 eV peak and only one peak associated with each of the three vibrational modes shown in the figure inset: C—H stretching, C=O stretching, and H—C—H bending vibrations. The vibrational frequencies observed agree closely with those of formaldehyde in its ground electronic state and allow us to confirm our assignment of the HOMO as the nonbonding orbital. Let's examine the set of peaks between 14 and 15 eV. The frequency observed in the vibrational progression corresponds to multiple excitations of a single mode with a frequency of about 1200 cm^{-1} and deuterium isotope substitution has no effect on the frequency observed. We assign this mode to the C=O stretch in the ion and identify the orbital as the bonding π orbital on the basis of the decrease in vibrational frequency (the ground-state frequency is 1744 cm^{-1}) and the insensitivity to isotopic substitution. The lower vibrational frequency is consistent with a reduction in the CO bond order that results from the removal of an electron from a bonding orbital. The vibrational frequency measured in the progression around 16 eV is lower than that in the ground state of formaldehyde, and it is further reduced on deuterium substitution by almost exactly $1/\sqrt{2}$ which suggests that the mode involves one of the bonding CH σ orbitals.

The family of excitations we have discussed thus far is used to describe the spectroscopy and photochemistry of many different organic molecules because the electronic properties of these chromophores, just like the other properties of functional groups, are largely independent of the nature of the groups to which they are bonded in a particular molecule. C=C double bonds, conjugated C=C double bonds, the carbonyl group (C≡O), aromatic functional groups like the phenyl group (and larger aromatic hydrocarbons), and heteroaromatic functional groups

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

like pyridine (and larger nitrogen-containing aromatics) are among the most important chromophores in organic chemistry and in biology. Structures for a number of representative chromophores are illustrated in Figure 20.36.

The various kinds of transitions we have discussed have characteristic features that allow us to classify them broadly, but the details also depend, to some extent, on the nature of the individual chromophores. As a general rule $\pi \longrightarrow \pi^*$ transitions are the strongest with molar absorption coefficients (ε_{max}) for the most intense peaks (λ_{max}) in the range 10^3–10^5 M^{-1} cm^{-1}. The strength of these absorptions arises largely because the electric field of the radiation is especially effective at inducing motion along a line. $\pi \longrightarrow \pi^*$ transitions are responsible for the colors of dyes, the color of carrots, and for the absorption of light by the visual pigment rhodopsin, for example. These transitions are excited by electromagnetic radiation with electric fields oriented parallel to the molecular planes. $n \longrightarrow \pi^*$ transitions, in contrast, are generally weaker than $\pi \longrightarrow \pi^*$ transitions with ε_{max} in the range 10–10^3 M^{-1} cm^{-1}. The $n \longrightarrow \pi^*$ transition is weaker than the $\pi \longrightarrow \pi^*$ transition because the nonbonding orbital is oriented perpendicular to the antibonding π^* orbital. The force that must be applied to induce this motion classically is a torque, as opposed to the linear force required to excite the $\pi \longrightarrow \pi^*$ transition. The electric field of the radiation is much more effective at providing a linear force than a torque, accounting for the relative strengths of the two transitions using a simple classical picture. These transitions are excited by electromagnetic radiation with electric field components oriented perpendicular to the molecular planes. $n \longrightarrow \pi^*$ transitions are an important class of transitions for molecules with heteroatoms like O, N, and S that have nonbonding lone pairs. They are central to the spectroscopy and photochemistry of molecules containing carbonyl and heteroaromatic chromophores, for example, like those found in amino acids and nucleic ac-

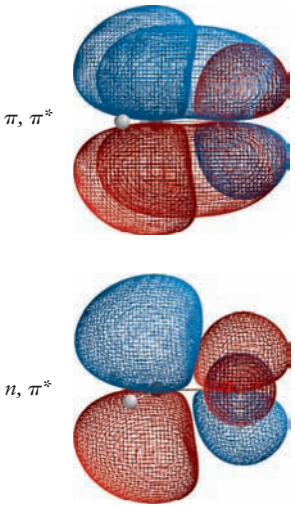
ids. Table 20.6 shows λ_{max} and ε_{max} for a few characteristic transitions in a number of common chromophores, the structures of which are shown in Figure 20.36.



Excited State Relaxation Processes

We restricted our discussion in the previous section to singlet states, in order to introduce you to the basic concepts and language of electronic spectroscopy. We now consider the triplet states of molecules and discuss the physical processes that follow excitation into singlet states. Electrons in excited configurations, unlike the ground-state configuration, may have their spins oriented either parallel or antiparallel (paired) to one another because they occupy different MOs. We used the terms *states* and *configurations* interchangeably in our discussion of singlet states because we restricted that discussion to states of the same total spin angular momentum; we must now make the distinction between those terms clear. A configuration is just a listing of the occupied orbitals with no specification of the electron spins; one of the excited state configurations of formaldehyde is n, π^*, for example. A state is specified not only by the occupancy of the orbitals but also by the spins of the electrons. There are two states of formaldehyde derived from the n, π^* configuration, a singlet state that we label $^1(n, \pi^*)$and a triplet state that we label $^3(n, \pi^*)$ on the basis of the degeneracy of their total spin angular momentum levels. The total spin angular momentum for a system of two electrons is calculated as follows. $S_z = s_z(1) + s_z(2)$ where S_z is the z component of the total spin angular momentum and $s_z(1)$ and $s_z(2)$ are the z components of the individual electron spin angular momenta. $S_z = s_z(1) + s_z(2) = +\frac{1}{2} - \frac{1}{2} = 0$ if the spins are paired and the degeneracy of the level is given by $g(S) = 2S + 1 = 1$ for this state, which is called a singlet state. In contrast, the z-components of the individual spin angular momenta can combine in three ways for the configuration with parallel spins:

$$\begin{aligned} S_z &= +\tfrac{1}{2} + \tfrac{1}{2} = +1 \\ &= +\tfrac{1}{2} - \tfrac{1}{2} = \ \ 0 \\ &= -\tfrac{1}{2} - \tfrac{1}{2} = -1 \end{aligned}$$

These are the three components of a **triplet state** with $S = 1$, which exist for both atoms and molecules. The ground electronic state of the carbon atom is a triplet

Overlap between n and π^* orbitals and π and π^* orbitals of formaldehyde.

state, as is the ground electronic state of O_2, for example. (see Figs. 5.16 and 6.17). The existence of triplet states in organic molecules had been the subject of speculation for many years. The association of paramagnetism (see Fig. 6.17) with a very long-lived emission was perhaps the most important piece of evidence. Definitive characterization of these states was provided by the results of two different kinds of experiments that were reported in 1958: (1) *transient* triplet-triplet absorption spectra of triplet states produced by microsecond flashlamp excitation, and (2) an electron spin resonance experiment, analogous to an NMR experiment, in which microwave radiation induces transitions between the triplet sublevels split by a magnetic field.

The singlet and triplet energy levels of formaldehyde are shown in Figure 20.37. It is customary to place the singlet energy levels on the left side of energy level diagrams of this type and the triplet energy levels on the right. This diagram illustrates a number of important general features of the energy levels involved. First note that there is no triplet state with the same electronic configuration as the ground electronic state because of the Pauli principle. Second, the energies of the triplet states are always lower than the energies of singlet states of the same configuration, a fact also explained by the Pauli principle, using the same argument as that underlying Hund's rules (see Section 5.3). Electrons with the same spin are, on average, farther apart than electrons with paired spins, so the Coulomb repulsion between electrons in triplet states is lower than that in singlet states. Finally, energy level separations between states of the same configuration are greater for π, π^* configurations than for n, π^* configurations because the overlap between n and π^* orbitals is much smaller than the overlap between π and π^* orbitals as shown schematically in the adjacent figure. Table 20.7 shows the singlet-triplet splitting for a number of representative molecules that confirms this general rule.

Having introduced you to the characteristic absorption bands and extinction coefficients of some representative chromophores, as well as the kinds of single-triplet energy level separations found in these molecules, we now discuss the nature of the various kinds of transitions that occur between these states. It is customary to use potential energy diagrams, like that shown in Figure 20.38, to illustrate these **photophysical** processes that return excited molecules to their ground states. Intermolecular energy and electron transfer processes as illustrated in Figure 20.28, and **photochemical** processes are not considered. There is a great deal of information contained in Figure 20.38 that you should take time to understand.

The figure shows the potential energy functions and energy levels for the ground state and the lowest energy singlet and triplet states, with vibrational levels represented by the horizontal lines. Although we show only the lowest-energy excited

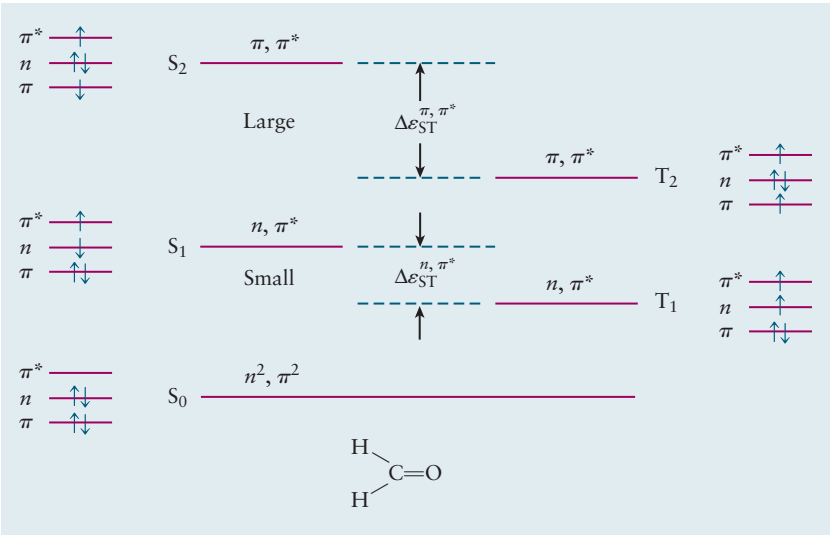

FIGURE 20.37 Energy level diagram for formaldehyde. The singlet energy levels are shown on the left and the triplet energy levels are shown on the right. The singlet-triplet splitting energy ΔE_{ST} is greater for π, π^* states than for n, π^* states. Nicholas J. Turro, V. Ramamurthy, and J. C. Scaiano. states in this figure, molecules have a series of singlet and triplet states that are identified and numbered in order of increasing energy as follows: S_0, S_1, S_2 . . . and T_1, T_2, T_3 . . . Each triplet state lies lower in energy than the singlet state of the same configuration, just as in formaldehyde. There is a convention for labeling various kinds of transitions in diagrams of this type. Solid lines represent **radiative** transitions (in which light is absorbed or emitted) between states of the same spin whereas dashed lines represent radiative transitions between states of different spin. Wavy lines represent **nonradiative** transitions in which no light is emitted. We do not use wavy or dashed lines when representing these transitions as chemical equations, preferring instead to name the transitions explicitly. Absorption is referred to either as $S_i \longrightarrow S_f$ or $T_i \longrightarrow T_f$ absorption where the subscripts identify the particular states involved. Emission resulting from transitions between states of the same spin

is called **fluorescence** and is referred to as $S_i \longrightarrow S_f$ or $T_i \longrightarrow T_f$ fluorescence whereas emission resulting from transitions between states of different spin is called **phosphorescence** and is referred to as $T_1 \longrightarrow S_0$ phosphorescence, for example. The nonradiative process that causes transitions between states of the same spin is called **internal conversion** whereas the nonradiative process that causes transitions between different spin states is called **intersystem crossing**. Nonradiative transitions between specific states are referred to using the same notation as that for radiative transitions. Finally, excited vibrational levels within a given electronic state return to a thermally equilibrated distribution among the lower vibrational levels of that state by dissipating the energy as heat through collisions with solvent molecules in condensed phases, a process generally referred to as vibrational relaxation.

The total angular momentum of the system is always conserved in both classes of transitions; it includes the spin and orbital angular momenta of the electrons for nonradiative transitions and also the spin angular momentum of the photon for radiative transition. In both cases a change in the total electron spin angular momentum requires coupling between spin and orbital angular momenta, which can occur in several different ways. A detailed discussion of spin–orbital coupling is beyond the scope of this textbook but the brief discussion of spin–orbit coupling in nuclei presented in Section 19.8 provides a simple physical model that should help you visualize the mechanism. Transitions between states of different spin occur with a lower probability that those between states of the same spin; the former are commonly called "forbidden" and the latter "allowed". The intensities of spin-forbidden transitions depend upon the degree of spin–orbit coupling in molecules; spin–orbit coupling is weak in atoms with low atomic numbers, but increases with increasing Z. The intensities of "forbidden" transitions are greater in molecules that contain heavy atoms such as chlorine, bromine, and sulfur, for example, compared with molecules that contain only C, H, N, and O because of the increased spin–orbit coupling in those heavy atoms. Substituting heavy atoms for one or more hydrogen atoms increases the intensities of "forbidden" transitions significantly.

Table 20.8 lists representative values of the molar absorption coefficients for "allowed" and "forbidden" singlet–singlet and singlet–triplet transitions. Notice that the extinction coefficients for the singlet–triplet transitions are much smaller that those of the singlet–singlet transitions because a change in spin state is required. The splitting between the singlet and triplet π, π^* states is greater than for the n, π^* states, as noted previously. Finally there is a range of extinction coeffi-

cients associated with each specific class of transition, for example the singlet–singlet $\pi \longrightarrow \pi^*$ transitions. This range arises because of symmetry considerations; the symmetries of the initial and final wave functions and that of the electric field vector associated with the transition, when multiplied together, must be totally symmetric for a transition to be fully allowed. A detailed treatment is beyond the scope of this textbook but we can provide a simple illustration using inversion symmetry, to which you were introduced in Chapter 6. Vectors are antisymmetric with respect to inversion; $x \longrightarrow -x$, for example. The symmetry requirement for atoms and molecules that have centers of inversion is simply that the initial and final states must have different symmetries with respect to inversion. Allowed transitions for atoms occur between *s* and *p* states, for example, and those in molecules occur between *g* and *u* states. Forbidden transitions between states of the same spin show some intensity because coupling between the electronic and vibrational motions of molecules relaxes this symmetry selection rule.

Let's follow what happens after excitation from the ground vibrational level of the ground electronic state of a diatomic molecule to an excited vibrational level of S_1, for example. We consider here only those unimolecular photophysical processes that return molecules to their ground electronic states, excluding intermolecular charge transfer, energy transfer, or photochemistry. Vibrational relaxation of the initially excited vibrational states to a thermally equilibrated distribution over the vibrational states of S_1 is rapid, occurring on a time scale of picoseconds. The process is often described by photochemists as occurring in two steps: a very fast (0.1 − 10 ps) internal vibrational relaxation followed by a slower (10 ps − 1 ns) rate of intramolecular energy transfer to solvent. These processes are so fast that we need only consider the vibrationally relaxed states of S_1 in our discussion of subsequent photophysical and photochemical processes, a conclusion that has become known as Kasha's rule. The American physical chemist, Michael Kasha, along with his mentor G. N. Lewis, was a pioneer in the fields of molecular photophysics and photochemistry.

Let's examine absorption and fluorescence spectra in a bit more detail before considering the rates of photophysical processes, including those that involve triplet states, which determine that fates of excited states. Figure 20.39 shows potential

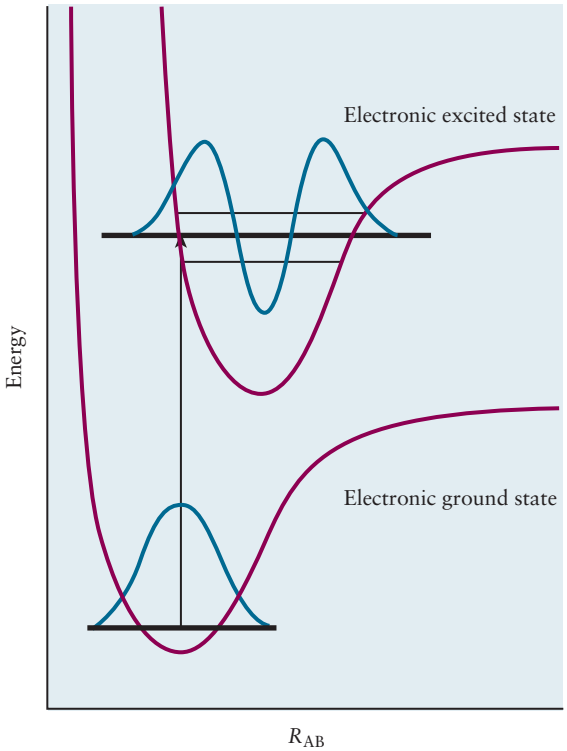

FIGURE 20.39 Illustration of the Franck Condon principle showing that the most probable electronic transition occurs between states at the same internuclear separation, a transition that maximizes the overlap between the vibrational wave functions in the two states.

energy curves for the ground state and an excited state of a diatomic molecule with a few vibrational levels shown for each state. The minimum in the excited state potential energy curve occurs at a greater internuclear separation than the equilibrium bond length of the ground state; this is quite commonly observed because the excited state often results from the transfer of an electron from a bonding orbital to an antibonding orbital, weakening the bond. (We rationalized the correlation between bond strength and bond length in Section 20.3.) The **Franck–Condon principle** asserts that the most probable transition (a vertical transition) is one in which the nuclear geometry does not change, because nuclei move much more slowly than electrons. The black vertical line represents such a transition in which the molecule has been excited from the $v = 0$ level of the ground electronic state to the $v = 2$ level of the excited electronic state in this example. Transitions to the $v = 0$ and $v = 1$ levels of the excited state are also observed but are much weaker. The absorption spectrum that results consists of a series of equally spaced lines separated by the *excited-state* vibrational frequency. The relative intensities of the lines is determined by the overlap of the vibrational wave functions in the ground and excited electronic states; these **Frank–Condon factors** can be estimated by inspection (as in the example illustrated in Figure 20.39) or calculated using the quantum mechanical harmonic oscillator model.

The $S_0 \longrightarrow S_1$ absorption and $S_1 \longrightarrow S_0$ fluorescence spectra of anthracene, shown on the left side of Figure 20.40, illustrate how the Franck–Condon principle explains the shapes of the envelopes of spectral lines and can be used to estimate displacements of excited state potential energy surfaces from that of the ground state. (We discuss the $S_0 \longrightarrow T_1$ absorption and $T_1 \longrightarrow S_0$ phosphorescence spectra later.) Absorption spectra are plotted as dashed blue lines and emission spectra are plotted as solid red lines. A series of bands is observed both in absorption and in fluorescence, due to simultaneous vibrational and electronic transitions. These **vibronic** bands are labeled using the notation (v', v'') where v' is the vibrational quantum number of the lower state and v'' is the vibrational quantum number of the upper state. The shape of the vibrational fine structure envelope observed tells us that the potential energy functions of the ground and excited states are very similar to one another, with only a slight displacement of the minimum in the excited state curve. That conclusion is also supported by the observation that the 0,0 and 0,1 bands are the most intense, both in absorption and in emission, and that the 0,0 bands are virtually superimposed on one another. These spectral features are characteristic of rigid molecules such as the aromatic hydrocarbons.

Comparing the singlet–singlet and singlet–triplet absorption and emission spectra of anthracene reveals large differences in extinction coefficients and emission intensities. We explained the nature of spin-forbidden transitions earlier and the role of spin–orbit coupling in determining the intensities of those transitions; we now explain how the fates of excited electronic states are determined by the relative rates of the processes identified in Figure 20.38. The **quantum yield** of a photophysical (or photochemical) process is defined as the fraction of the number of photons absorbed that produces a particular result; the fluorescence quantum yield, for example, is the ratio of the number of fluorescent photons emitted to the number of photons absorbed. The quantum yield for a particular process can be calculated if the rate constant for that process, and those for all other processes that deplete the population of a state are known. It has been possible for some time to measure these individual rate constants directly using time-resolved spectroscopy. Rate constants for both radiative and nonradiative processes were first estimated historically, however, by measuring fluorescence and phosphorescence quantum yields for chromophores, like those illustrated in Figure 20.36, under different sets of conditions to enhance or suppress different contributions to the overall decay rate. Molecules were studied in solid solutions at 77 K to enhance spectral resolution and to suppress thermally activated processes, for example, and chromophores with different heavy atom substituents were studied to investigate the role of spin–orbit coupling in systematic ways. The results obtained were correlated with the

energy level structures of the molecules to produce an understanding of the factors that determine the rates of these photophysical processes. A detailed discussion is beyond the scope of this textbook but introducing you to a few general principles using the historical approach provides a great deal of insight into the photophysical properties of different classes of molecules that will help you understand and predict the properties of particular molecules of interest.

The fluorescence quantum yield Φ_f is given by

$$\Phi_f = \frac{k_f}{k_f + k_{ic} + k_{isc}}$$

where k_f is the radiative rate constant for fluorescence, k_{ic} is the rate constant for $S_1 \longrightarrow S_0$ internal conversion and k_{isc} is the rate constant for $S_1 \longrightarrow T_1$ intersystem crossing. Large fluorescence quantum yields can result from large radiative rate constants, very inefficient nonradiative relaxation processes, or both. Let's see how the values of the individual rate constants can be estimated from the measured values of fluorescence quantum yields. Radiative rate constants are formally related to absorption cross sections through the Einstein radiation relations (see Section 20.8) and we established an empirical relationship between the magnitudes of absorption cross sections and those of molar absorption coefficients earlier. Connecting these two relationships allows us to estimate radiative rate constants from mo-

lar absorption coefficients using the following empirical equation: $k_f \approx 10^4 \varepsilon$, in which k_f and ε are expressed in their customary units. Radiative rate constants range between 10^9 s^{-1} for strongly allowed transitions with $\varepsilon_{max} \approx 10^5$ M^{-1} cm^{-1} (*p*-terphenyl, 9,10-diphenylanthracene) to 10^5 s^{-1} for weakly allowed transitions with $\varepsilon_{max} \approx 10$ M^{-1} cm^{-1} (acetone), for example. The fluorescence quantum yields of *p*-terphenyl and 9,10-diphenylanthracene are very close to 1, which implies that the sum of the internal conversion and intersystem crossing rates in those molecules is much less than 10^7 s^{-1}. The fluorescence quantum yield for acetone, on the other hand, is about 0.001, which implies that the sum of the rates of the nonradiative processes is larger than 10^8 s^{-1}.

$S_1 \longrightarrow S_0$ internal conversion rates depend upon a number of factors but two general observations are helpful: 1) $k_{ic} < k_f$ for molecule, with rigid frameworks, such as the aromatic hydrocarbons, at low temperatures. Internal conversion competes effectively with fluorescence in molecules that have low-frequency twisting vibrational modes, such as those in *cis*- and *trans*-stilbene (1,2-diphenylethylene) that have fluorescence quantum yields of 0.0 and 0.05, respectively. 2) There is an energy gap law which states that the rates of $S_1 \longrightarrow S_0$ internal conversion decrease exponentially with the difference in energies of the two states, being negligible for benzene and naphthalene, for example, but becoming increasingly important for larger aromatic hydrocarbons such as pentacene. Understanding these general guidelines is useful in separating the relative contributions made by internal conversion and intersystem crossing to the overall nonradiative rate constant. The fluorescence quantum yield for 9,10-diphenylanthracence $\Phi_f \approx 1$ at 77 K, for example, and $k_f \approx 5 \times 10^8$ s^{-1} as estimated from the molar absorption coefficient. We can infer from these data, and the fact that internal conversion is negligible in this molecule, that $k_{isc} < 10^7$ s^{-1}. Benzene, on the other hand, has a fluorescence quantum yield $\Phi_f \approx 0.2$, and a much smaller radiative rate constant ($k_f = 2 \times 10^6$ s^{-1}), from which we infer that the rate constant for intersystem crossing must be significant.

The phosphorescence quantum yield is defined as

$$\Phi_p = \frac{\Phi_{ST} k_p}{k_p + k_{isc}}$$

where Φ_{ST} is the quantum yield for the production of the lowest triplet state, k_p is the radiative rate constant for phosphorescence, and k_{isc} is the rate of $T_1 \longrightarrow S_0$ intersystem crossing. Radiative rates for phosphorescence range between 10^{-2} and 10^2 s^{-1}, as expected from the values of the molar absorption coefficients for spin-forbidden transitions. The quantum yield for the production of T_1 in benzene at 77 K is large, $\Phi_{ST} \approx 0.7$, as inferred earlier, but the phosphorescence quantum yield is much smaller, $\Phi_p \approx 0.2$, due to the small radiative rate constant for phosphorescence ($k_p \approx 10^{-1}$). There is a rule, analogous to the set of guidelines given earlier for internal conversion, that allows us to estimate the relative rates of intersystem crossing. El-Sayed's rule, named after the Egyptian-born American physical chemist Mostafa El-Sayed, states that the rates of intersystem crossing between singlet and triplet states of different orbital configurations are significantly larger than those between states of the same configuration. The phosphorescence quantum yield of the aza-aromatic molecule quinoline, for example, was found to be much larger that that of the parent compound naphthalene. This observation was explained by postulating the existence of a second excited triplet state of n, π^* character located in energy between the singlet and triplet π, π^* states. The enhanced intersystem crossing was attributed to the greater efficiency of $S_1(\pi, \pi^*) \longrightarrow T_2(n, \pi^*)$ process compared with the $S_1(\pi, \pi^*) \longrightarrow T_1(\pi, \pi^*)$ process. The rule has been interpreted as arising from weak to non-existent spin–orbit coupling between states of the same orbital configuration and its general validity has been confirmed experimentally. Differences in the rates of the "allowed" and "forbidden" intersystem crossing processes can be as large as 10^3. Table 20.9 lists radiative rate constants and quantum yields

TABLE 20.9

Photophysical Properties of Some Representative Molecules

Compound	S_1	ε_{max}	k_f	Φ_{ST}	T_1	k_p	Φ_f	Φ_p
Benzene	π, π^*	250	2×10^6	0.7	π, π^*	0.1	0.2	0.2
Naphthalene	π, π^*	270	2×10^6	0.7	π, π^*	0.1	0.2	0.05
Bromonaphthalene	π, π^*	300	10^6	1	π, π^*	30	≈0	0.3
Anthracene	π, π^*	8,500	5×10^7	0.3	π, π^*	0.5	0.7	
9,10-diphenylanthracene	π, π^*	12,600	5×10^8	≈0	π, π^*	0	1	≈0
p-terphenyl	π, π^*	36,000	10^9	≈0	π, π^*	0	0.9	≈0
Acetone	n, π^*	20	10^5	1	n, π^*	100	:0	0.3
Benzophenone	n, π^*	200	10^6	1	n, π^*	100	:0	0.9

Units for ε_{max} are $M^{-1}cm^{-1}$, radiative rate constants are given in s^{-1}, and quantum yields are dimensionless.

Nicholas J. Turro, V. Ramamurthy, and J. C. Scaiano. Principles of Modern Photochemistry, University Science Books, Sausalito 2009

measured at 77 K for a number of molecules that were chosen to illustrate patterns in photophysical properties.

Benzene, naphthalene, and anthracene are condensed aromatic hydrocarbons with different "lengths" but similar "widths." The relevant states are all π, π^* states; benzene and naphthalene absorb only weakly but anthracene has a large molar absorption coefficient. The transitions in all three cases are allowed by the spin selection rule but those of benzene and naphthalene are "weak" as a result of symmetry considerations. The radiative rate constants are proportional to the molar absorption coefficients, as expected, and the intersystem crossing rates to T_1 are significant for all three molecules. Phosphorescence quantum yields are low, however, as a result of the small values of the radiative rate constants for these spin-forbidden transitions. Substituting bromine for hydrogen in naphthalene changes the photophysics dramatically. The molar absorption coefficient remains about the same, the quantum yield for intersystem crossing increases somewhat, but the radiative rate constant for phosphorescence increases by a factor of about 300, resulting in a phosphorescence quantum yield of 0.3. Substitution of the heavy atom bromine significantly increases the extent of spin–orbit coupling, relaxing the spin selection rule, and increasing the radiative rate constant proportionally. This **heavy atom effect** completely changes the nature of the emission, fluorescence dominating in naphthalene and phosphorescence dominating in bromonaphthalene. *p*-terphenyl and 9,10-diphenylanthracene have fluorescence quantum yields and radiative lifetimes that represent upper limits, due to the combination of large molar absorption coefficients and negligible rates for internal conversion (structural rigidity) and intersystem crossing (El-Sayed's rule).

Let's now examine how the presence of n, π states affects the photophysical properties of molecules. Acetone and benzophenone both have carbonyl functional groups with S_1 and T_1 both being n, π^* states. The molar absorption coefficients are small, as is characteristic for $n \longrightarrow \pi^*$ transitions, with correspondingly small radiative rate constants for fluorescence. The quantum yield for $S_1 \longrightarrow T_1$ intersystem crossing is 1, and the phosphorescence quantum yields are large: $\Phi_p = 0.3$ for acetone and $\Phi_p = 0.9$ for benzophenone, respectively. The large value for the phosphorescence quantum yield of benzophenone is particularly striking and comparing the photophysical parameters of acetone and benzophenone provides some additional insight into the general mechanisms involved. Although the intersystem crossing quantum yields are essentially the same for the two molecules, independent measurements have shown that the intersystem crossing rate in benzophenone is the largest known, 10^{11} s^{-1}, whereas that for acetone is only about 10^8 s^{-1}. The existence of a $T_2(\pi, \pi^*)$ state near the $S_1(n, \pi^*)$ in benzophenone and the enhanced

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

intersystem crossing rates that occur between states of different orbital configurations accounts for the difference between the two molecules.

The general guidelines presented should allow you to make predictions about the photophysical properties of molecules based upon their energy level structures and the nature of the transitions involved. Radiative rate constants for transitions that are "allowed" by the spin selection rule are larger for $\pi \longrightarrow \pi^*$ transitions than for $n \longrightarrow \pi^*$ transitions, typically by several orders of magnitude. Fluorescence quantum yields are large for molecules with large radiative rate constants and small nonradiative rate constants that arise under the following conditions. $S_1 \longrightarrow S_0$ internal conversion is not important for molecules with rigid structures and large energy differences between the S_1 and S_0 states. Similarly, $S_1 \longrightarrow T_1$ intersystem crossing is not important between states of the same orbital configurations for organic molecules containing only the lighter elements (C, H, O, N). Phosphorescence quantum yields are large for molecules that have rapid $S_1 \longrightarrow T_n$ intersystem crossing rates, with rate constants that are larger than the radiative rate constants for fluorescence or internal conversion to the ground state. Rapid intersystem crossing arises as a result of strong spin–orbit coupling, which occurs under several different circumstances. Intersystem crossing is enhanced between states of different orbital configurations for organic molecules containing only the lighter elements. It is also enhanced in molecules that contain the heavier elements such as the heavier halogens, sulfur and phosphorous.

20.6 INTRODUCTION TO ATMOSPHERIC CHEMISTRY

A great deal of attention has been focused on three areas of atmospheric science in the last forty years or so: increased air pollution in the troposphere, the depletion of ozone in the stratosphere, and climate change. Oxides of nitrogen (collectively called NO_x) and oxides of sulfur (collectively called SO_x) come from the combustion of fuels, the former mostly from vehicles and the latter mostly from power plants. They lead to the production of ground-level ozone as well as to acid rain, both of which are serious environmental pollutants. Stratospheric ozone depletion is considered to be a contributing factor to the significant increases in the incidence of skin cancer observed over the past 30 years, based upon both epidemiology and animal model studies. Ozone depletion has been traced to a class of refrigerants and propellants called chlorofluorocarbons (CFCs), which have been banned by international agreement. Climate change has generally been attributed to increases in the concentrations of CO_2, CH_4, N_2O, and other atmospheric "greenhouse gases" over the past 150 years that have been attributed to human activities, and we discuss the climate scientists' consensus opinion in the sections that follow.

These three issues provide excellent examples of the need for good science to inform public policy. The issues differ significantly in their history, their scale, the nature of and confidence in the scientific evidence involved, and progress toward solutions. To summarize briefly, the health effects of air pollution were so severe, and the origins of the problem were so clear, that Congress created the Environmental Protection Agency and passed the Clean Air Act in 1970, giving the government the authority to regulate emissions. Improvement in air quality across the United States since that time has been significant. Evidence for stratospheric ozone depletion began to appear globally in the early 1970s, and the existence of a dramatic "ozone hole" over Antarctica was confirmed by the mid 1980s. A mechanism for the catalytic destruction of ozone by chlorine radicals produced by photolysis of CFCs was first proposed in the early 1970s, and by 1987 the evidence was so convincing that the international community banned the production of these chemicals worldwide. There is already evidence that the stratospheric concentrations of CFCs are on the decline, with expectations that stratospheric ozone

levels will recover. Climate change is certainly the least settled of the three issues, even within the scientific community, but certainly among policy makers and other stakeholders because of the complexity and the enormous scale of the problem.

Chemists have made seminal contributions to the understanding of the origins of each of these problems and, in particular, in assessing the relative "natural" and "anthropogenic" (attributable to humans) contributions to each issue. They have also been key players in developing, proposing, and implementing solutions. In this section we discuss the chemistry and photochemistry central to each problem, review the evidence supporting the scientific conclusions, and discuss solutions.

The Atmosphere

Although the chemical composition of the atmosphere summarized in Table 9.1 describes the average makeup of the portion of the atmosphere closest to the Earth's surface, it masks the variation in chemical composition with height, the dramatic role of local fluctuations in the concentrations of trace gases, and the dynamics underlying the observed average concentrations. The atmosphere is a complex chemical system that is far from equilibrium. Its properties are determined by an intricate combination of thermodynamic and kinetic factors. It is a multilayered structure, bathed in radiation from the sun, which interacts with the oceans and landmasses at the Earth's surface. We generally identify four layers of the atmosphere, on the basis of characteristic temperatures, temperature profiles, and densities (Fig. 20.41). In the outer two layers (the **thermosphere** and the **mesosphere,** above 50 km), the density is low and the gases have been extensively ionized by intense, high-energy solar radiation. The third layer, the **stratosphere,** occupies the region from 12 km to 50 km (approximately) above the Earth's surface. The **troposphere** is the lowest region, reaching up to about 12 km from the Earth's surface. In the troposphere, warmer air lies beneath cooler air. This is a dynamically unstable situation because warmer air is less dense than cooler air and tends to rise so convection takes place, mixing the gases in the troposphere and determining the

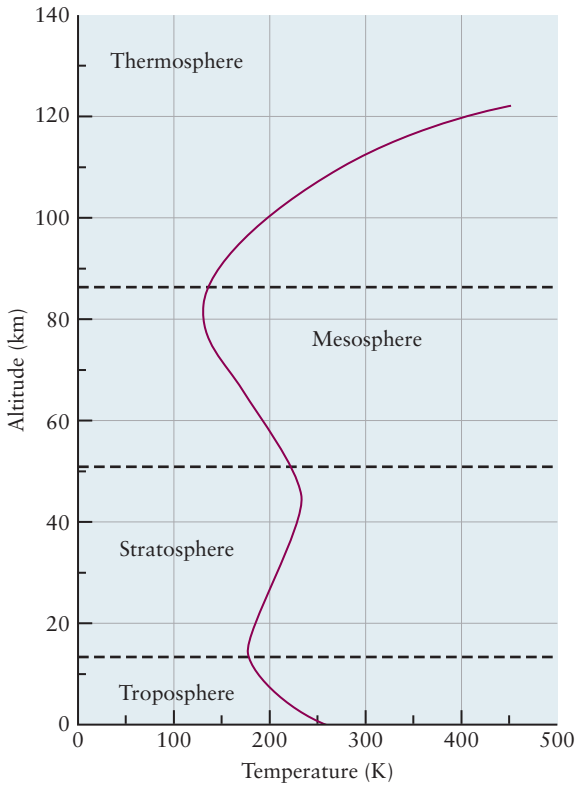

FIGURE 20.41 Variation of temperature with altitude in the atmosphere, showing its layered structure.

weather. In the stratosphere the temperature increases with height and there is little vertical mixing from convection. Mixing across the borders between the layers is also slow, so most chemical processes in each layer can be described separately.

The study of atmospheric chemistry dates back to the 18th century. Cavendish, Priestley, Lavoisier, and Ramsay were the first scientists to study the composition of the atmosphere. Recent advances in atmospheric science have come from the further development and integration of a number of scientific disciplines. The sensitivity of chemical analysis has greatly improved; concentrations of trace gases in the atmosphere are routinely measured at the part-per-trillion (ppt) level. We are now able to generate high-spatial-resolution maps of the distributions of chemical species across the globe daily using a combination of land-based, airborne, and satellite sensors. NASA's Aura satellite, for example, has four spectrometers that measure microwave, infrared, visible, and ultraviolet spectra of some 30 atmospheric constituents each day to map out the spatial distributions of these species in three dimensions. These maps provide important data that atmospheric chemists and meteorologists use to test and refine their climate models. Laboratory studies of the relevant reactions provide rate constants, activation energies, and mechanisms that must be included in these models. The role of heterogeneous chemical reactions in the atmosphere began to be appreciated about 15 years ago, and we have learned a great deal about the reactions of molecules like $ClONO_2$ that occur on, and can be catalyzed by, particulates like ice crystals and sulfate aerosols, for example; these reactions are part of a series of reactions that lead to the formation of the ozone hole. Finally, large-scale computer simulations are now able to tackle the very difficult problem of analyzing systems of coupled chemical reactions including transport. Dynamic simulations of the reactions within and diffusion between the layers of the atmosphere have contributed a great deal to our understanding of atmospheric chemical processes.

Tropospheric Chemistry

The troposphere is the part of the atmosphere in contact with the Earth's surface. It is therefore most directly and immediately influenced by human activities, especially by the gases or small particles emitted into the air by motor vehicles, power plants, and factories. Some pollutants have long lifetimes and are spread fairly evenly over the Earth's surface; others are localized around cities or in regions where they are produced and where local weather patterns keep them from dispersing. Six pollutants are of the greatest concern: carbon monoxide, nitrogen oxides (NO_x), ozone, sulfur oxides (SO_x), particulate matter and lead. We do not discuss particulate matter or lead, except to point out their effects on health, because the chemistry involved is unrelated to the chemistry of the other four pollutants. We begin by discussing the atmospheric chemistry and photochemistry of carbon monoxide, the nitrogen oxides, and ozone, because they arise mostly from vehicle emissions and because their reactions are coupled. Carbon monoxide, a product of incomplete combustion of fuels, is a poison at sufficiently high concentrations. Nitrogen oxides, generated at high temperatures in engines, lead to the production of both ground-level ozone and photochemical smog. Ozone is considered a secondary pollutant because it is generated by subsequent reactions of the primary pollutant, the nitrogen oxides. Finally, we discuss the atmospheric chemistry of sulfur oxides, which are produced primarily by the combustion of coal and oil to generate electricity. Sulfur oxides, and to a lesser extent nitrogen oxides, are precursors to acid rain. All of these criteria pollutants pose serious threats to human health as well as to the health of plants and animals. We discuss the sources and chemistry of these pollutants, their effects on health, remediation strategies, and results.

Most of the anthropogenic carbon monoxide in the atmosphere is produced by incomplete combustion of fuel in motor vehicles; this source is responsible for

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

about 60% of the CO produced across the United States, but up to 95% of the CO produced in urban areas with high densities of motor vehicle traffic. Other sources include off-road vehicles and lawnmowers, wood-burning fireplaces and stoves, and a variety of industrial and power generating processes. CO concentrations show seasonal variations with the highest levels occurring in the winter, due to a combination of increased combustion for heating as well as atmospheric conditions (inversion layers) that tend to trap CO and other pollutants.

Nitrogen oxides are major air pollutants. Although they are produced by natural sources such as volcanoes and lightning, most of the nitrogen oxides that enter the atmosphere are byproducts of combustion reactions used to generate energy for transportation or other purposes. About half come from motor vehicle emissions and half from industrial, commercial, and residential sources. The most important of these nitrogen oxides are NO and NO_2, which, along with their atmospheric oxidation products such as HNO_3, are collectively referred to as "NO_x." All of the oxides of nitrogen have positive free energies of formation at 25°C, making them thermodynamically unstable with respect to decomposition to the elements. The standard free energy of formation (ΔG_f^0) for NO, for example, is +86.6 kJ mol^{-1}, which implies an equilibrium constant for the reaction $K_{298} = 6 \times 10^{-16}$ for the reaction

$$\tfrac{1}{2}\,N_2(g) + \tfrac{1}{2}\,O_2(g) \longrightarrow NO(g),$$

giving equilibrium concentrations of NO of approximately 10^{-10} ppm at room temperature. Nitrogen oxides form to a greater extent when air is heated to higher temperatures in industrial processes or in automobile engines; the equilibrium concentration of NO rises to about 100 ppm at 800°C, the operating temperature of an internal combustion engine, and to about 1000 ppm at 1500°C, the operating temperature of a gas turbine. Nitrogen oxides accumulate to concentrations much higher than their equilibrium concentrations at ambient temperatures because they decompose slowly. The long residence times of these oxides in the atmosphere demonstrates the greater importance of kinetics, relative to thermodynamics, in atmospheric chemistry.

NO is the primary product of the high temperature combustion of nitrogen, but NO_2 is the key player in the tropospheric chemistry of the nitrogen oxides. NO_2 is the reddish-brown gas that obscures visibility on smoggy days in urban areas such as Los Angeles and Houston. The photolysis of NO_2 is responsible for the generation of ground-level ozone, as well as for initiating a series of reactions that lead to photochemical smog, beginning with the following reactions.

$$NO_2 + h\nu \longrightarrow NO + O$$

$$O_2 + O + M \longrightarrow O_3 + M$$

where M is a third body that carries away some of the excess vibrational energy of the products (see Section 18.4). Ground-level ozone concentrations are controlled to some extent by the following reaction in which NO acts as a scavenger.

$$O_3 + NO \longrightarrow O_2 + NO_2$$

Ozone concentrations in metropolitan areas begin to increase in the mornings, as commuters head off to work, and then decrease during the evenings and overnight. The NO scavenging reaction reduces ozone concentrations, and the NO_2 that is produced is not photolyzed during those hours. The NO_2 and O_3 concentrations predicted by the preceding mechanism are much lower than observed, so other mechanisms for producing these species must contribute. The most important of these involve the hydroxyl radical, which is produced in the atmosphere by photolysis of ozone and subsequent reaction of the photogenerated oxygen atom with water as follows. (The single dot represents a free radical.)

$$O_3 + h\nu \longrightarrow O_2 + O$$

$$O + H_2O \longrightarrow 2\ \bullet OH$$

The hydroxyl radical is an extremely powerful oxidizing agent not only because it has an unfilled valence shell but also because of the extraordinary thermodynamic stability of the products created: CO_2 from CO oxidation and H_2O from H atom abstraction reactions. The hydroxyl radical is sometimes called "the detergent of the atmosphere" because it cleans up harmful pollutants like CO and hydrocarbons. It also prevents hydrochlorofluorocarbons from leaving the troposphere and entering the stratosphere, where they have the potential to destroy ozone. Unfortunately, however, the hydroxyl radical also plays an important role in the generation of photochemical smog and in the reactions that lead to acid rain through the following series of reactions.

$$CO + \bullet OOH \longrightarrow CO_2 + \bullet OH$$

$$RH + \bullet OH \longrightarrow \bullet R + H_2O$$

$$\bullet R + O_2 + M \longrightarrow \bullet ROO + M$$

where RH is a hydrocarbon and $\bullet R$ is the radical produced by hydrogen abstraction. The hydroperoxyl radical $\bullet OOH$ and any number of peroxyl radicals $\bullet ROO$ formed from various hydrocarbons oxidize NO to NO_2 as follows

$$NO + \bullet OOH \longrightarrow NO_2 + \bullet OH$$

$$NO + \bullet ROO \longrightarrow NO_2 + \bullet RO$$

thus providing the source of the "extra" NO_2 to account for the levels of ozone produced from its photolysis and subsequent reactions.

The last set of reactions we consider are those between peroxyl radicals ($\bullet ROO$), peroxyacyl radicals ($\bullet RC(O)OO$), and NO_2 to form peroxyalkylnitrates and peroxyacylnitrates as follows

$$\bullet ROO + NO_2 \longrightarrow \bullet ROONO_2$$

$$\bullet RC(O)OO + NO_2 \longrightarrow \bullet RC(O)OONO_2$$

The latter class of compounds, the peroxyacylnitrates or **PANs,** are among the most abundant nitrogen-containing compounds in the troposphere, and they are distinct signatures of photochemical smog in polluted urban areas. The oxides of sulfur create pollution problems on regional and even global scales because they have longer lifetimes in the atmosphere than the nitrogen oxides. Some of the SO_2 and SO_3 in the air comes from biological processes and volcanoes, but about 70% of SO_2 emissions have anthropogenic origins, the most important of which is the combustion of fossil fuels (coal in particular) to generate electricity in power plants. If the sulfur is not removed from the fuel or the exhaust gas, SO_2 enters the atmosphere as a stable but reactive pollutant. Direct oxidation of SO_2 by atmospheric oxygen is allowed thermodynamically, but the kinetics are so slow in the absence of a catalyst that the reaction does not contribute significantly to tropospheric SO_3 concentrations. Further oxidation of SO_2 by atmospheric radicals leads to sulfur trioxide by the following series of reactions, and the reaction of the atomic oxygen produced by the decomposition of the hydroperoxy ($\bullet OOH$) radical can react with molecular oxygen in the third step to provide another source of ground-level ozone.

$$SO_2 + \bullet OH \longrightarrow SO_2OH$$

$$SO_2OH + O_2 \longrightarrow SO_3 + \bullet OOH$$

$$\bullet OOH \longrightarrow \bullet O + \bullet OH$$

NO_2 and SO_3 are both acid anhydrides that react with hydroxyl radicals and water vapor in the air to form nitric (HNO_3) and sulfuric (H_2SO_4) acids, respectively, which may deposit on the Earth in both wet and dry forms.

$$NO_2 + \bullet OH \longrightarrow HNO_3$$

$$SO_3 + H_2O \longrightarrow H_2SO_4$$

Acid deposition is the most general term for this set of processes; acid precipitation refers to the wet processes that include rain, snow, sleet, or hail, with **acid rain** being the process most familiar to the public. Even "pure" rainwater is slightly acidic due to the reaction of atmospheric CO_2 with H_2O to form carbonic acid, H_2CO_3, resulting in a pH in the range 5.3–5.6 (the presence of other acidic species contributes to this variability). Acid rain, on the other hand, is characterized by pH values in the pH = 4–5 range, which is deleterious to both health and the environment. The pH of acid rain varies considerably across the United States, ranging from 5.3 in the West to less than 4.3 in parts of the Northeast. The acid rain problem in the Northeast is due to the large number of coal-fired power plants, steel mills, and other industries that rely on coal and emit SO_2 in neighboring states such as Ohio and Pennsylvania. The environmental consequences are also more serious, particularly for aquatic species, because lakes in the Northeast tend to have granite beds, which do not provide any buffering capacity like lakes in which limestone ($CaCO_3$) is the lakebed.

The EPA has established a set of standards, based on health concerns, for the maximum permissible levels of six "criteria" pollutants, so-called because the levels were set by evidence of their effects on human health and on the environment. Table 20.10 lists the current primary National Ambient Air Quality Standards established by the EPA. The primary standards are based upon human health concerns whereas the secondary standards (not shown in the table) are based upon public welfare issues, such as reduced visibility, damage to crops, livestock, and physical structures, such as buildings and bridges.

Carbon monoxide is often called the "silent killer" because it is colorless and odorless. It displaces oxygen from hemoglobin in blood and symptoms of carbon monoxide poisoning at low levels are similar to those arising from other causes; these include headache, fatigue, nausea, and dizziness, for example. Carbon mon-

TABLE 20.10

National Ambient Air Quality Standards (Primary)†

Pollutant	Level
Carbon Monoxide	
8 hour average	9 ppm (10 mg/m^3)
1 hour average	35 ppm (40 mg/m^3)
Lead	
Rolling 3 month average	0.15 μg/m^3
Quarterly average	1.5 μg/m^3
Nitrogen dioxide	
Annual average	53 ppb
1 hour average	100 ppb
Particulate matter (PM_{10})	
24 hour average	150 μg/m^3
Particulate matter ($PM_{2.5}$)	
Annual average	15.0 μg/m^3
24 hour average	35.0 μg/m^3
Ozone	
8 hour average	0.075 ppm (2008 std.)
1 hour average	0.12 ppm (some regions)
Sulfur dioxide	
Annual average	0.03 ppm
24 hour average	0.14 ppm
1 hour average	75 ppb

†These standards are updated periodically. Please check the U.S. Environmental Protection Agency website (http://epa.gov/air/criteria.html) for the current standards.

oxide poisoning can be fatal at higher doses. Ozone has a pungent odor that makes it easy to detect at low concentrations; you may have smelled ozone near photocopiers or electric motors. Ozone is toxic even at very low concentrations with symptoms that include itching of the eyes, nose, and throat, coughing and chest pain, and increased susceptibility to respiratory disorders such as asthma. The oxides of nitrogen and sulfur are respiratory irritants that are especially problematic for those in "sensitive groups" that include children, the elderly, and individuals with respiratory problems. Health effects can be serious and even catastrophic. More than 4,000 people died in London during a five-day period in 1952. Cold weather necessitated burning large quantities of sulfur-rich coal, the emissions from which reacted with the typical London fog to form the deadly acid aerosol. As recently as 1982, the pH of the air in the Los Angeles basin fell to 1.5, in some areas leaving residents breathing nearly 0.1 M nitric acid.

Particulate matter (PM) falls into two broad classes: PM_{10}, which comprises a variety of solid particles and liquid droplets with a mean diameter of 10 μm, and $PM_{2.5}$, with a mean diameter of 2.5 μm. These particles include fine dust, soot, smoke, and droplets produced by chemical reactions, including combustion. These very fine particles can penetrate very deep into the lungs, aggravating asthma and causing acute respiratory distress. They may also lead to cardiovascular disease and cancer. A 2006 report in the *American Journal of Respiratory and Critical Care Medicine* claimed that reducing soot by 1 $\mu g\ m^{-3}$ could save 75,000 lives annually in the United States alone. Lead used to be emitted in large quantities by vehicles fueled by "leaded" gasoline that contained the anti-knock agent tetraethyl lead, $(CH_3CH_2)_4Pb$. Lead, like other heavy metals, tends to accumulate in the body over time, so extended exposure to even small concentrations can be very serious. Lead poisoning damages vital organs and the nervous system, leading to a variety of neurological disorders and heart disease. It can be fatal at high doses.

The EPA has the authority to regulate emissions of the six criteria pollutants, and the agency has developed a number of mechanisms to enforce compliance. Emissions from cars, buses, and "nonroad" equipment have been reduced by requiring manufacturers to build cleaner engines and refiners to produce low sulfur fuels. Emissions from automobiles have been reduced by over 90% since 1970. Elimination of tetraethyl lead from gasoline by regulation has reduced lead emissions by more than 98%. Regions of the country having difficulty meeting air quality standards may be required to implement vehicle emissions testing programs and use reformulated gasoline, which is less volatile, contains smaller quantities of certain VOCs, and includes oxygen-containing molecules like ethanol to achieve cleaner combustion. Sulfur emissions from electric power plants have been reduced by setting caps on the total amount of SO_2 that may be emitted and by establishing a system for trading emissions credits that penalizes those utilities who exceed their allowances and rewards those who emit less than they are allowed. The EPA can also issue fines to the operators of power plants that exceed their allowances. Continuous monitoring of SO_2 and NO_x is required and quarterly reports must be submitted to the EPA to prove compliance. As a result of all of these measures, emissions of the six criteria pollutants has been reduced by more than 50% during a period in which the gross domestic product (GDP) of the United States has tripled, energy consumption has increased by 50%, and vehicle use has increased by nearly 200%.

Stratospheric Chemistry

Light emitted from the sun resembles that of a 6000K black body (see Section 4.2). Although the intensity of the radiation drops rapidly toward shorter wavelengths in the UV region of the spectrum, a considerable number of very high-energy UV photons strikes the Earth's atmosphere every second. The energy of a 200 nm photon (at the border between the ultraviolet and vacuum ultraviolet) is more than

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

6 eV, or about 600 kJ mol^{-1}, which is sufficient to break all but the strongest chemical bonds. Radiation at shorter wavelengths causes ionization, which is even more damaging to molecules and biological tissues. Fortunately, there is a substantial layer of ozone in the stratosphere (see Fig. 20.42) that absorbs most of this harmful ultraviolet radiation, affording us substantial protection. In the mid-1970s, evidence began to accumulate that suggested that the concentration of stratospheric ozone was decreasing dramatically and that CFCs transported from the troposphere to the stratosphere were responsible. We describe the natural cycle for the production and destruction of O_3 in the stratosphere, the mechanism by which it absorbs UV radiation, the role of Cl radicals in ozone depletion, the factors that led to the dramatic seasonal variation in the ozone concentrations over the Antarctic (and more recently, the Arctic) and, finally, the corrective steps that have been taken and the results observed to date.

The steady-state concentration of O_3 in the stratosphere is reasonably well accounted for by the Chapman cycle (Fig. 20.43), named after the English physicist, Sydney Chapman. Chapman proposed the following series of coupled photochemical and thermal reactions: Photolysis of O_2 by UV radiation ($\lambda < 242$ nm) produces oxygen atoms, which then react with O_2 in the second step of the cycle to produce O_3. The second reaction may be reversed photochemically by the absorption of longer wavelength ($\lambda < 340$ nm) UV radiation, or the ozone produced may react thermally with oxygen atoms to regenerate O_2. The *steady state* concentration of O_3 depends upon: (1) the O_2 concentration at the altitude of interest and (2) the flux and wavelength distribution of UV radiation at that altitude. The average ozone concentration in the atmosphere is plotted as a function of altitude in

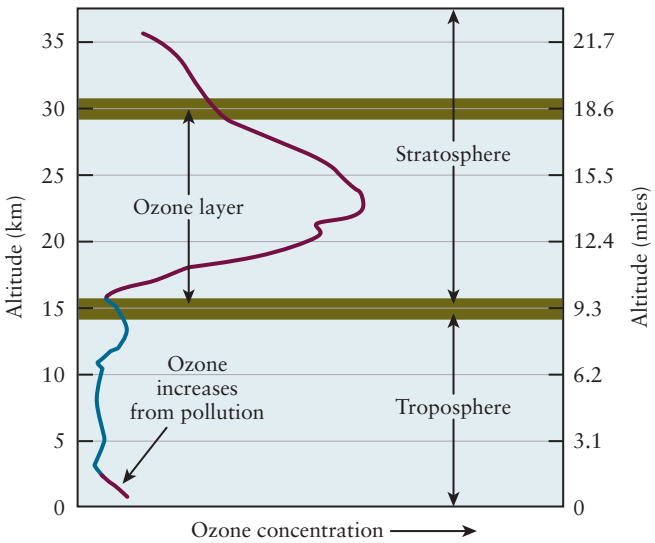

FIGURE 20.42 Variation in ozone concentrations with altitude in the atmosphere showing the stratospheric ozone layer and accumulation in the troposphere. Lucy Pryde Eubanks, Catherine H. Middlecamp, Carl E. Heltzel and Steven W. Keller. Chemistry in Context 6th Edition, McGraw-Hill New York 2009. p.58

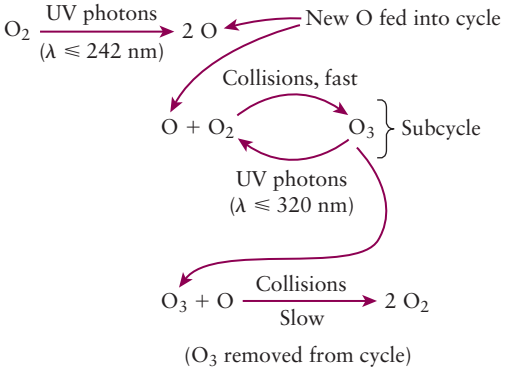

FIGURE 20.43 The Chapman cycle showing the key reactions for ozone formation and destruction in the stratosphere. Lucy Pryde Eubanks, Catherine H. Middlecamp, Carl E. Heltzel and Steven W. Keller. Chemistry in Context 6th Edition, McGraw-Hill New York 2009. p.74.

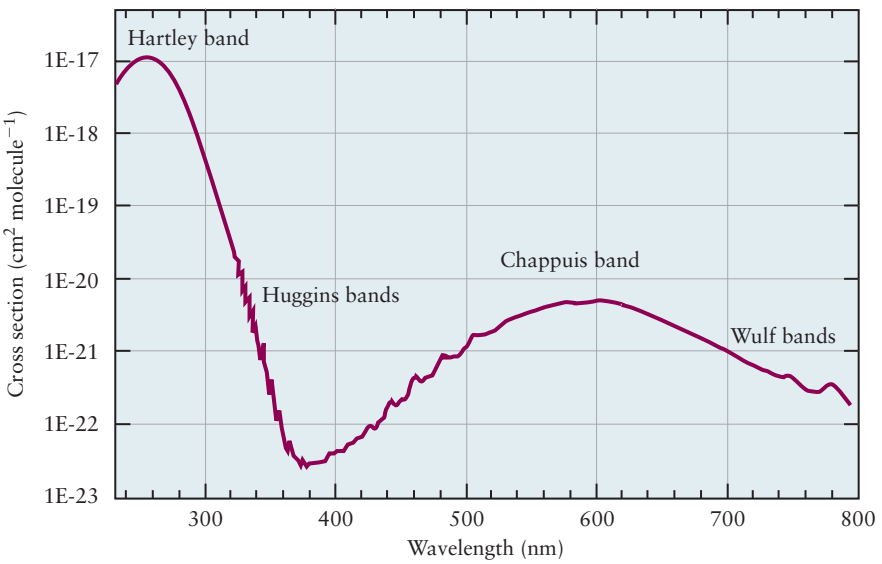
Figure 20.42; note the accumulation of ozone over a rather broad region of the stratosphere. The Chapman cycle actually overestimates stratospheric ozone concentrations because it does not consider other naturally occurring pathways for ozone depletion, the most important being reactions with •H and •OH radicals formed by the photolysis of stratospheric water vapor, but also reactions catalyzed by NO and NO_2, natural sources of which include oxidation of N_2 in forest fires, by lightning or volcanic eruptions.

UV radiation has been classified into three types based upon its absorption by a series of chosen glasses, rather like the three kinds of ionizing radiation were classified by their ability to penetrate three different kinds of matter. Ozone does not absorb appreciably at wavelengths longer than 340 nm, so the solar flux at the surface of the Earth over the region 400 − 340 nm is about the same as at the "top" of the atmosphere. Radiation from this region is called UV-A, and it is the least damaging to biological tissues. O_3 begins to absorb strongly below 340 nm, whereas O_2 begins to absorb strongly only below 242 nm, reflecting the relative strengths of their O—O bonds. (Recall that the bond order of the O—O bond in O_3 is 1 1/2, whereas that in O_2 is 2.) Radiation with wavelengths between 340 and 280 nm (where proteins begin to absorb) is called UV-B radiation, and it is more damaging to biological tissues. UV-B radiation can ionize molecules and form reactive free radicals, which are damaging to cells. It can also cause specific mutations in DNA that lead to skin cancers. UV-C radiation, with wavelengths less than 280 nm, is the most damaging of all but it is effectively absorbed by atmospheric O_2.

The extent of biological damage caused by UV radiation is a strong function of frequency; 280 nm radiation is a million times more damaging than 340 nm radiation. The strongest of the ozone UV absorption bands begins at about 350 nm, reaching a peak at about 280 nm, as shown in Figure 20.44. The absorption cross section is significant, $\sigma \approx 10^{-17}$ cm^{-2}, which corresponds to a molar extinction coefficient $\varepsilon \approx 10^3$. Stratospheric ozone concentrations, measured from the ground in a station at Arosa, Switzerland, were stable during the period 1926–1973 and begin to decline at a rate of about 3% per decade at that point (graph not shown here). The first satellite measurements of global ozone concentrations were made using the Total Ozone Mapping Spectrometer (TOMS), which entered service in 1978. The agreement between the satellite and ground-based measurements has been excellent.

There is both laboratory and epidemiological evidence that increasing UV-B reaching the surface of the Earth due to depletion of the ozone layer causes nonmelanoma skin cancer and plays a role in malignant melanoma development. Malignant melanoma rates increased among U.S. white males by more than a factor of three and among white females by more than a factor of two over the past 30 years.



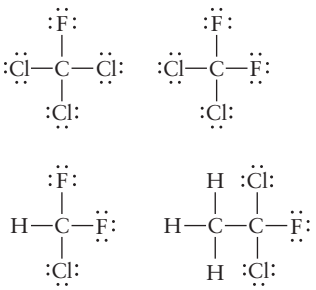


FIGURE 20.44 Ozone absorption in the visible and ultraviolet. Orphal, J. A critical review of the absorption cross-sections of O_3 and NO_2 in the ultraviolet and visible. Journal of Photochemistry and Photobiology A: Chemistry 157 (2003) 185–209.

CFCs

The increase of melanoma among white males and females is significant, though it is hard to discern any significant increase among black men or women. The incidence of melanoma among white Australians is twice that of white Americans.

The German meterologist Paul Crutzen at Mainz was the first to demonstrate the catalytic destruction of ozone by a free radical, NO, which was produced by natural processes. This discovery led Harold Johnston at Berkeley to propose that the NO produced by supersonic transports could pose a serious threat to the ozone layer, and scientists began to consider other potential ozone-depleting molecules. The American chemists Mario Molina and Sherwood Rowland, both then at the University of California at Irvine, proposed that the photolysis of CFCs could produce reactive chlorine-containing free radicals that could also catalyze ozone destruction, by the mechanism proposed below. The Freons CFC-11 and CFC-12 shown are two of the most important CFCs developed commercially in the 1930s for use as refrigerants and propellants.

Photolysis of CFCs with UV light with wavelengths shorter than 220 nm produces chlorine atoms and radical fragments as shown below, for example

$$CFCl_3 + h\nu \longrightarrow \bullet CFCl_2 + \bullet Cl$$

$$CF_2Cl_2 + h\nu \longrightarrow \bullet CF_2Cl + \bullet Cl$$

The chlorine atom is a very reactive free radical that is thought to destroy ozone by the catalytic mechanism shown below. The net reaction is the conversion of two O_3 molecules into three O_2 molecules.

$$2\,[Cl\bullet + O_3 \longrightarrow ClO\bullet + O_2]$$

$$2\,ClO\bullet \longrightarrow ClOOCl$$

$$ClOOCl + h\nu \longrightarrow ClOO\bullet + Cl\bullet$$

$$ClOO\bullet \longrightarrow Cl\bullet + O_2$$

$$2\,O_3 \longrightarrow 3\,O_2$$

How were these reactions, which were studied in the laboratory, linked to the stratospheric ozone problem, and how did scientists rule out naturally occurring sources of Cl radicals as the active catalyst? Several lines of evidence supported the conclusion that the photolysis of CFCs was the source of the reactive Cl. First, an inverse correlation between $ClO\bullet$ and ozone concentrations was established in an experiment in which a NASA jet measured the concentrations of these gases as it flew from Chile to Antarctica, entering the ozone hole as shown in Figure 20.45. (The seasonal depletion of the ozone layer over Antarctica is particularly dramatic, so this region was chosen for this experiment.) Although correlation does not prove causality, the level of detail shown in the mirror images was considered extremely good evidence that CFCs were responsible for ozone depletion. Second, satellites began to observe that the concentrations of halogen-containing compounds in the stratosphere were appreciable. Finally, the appearance of HF and other fluorine-containing compounds in the stratosphere and the correlation of their concentrations with the amounts and compositions of the CFCs provided the definitive proof. There are no naturally occurring sources of fluorine that could account for the HF appearing in the stratosphere. Detailed climate models, using accurate kinetic data measured in the laboratory, provided additional supporting evidence for the proposed mechanism. Molina, Rowland, and Crutzen were awarded the 1995 Nobel Prize in Chemistry for their pioneering work on this problem.

The ozone concentrations above Antarctica show dramatic seasonal variations in the ozone concentrations and depletion much greater than that averaged over the entire atmosphere. Figure 20.46 shows the ozone "hole" over Antarctica on September 25, 2006 and a corresponding image taken on December 25, 2006.

The purple in the false color scale represents the lowest ozone concentrations, green is the average, and red the highest. A Dobson Unit is about 1 part per billion

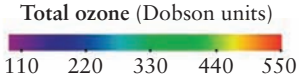

FIGURE 20.46 (a) Image of the Antarctic ozone hole taken by the Ozone Monitoring Instrument on September 25, 2006. The hole covered an area greater than North America and the ozone levels were below 150 ppb, compared with the global annual average of about 350 ppb. (b) Ozone levels above Antarctica on December 25, 2006 showing substantial recovery.

(ppb). Comparing the two images, we see that the ozone concentration over Antarctica during the Antarctic spring has dropped to less than a third of its average value. What mechanism causes such a dramatic variation? Several factors, acting in concert, are responsible. The Antarctic land mass is huge, and the region above the South Pole is the coldest spot on Earth. Circulating air masses prevent warmer air from entering the region during the Antarctic winter (July through September), creating conditions favorable for the formation of polar stratospheric clouds (PSCs). These PSCs are thought to catalyze the conversion of less reactive molecules like $ClONO_2$ and HCl into more reactive species like HOCl and Cl_2, which are then stored on the surfaces of these clouds during the winter months, effectively "pre-concentrating" them. Sunlight returns in spring and photolyzes the accumulated store of chlorine-containing precursors, releasing relatively large amounts of $Cl\bullet$ in a relatively short period of time. The hole appears quickly and dramatically. As spring turns into summer the clouds evaporate, the weather patterns change, and air from other regions of the atmosphere flow into the region, refilling the ozone hole. The situation is not as dramatic in the Arctic, presumably due to the smaller land mass, warmer temperatures, and lack of circulating winds, but ozone depletion over the North Pole is clearly evident and being closely monitored.

It is remarkable, in our opinion, how quickly the international community came together to address this problem globally, once the underlying science had been established and accepted. As early as the late 1970s, just a few years after Rowland and Molina's pioneering work, the U.S. banned the use of CFCs as propellants in spray cans and, a decade later, as foaming agents. In 1987, the Montreal Protocol was signed by nearly 100 countries. It called for the reduction of global CFC production to half the 1986 levels by 1998; underdeveloped countries were given longer to comply. The phase-out was accelerated after several subsequent meetings involving about 140 countries and all signatories (almost 200 to date) agreed to stop CFC production by 2010, regardless of their national economic needs. The United States ended its production of CFCs in 1995 and accelerated the phase-out of other ozone-depleting chemicals like chlorinated solvents (chloroform and methyl chloroform), methyl bromide (an agricultural fumigant), and fire-fighting halons (mixed chlorinated and brominated hydrocarbons) so that most of these chemicals are now out of large-scale production. By international agreement these chemicals are to be phased out globally by 2010. Global CFC production increased exponentially during the period 1950 through 1987, followed by a precipitous decrease to a level that is now essentially zero.

What effect has the ban on CFCs had on the ozone levels in the stratosphere, and what makes replacements more "ozone friendly"? The measured effective

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

chlorine concentrations increased exponentially beginning in 1950, but reached a peak in 1995 and are now beginning to decline with a projected half-life of 50 years. Ceasing production of CFCs has caused the trend in the stratospheric chlorine concentrations to reverse, but it is important to note that it will be 2040 before the concentrations return to pre-1980 levels. The important lesson here is that human activities can have rather rapid and dramatic impacts on the environment that can take decades to reverse, even after corrective action has been taken. It is ironic that the characteristic (chemical inertness) of CFCs that made them desirable replacements for earlier refrigerants and propellants makes them so stable with respect to destruction by natural atmospheric chemical reactions.

CFCs have been replaced by hydrochlorofluorocarbons (HCFCs), in which one or more of the CFC chlorine atoms have been replaced by hydrogen, to make them much more reactive with the atmospheric gases of the troposphere, precluding their transport to and accumulation in the stratosphere. Even these molecules provide only interim solutions, however, because they lead to measurable rates of ozone depletion. The 1992 Copenhagen amendment to the Montreal Protocol requires discontinuing their production by 2030. HCFCs are being replaced by hydrofluorocarbons (HFCs) which do not contain any chlorine at all. They react even more readily with atmospheric gases than HCFCs, making them less likely to make it to the stratosphere and less damaging even if they do.

We believe that the stratospheric ozone depletion problem and its solution provide a successful paradigm for identifying and addressing global environmental issues. There was scientific collaboration and communication that established the basis for remediation, and there was cooperation among countries around the world to work out an acceptable solution.

Climate Change: The Greenhouse Effect

Climate change is by far the most complicated of the three atmospheric chemistry issues we discuss, for a number of reasons. It is complicated scientifically because we need to understand how the atmosphere, the land masses, and the oceans interact with each other; physical and chemical interactions are both important, they are often coupled and they are often nonlinear. The climate system is subject to many kinds of feedback, both positive (destabilizing) and negative (stabilizing), and it is often difficult to quantify the effects of a given perturbation on the system. Climate science has evolved over the past 30 years or so to become an interdisciplinary field that draws from chemistry, physics, meteorology, geology, oceanography, and computer science, and it has made great progress in helping us understand this complicated system. In contrast to the atmospheric chemistry we discussed earlier, climate change is a much more politically contentious problem because of its much greater scale and scope and the conflicting interests of its many stakeholders. Unfortunately, as a result of the highly politicized nature of the issue, the underlying science is often omitted in public policy debates and by the media. Our objective is to provide you with an introduction to the problem of climate change so that you can understand the basic scientific issues involved, evaluate policy and media statements intelligently, and, perhaps, become sufficiently interested in the problem to make your own scientific contributions to its solution.

The key issues in the climate change debate are:

1. Are human activities largely responsible for the warming of the Earth observed since the Industrial Revolution, or is the warming part of the natural cycling of the Earth's temperature?
2. If human activities are contributing significantly to climate change, what are the most likely consequences over the next century or so?
3. What can be done to protect against the adverse consequences?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The key scientific issues we need to understand to inform the debate are:

1. How has the temperature of the Earth varied over geological time scales?
2. What caused the variations in temperature over geological time scales?
3. What evidence suggests that the recent warming is different from warming in the past and that it is due to human activities, especially the burning of fossil fuels?

We present, in the discussion that follows, a summary of the consensus view published by the Intergovernmental Panel on Climate Change (IPCC) in *Climate Change 07*. We recognize that others, including your instructors, may have different views, but we feel that presenting the consensus view allows us to introduce you to the problem and to identify some of the important issues involved.

Figure 20.47 shows a simplified schematic of the Earth's energy balance. The emission spectrum of the sun resembles that of a 6000K blackbody with approximately 50% of the energy in the near infrared, 40% in the visible, and 10% in the ultraviolet regions of the electromagnetic spectrum. About one-third of the energy incident on the Earth is reflected back into space, with the remaining two-thirds being absorbed by the atmosphere and the surface. The energy that is absorbed is ultimately degraded into heat, which leads to the emission of blackbody radiation over a wide range of frequencies in the IR, the peak wavelength occurring at 2000 cm^{-1} at 300K. Some of this radiation is absorbed by atmospheric gases, the most important of which is water vapor, effectively trapping the energy in the atmosphere. The schematic clearly shows that the energy incident on the Earth is exactly balanced by the energy reflected and emitted back into space, resulting in a stable, steady state temperature. The steady state temperature reached depends upon how much of the energy emitted from the surface is re-absorbed by the atmosphere, which, in turn, depends upon the composition of the atmosphere. These

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

effects can be quite dramatic; the temperature of the Earth would be about −18°C (0 °F) without water vapor and CO_2, and the oceans would be frozen year-round.

Figure 20.48 shows the increase in annual global mean temperatures for the period 1850–2005, relative to the 1961–1990 average. The post-industrial increase in the average global temperature has been about 0.8°C. The colored lines show the linear trends for different periods extending back from 2005. The increase in the slopes of these lines observed for periods closer to the present suggest that the rate of the temperature rise is increasing.

Ice core data show a strong correlation between atmospheric CO_2 concentrations and global temperatures over geological time scales. These experiments, conducted on both the Greenland and Antarctic ice sheets by a number of expeditions, use a hollow bore to drill down through the ice and extract 4" diameter cores that are up to several thousands of meters long. The composition of the ice is painstakingly analyzed to calibrate depth with age and to measure the temperature and the concentration of CO_2 trapped in bubbles as a function of depth. Annual cycles of not-quite melting followed by the deposition of fresh snow appear as rings and can be used to date relatively young layers, much like counting tree rings is used to estimate the age of trees. More complicated models, based on the physics of ice flow and accumulation, are used to establish a glaciological time scale. These time scales are carefully cross-calibrated using other events, notably periodic variations in the Earth's orbit that affect the intensity and distribution of the incident sunlight. The temperature at which the ice formed is measured as a function of depth using proxies, the ratios of the concentrations of several heavy isotopes of water to that of the most abundant isotope $H_2{}^{16}O$. We label the HDO/H_2O ratio as the D/H ratio and the $H_2{}^{18}O/H_2{}^{16}O$ ratio as the $^{18}O/^{16}O$ ratio for convenience. The vapor pressure of the heavy water isotopes is less than that of ordinary water because of a primary kinetic isotope effect. The heavy isotopes have lower zero-point vibrational energy levels than the light isotope, which increases the activation energy for vaporization. Heavy water evaporates at higher temperatures than light water. The converse is true for condensation. During the ice ages, for example, the oceans were relatively cooler and the water vapor relatively enriched in light water. As the water vapor moved from the equator to the poles it became even more enriched in light water as the heavy water rained out preferentially. Cooler periods are characterized by lower D/H and $^{18}O/^{16}O$ ratios in ice cores, whereas warmer periods are characterized by higher D/H and $^{18}O/^{16}O$ ratios. The shift in the $^{18}O/^{16}O$ composition from standard seawater is an accurate proxy for temperature. CO_2 concentrations were

measured by crushing the ice under vacuum without melting and analyzing the gases using gas chromatography.

Ice core data show reasonably strong correlations between temperature and CO_2 concentrations over more than 650,000 years, as measured by the EPICA project. The temperature varied over a range of about 10°C during this time; there were four warm periods observed during the past 400,000 years that are called the interglacial periods. The arguments presented above suggest that increasing CO_2 concentrations cause an increase in global temperatures, but most climate scientists now believe that the increase in CO_2 was actually driven by an increase in temperature, which released CO_2 from the oceans. The changes in CO_2 concentrations are thought to lag the temperature increases by about 800 years.

Let's now examine the increases in CO_2 concentrations that have occurred since 1860, as shown in Figure 20.49. The early measurements were taken by measuring the amount of CO_2 trapped in air bubbles in ice cores; data shown after 1960 were obtained by measuring the infrared spectra of CO_2 at an observatory on Mauna Loa. The data clearly show that: (1) the concentration of atmospheric CO_2 has been steadily increasing, (2) the rate of increase is also increasing, and (3) current levels are significantly higher than at any time in the past 800,000 years, as inferred from ice core data.

So far we have established that global temperatures are strongly correlated with atmospheric CO_2 concentrations and that current CO_2 concentrations are significantly higher than in any period over the past 800,000 years. What evidence attributes the recent increases in CO_2 concentrations to human activities, and what are the likely consequences of different emissions scenarios with respect to future warming? The strongest evidence that most of the post-industrial CO_2 arises from the combustion of fossil fuels comes from an analysis of its isotopic composition. The CO_2 that has been added to the atmosphere over the past 150 years or so is relatively depleted in the heavier carbon isotopes ^{13}C and ^{14}C. This observation strongly suggests that the carbon came from the combustion of fossil fuels. It is well known that plants preferentially fix $^{12}CO_2$, and so fossil fuels, derived mostly from plants, are slightly enriched in ^{12}C. In addition, the half-life of the radioactive isotope ^{14}C is 5,730 years, leaving essentially no ^{14}C in fossil fuels. The observation that there has been an increase in atmospheric CO_2 levels during the post-industrial era, taken together with the observation that the fraction of the heavier isotopes has been steadily declining, provides strong evidence of its fossil fuel origin.

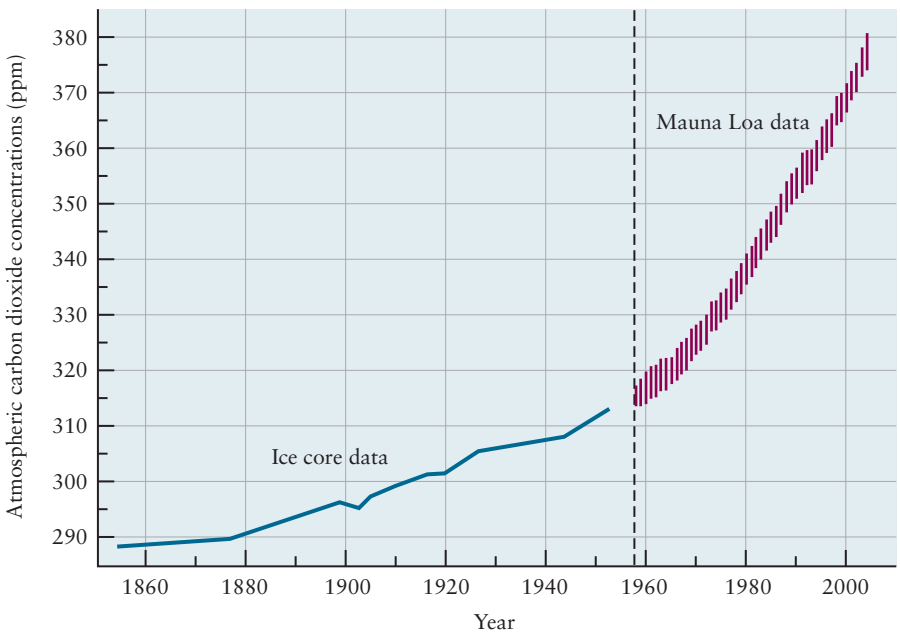

FIGURE 20.49 Post industrial revolution increases in atmospheric CO_2 levels measured in ice cores and at the Mauna Loa observatory by infrared spectroscopy. Lucy Pryde Eubanks, Catherine H. Middlecamp, Carl E. Heltzel and Steven W. Keller. Chemistry in Context 6th Edition, McGraw-Hill New York 2009 p.108.

We suggested earlier that most climate scientists believe that CO_2 lags the temperature, the CO_2 being released as the oceans heat up. If that is the case, what is the basis for the current concern over the increased CO_2 levels? We believe that climate scientists are concerned because there is a known mechanism by which CO_2 traps IR radiation that leads to global warming and that if additional warming begins the climate system could be subject to positive feedbacks that would be destabilizing. Increases in atmospheric CO_2 would cause the temperature to rise, which would in turn cause more CO_2 to be released from the oceans, causing a further temperature rise, and so forth.

CO_2 is not the only important greenhouse gas; methane, N_2O, halogenated compounds like those discussed above, and ozone all absorb infrared radiation and can contribute to warming. Aerosols, like the water vapor in clouds, reflect incoming light and can contribute to cooling. The amount of warming or cooling caused by each of these species is expressed quantitatively by a quantity called the radiative forcing, which is the net (down minus up) flux of energy being delivered at the boundary between the troposphere and the stratosphere in units of W m^{-2}. Estimates of the radiative forcing from a number of compounds and mechanisms, as well as an estimate of the total forcing are shown in Figure 20.50.

Climate models that take into account both natural and anthropogenic causes continue to evolve; they provide additional evidence that the anthropogenic contributions are important and allow us to make educated predictions about the future. Figure 20.51 shows a set of models that include anthropogenic contributions and a set of models that do not include anthropogenic contributions, compared with the experimental data. It certainly appears that anthropogenic sources make significant contributions to the warming that has occurred since 1960.

Predicting future climate change depends not only on applying our understanding of the scientific factors that govern the state of the climate system but also on making predictions about population growth and development in underdeveloped countries, as well as economic and geopolitical issues. These issues are beyond the scope of this textbook, but we close this section by commenting briefly on the nature of models being developed and on the conclusions made by the IPCC in its 2007 report. The IPCC based its projections primarily on four emissions sce-

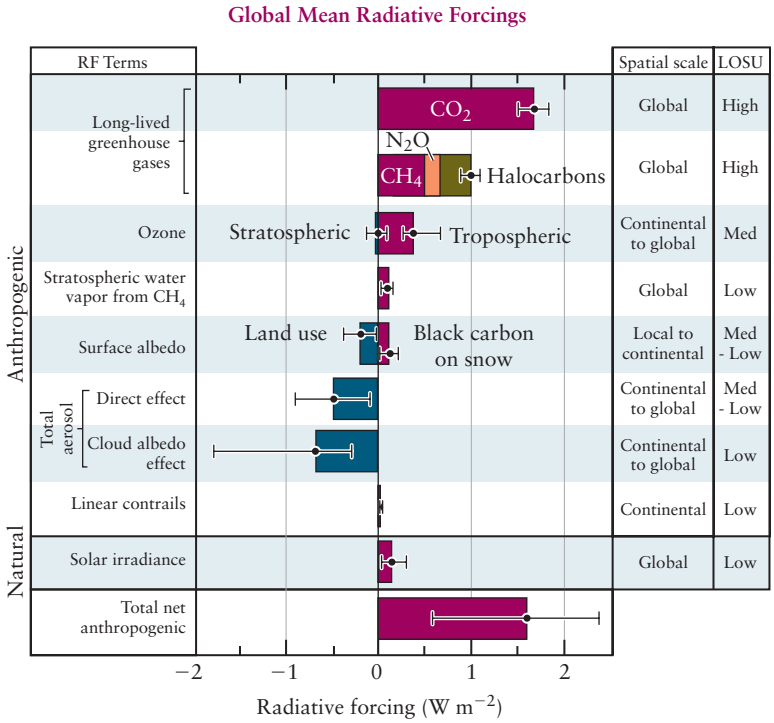

FIGURE 20.50 Estimates of global mean radiative forcings from various sources (IPCC 2007). LOSU is the level of scientific understanding.

narios that considered two economic/environmental extremes coupled with two globalization/regionalization extremes (rapid, global economic growth, for example), giving a total of four emissions scenarios. The panel reported the uncertainty in their conclusions and predictions using the following terms, which are loosely related to the number of standard deviations in the Gaussian (bell-shaped) probability distribution. *Likely* means a $> 66\%$ probability, *very likely* a $> 90\%$ probability, and *extremely likely* a $> 95\%$ probability. Similarly, *unlikely* means a $< 33\%$ probability, *very unlikely* a $< 10\%$ probability, and *extremely unlikely* a $< 5\%$ probability. Key predictions are:

- Most of the observed increase in global average temperatures since the mid-twentieth century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations.
- Doubling of atmospheric CO_2 concentrations would *likely* result in a temperature rise in the range 2.4°C–6.4°C with a best estimate of 3°C. Average global surface temperatures at the end of the 21st century are *likely* to be 1.8°C (1.1°C–2.9°C) to 4.0°C (2.4°C–6.4°C) higher than at the end of the 20th century for the four scenarios.
- Sea levels are *likely* to be 0.2 to 0.5 m higher at the end of the 21st century than at the end of the 20th century.

The international community came together to begin to address the issue of climate change in 1994, and the resulting treaty, The United Nations Framework Convention on Climate Change, was signed by 194 countries. The framework encouraged governments to share information and develop strategies for adapting to the impacts of climate change. The Kyoto Protocol, adopted in 1997 and ratified in 2005, set binding emissions targets for some 38 industrialized nations—the United States, for example, was to cut its 2012 emissions to 93% of its 1990 emissions. The United States has not ratified the treaty because no binding limits were set for developing countries, notably China and India. The Kyoto Protocol set up mechanisms for achieving reductions, the most famous of which is a "cap and trade" system for exchanging emissions rights. Countries that are performing better than expected can sell emissions credits to countries that need them to meet their targets. This new commodities market is called the "carbon market." While this chapter was being written in late 2009, world leaders met in Copenhagen to try to work

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

out a successor to the Kyoto Protocol. The resulting agreement, the Copenhagen Accord, fell short of expectations by some, but established an agreement in principle to: (1) limit global temperature rise to 2°C above pre-industrial temperatures; (2) reduce greenhouse gas emissions to cap the temperature rise; (3) submit binding emissions targets for the developing nations by January 2010; (4) provide incentives to reduce emissions due to deforestation and forest degradation; and (5) provide significant incentives for underdeveloped countries to participate in mitigating climate change.

The Copenhagen Accord set goals but did not specify mechanisms by which to achieve these goals. We believe that there are many opportunities for scientists and engineers, as well as citizens, to address this problem, and it will be necessary to pursue a number of approaches in parallel. The easiest, of course, is conservation. Paying attention to our individual energy use and changing our behavior will lead to significant reductions without being very burdensome. Second, we need to more aggressively develop and deploy alternate sources of energy that do not involve fossil fuels; these include nuclear, wind, and solar, for example. There are tremendous opportunities for chemists to contribute to the development of these technologies.

The climate change problem is clearly more difficult than the ozone depletion problem; there are many more elements of the climate system involved, it is more difficult to separate natural from anthropogenic forcings, and the forcings may be either positive or negative, with feedback, making it difficult to calculate the net effect. The problem is also more challenging socially, economically, and geopolitically, making it one of the most difficult environmental problems faced by your generation. We encourage you to consider climate change as one of the many interesting problems you could tackle with your solid background in the chemical sciences.

20.7 PHOTOSYNTHESIS

About 1% of the energy that reaches the Earth's surface is converted into chemical energy by **photosynthesis**—a remarkably efficient sequence of photophysical processes and oxidation–reduction reactions that leads to the formation of a six-carbon sugar molecule plus molecular oxygen as follows

$$6\ CO_2 + 12\ H_2O \longrightarrow C_6H_{12}O_6 + 6\ O_2 + 6\ H_2O \qquad \Delta G_f^0 = +2872\ \text{kJ mol}^{-1}$$

This reaction is the reverse of the spontaneous oxidation of glucose to CO_2 and H_2O by combustion or metabolism, and it requires an external driving force to occur as written. The energy of the light absorbed in the photosynthetic process increases the Gibbs free energy of the reactants and provides the necessary driving force. The end result of this carbon dioxide fixation reaction is the conversion of solar energy into chemical potential energy. We focus, in this section, on the elementary physical and chemical photosynthetic processes and do not discuss in any detail the structures and organization of the components of the photosynthetic membranes that carry out the reactions. These components include a number of membrane-bound enzyme complexes that are highly organized spatially to catalyze the various light-driven and dark-driven reactions of photosynthesis. The biochemistry required to understand the details of these enzyme-catalyzed reactions is beyond the scope of this textbook. Our primary objective is to show how the concepts we introduced at the beginning of this chapter, along with the molecular level picture of redox processes developed in Chapter 17, can be used to explain the initial steps of energy transduction in photosynthesis.

Photosynthesis occurs both in bacteria and in green plants by similar mechanisms, the differences being in the nature of their respective photosystems and re-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ducing agents. Photosynthesis consists of a series of light reactions, discussed below, and dark reactions leading to CO_2 fixation that we just touch upon. The light reactions and dark reactions have been shown to be independent of one another. Irradiating photosynthetic systems in the absence of CO_2 generates O_2; transferring a system prepared in this way into the dark and supplying it with CO_2 results in CO_2 fixation. The most general reaction for CO_2 fixation can be written as

$$CO_2 + 2\ H_2A \longrightarrow (CH_2O) + 2A + H_2O$$

where H_2A is a hydrogen donor that is the reducing agent, and CH_2O is the carbohydrate group, the building block for sugars, starches, and cellulose in plants. The hydrogen donor in bacterial photosynthesis is often H_2S, and it is H_2O in plants. Isotope labeling experiments showed that the O_2 produced in plant photosynthesis came from the water and not the CO_2, and we write the general photosynthetic reaction as shown so that we can track the source of the oxygen atoms through the process. The energy provided by light is ultimately transduced in the form of the high-energy molecule ATP and a strong reducing agent called NADPH by the coupled reactions.

$$2\ H_2O + 2\ NADP^+ + x\text{ADP} + x\text{P}_i \xrightarrow{nh\nu} O_2 + 2\ \text{NADPH} + 2\ H^+ + x\text{ATP} + xH_2O$$

Hydrolysis of ATP to ADP is coupled to many otherwise nonspontaneous reactions in biochemistry because it provides a driving force (ΔG) of about 50 kJ mol^{-1}. ATP is synthesized as part of the photosynthetic process by an enzyme powered by a transmembrane proton gradient that is set up by a series of light-driven electron transfer reactions. It is used as a source of free energy that couples into the dark reactions leading to CO_2 fixation. The reducing agent NADPH, the other primary product of photosynthesis, provides reducing equivalents for CO_2 reduction to CH_2O.

The initial photosynthetic events are very similar in both bacteria and in plants. Light is absorbed by a number of pigments, the most important of which are the chlorophylls, which are shown along with their absorption spectra in Figure 20.52.

Chlorophylls are coordination complexes of magnesium and various substituted tetrapyrroles that are built around the large planar ring structure shown. The basic structure of chlorophyll is similar to that of heme, the iron-bearing component in myoglobin and hemoglobin (see the *Connection to Biology* in Chapter 8.). The two strong absorption bands observed near 650 nm and 450 nm arise from $\pi \longrightarrow \pi^*$ transitions in the large aromatic ring, and they are responsible for the green color of plants. The structures of accessory pigments like carotene (which gives carrots their color) and phycocyanobilin are shown in Figure 20.53; their function is to absorb light that is not absorbed by chlorophyll, thereby utilizing the solar spectrum more efficiently.

We discussed various pathways for excited state relaxation in Section 20.5 and alluded to the importance of energy transfer and electron transfer processes in photosynthesis. A photosynthetic unit comprises hundreds of chlorophyll molecules and accessory pigments whose purpose is to absorb large quantities of light and efficiently funnel the energy to a special pair of chlorophyll molecules called the reaction center. Most of the chlorophyll in the photosynthetic unit acts like a large antenna that captures light. Energy is transferred between the molecules that comprise the array by a dipole–dipole or Förster energy transfer mechanism, a nonradiative process by which excited molecules transfer energy to neighboring ground-state molecules without either emission by the donor or absorption by the acceptor. The mechanism is analogous to the coupling of two tuning forks by the air. A vibrating tuning fork will transfer energy to a quiet tuning fork if the two are placed close enough together. In a similar way the energy stored in the excited states of donor molecules is transferred to the ground states of acceptor molecules if they are near one another. The rate of Förster energy transfer falls off as the inverse sixth power of the distance between donors and acceptors (the same dependence as van der Waals forces) with a critical transfer distance R_0 that gives a rough measure of

the length over which energy is transferred efficiently. R_0 is typically of the order of a few nm, which explains why the antenna chlorophyll molecules must be packed together pretty tightly for efficient energy transfer. Even though the process is not radiative, the rate of energy transfer depends on the overlap of the emission spectrum of the donor and the absorption spectrum of the acceptor. Figure 20.54 shows

the energy transfer process and the overlap of the emission and absorption spectra.

Energy transferred to the special pair in the reaction center creates excited states that initiate a series of electron transfer reactions ultimately leading to oxygen evolution and/or CO_2 fixation. The structure of the reaction center in the bacterium *Rhodopseudomonas viridis* is shown in Figure 20.55. The crystal structure shown was determined by X-ray diffraction (see Section 21.1) in 1984 by three German biochemists, Hartmut Michel, Johann Deisenhofer, and Robert Huber, for which they received the Nobel Prize in Chemistry. Not only did they locate the bacteriochlorophyll molecules that form the special pair, but they also identified the positions of the molecules involved in the subsequent steps in photosynthesis.

Figure 20.56 shows how photoexcitation of the special pair creates excited states of bacteriochlorophyll that are both reducing equivalents (the electron promoted to the LUMO) and oxidizing equivalents (the "hole" left behind in the HOMO). The energies of the species are plotted as electrode potentials, referenced to the standard hydrogen electrode (SHE). Recall that the electrical potential is the potential energy per unit charge (see Section 17.3), and "more negative potentials" in electrochemistry means "higher energy" in spectroscopy because the charge on the electron is negative. Electrons excited to the LUMO undergo a series of enzyme-catalyzed electron transfer reactions that ultimately reduce $NADP^+$ to NADPH. Holes left behind in the HOMO oxidize a hydrogen donor, H_2S, in this example.

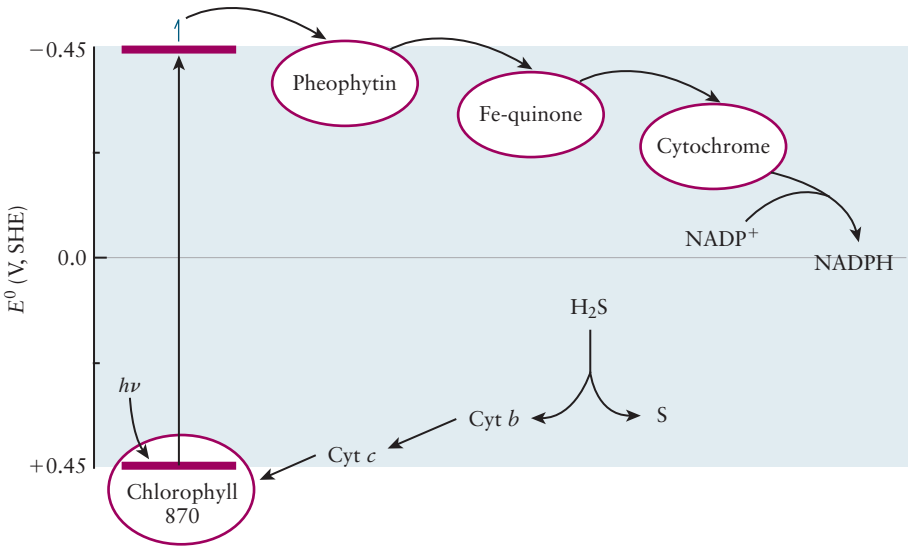

FIGURE 20.56 Energy levels (shown as reduction potentials vs. SHE) and electron transfer processes in bacterial photosynthesis.

The special pair in bacterial photosynthesis is called P780 because it absorbs light at 780 nm.

Returning to Figure 20.55 we see how the bacteriochlorophyll and related molecules are organized spatially to carry out these energy transfer reactions efficiently. A quinone is ultimately reduced to a hydroquinone that diffuses to the cytochrome shown, where it is oxidized back to quinone and the protons released generate a proton gradient that drives ATP synthesis as discussed.

Bacterial systems, in general, do not produce holes that are sufficiently oxidizing to oxidize water to O_2, so nature has created a second system that is used by green plants for this purpose. The *Z* scheme of photosynthesis is illustrated schematically in Figure 20.57; it consists of two coupled photosystems called PSI and PSII that produce reducing equivalents sufficiently negative to reduce $NADP^+$ to NADPH and oxidizing equivalents sufficiently positive to oxidize water. The oxygen evolving and the reducing functions of the photosynthetic system are separated and account for the existence of the light and dark reactions. The pigment in PSI absorbs light at 680 nm and is called P680, whereas that in PSII absorbs at 700 nm and is called P700. Not only does the absorption of two photons provide more energy than the absorption of one photon in bacterial photosynthesis, but the HOMO in P680 is at lower energy than either of the HOMOs in P780 or P700, and so the hole is sufficiently oxidizing to oxidize water. As illustrated in electrochemical terms, the potential is sufficiently positive.

The overall stoichiometry of photosynthesis depends on the pathways used by organisms to generate ATP from ADP when driven by light. The important key features of the process we emphasize can be summarized as follows:

1. Light is absorbed by chlorophylls and accessory pigments in bacteria and in green plants, and the energy is transferred in a few picoseconds (10^{-12} s) to a reaction center that contains a special pair of chlorophyll molecules.
2. Light absorbed by the special pair creates excited states that are both more strongly reducing and strongly oxidizing than the ground state. The basic mechanism of energy transduction is the creation of these oxidizing and reducing equivalents that initiate different series of redox reactions that ultimately lead to CO_2 fixation and oxygen evolution.
3. Bacteria have a single photosynthetic system that absorbs longer wavelengths than plants and does not produce holes sufficiently oxidizing to oxidize water.
4. Green plants have two photosystems that operate in tandem to generate more energy through the absorption of two photons and, more importantly, produce holes that can oxidize water to O_2.

A DEEPER LOOK

20.8 THE EINSTEIN RADIATION RELATIONS AND LASERS

The Einstein Radiation Relations

In 1917, Einstein published a landmark paper entitled "On the Quantum Theory of Radiation" in which he proposed a mechanism by which matter and radiation maintain thermal equilibrium with one another. His analysis was remarkable in that he, like Bohr, chose to ignore well-established physical principles when his intuition told him that something interesting might result. Einstein simply accepted the quantized energy levels and orbits of the Bohr model and proceeded to develop his arguments using the classical statistical analysis he had applied to other important problems like Brownian motion. He asserted that three kinds of processes are required to maintain thermal equilibrium between matter and radiation in a model system that has only two quantum levels. Two of these processes are stimulated by the presence of radiation and the third occurs spontaneously. Stimulated absorption and emission cause transitions from the lower to the upper level and vice versa. Electrons in the higher energy level may also return to the lower energy level by spontaneous emission. These three processes underlie all contemporary treatments of atomic and molecular spectroscopy. Einstein also derived the Planck blackbody distribution function independently and showed that the particles of the radiation field (later to be called photons) carry momentum as well as energy, nearly a decade before Paul Dirac developed the more complete quantum theory of the interaction between matter and radiation. We present the results of Einstein's analysis to introduce you to the fundamental concepts and to show you how they are used to interpret spectroscopic measurements.

Let's consider a system that has two quantized energy levels, E_1 and E_2, as illustrated in Figure 20.58. We assume, for simplicity, that the levels are not degener-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

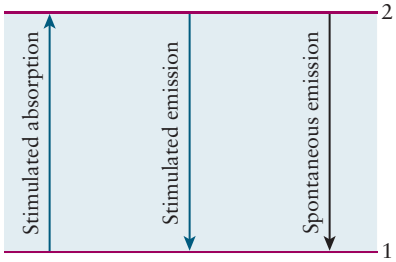

FIGURE 20.58 Two level system with absorption and emission processes identified.

ate. The formulas we derive can easily be modified to account for degeneracy if necessary. The populations (numbers of molecules) in these levels are N_1 and N_2 when the system is in thermal equilibrium with the radiation. For clarity we refer to the radiation as the "external radiation" in what follows to make it clear when we are illuminating the system with radiation from an external source or not. The arrows show the possible transitions between the two states: the blue arrows pointing up and down represent stimulated absorption and stimulated emission, and the black arrow represents spontaneous emission. Molecules in excited states—which may be populated thermally, or by absorption, scattering, or electron impact—decay spontaneously by first-order kinetics in the absence of external radiation. The rate equations are

$$-dN_2/dt = A_{21}N_2$$

$$N_2(t) = N_2(0)\exp(-A_{21}t)$$

where $N_2(0)$ is the initial population of the upper level and $N_2(t)$ is the population at some later time t. The first-order rate constant A_{21} is called the Einstein A coefficient with units s^{-1} and the radiative lifetime (the time it takes for the population to decay to $1/e$ of its initial value) is given by $\tau_{rad} = 1/A_{21}$ expressed in seconds.

B_{12} and B_{21} are the phenomenological rate constants for stimulated absorption and stimulated emission, respectively. The rate constants for the stimulated processes, unlike the rate constant for spontaneous emission, depend upon the intensity of the external radiation and must be multiplied by the radiation density to obtain the transition rates. The energy density is given by the Planck distribution for convenience, but the results obtained are independent of the model used; the rate constants depend only on the properties of the atoms or molecules under study. The energy density is generally taken to be the energy per unit volume per unit frequency interval with units J m^{-3} s in the SI system (recall that the frequency interval is 1 Hz or 1 s^{-1}). To make things as simple as possible (but not simpler) we integrate $\rho(\nu)$ over a 1 Hz region to get an energy density that is numerically equal to the conventional expression but with units J m^{-3}. The total absorption (W_{12}) and emission (W_{21}) rates are given by

$$W_{12} = N_1B_{12}\rho(\nu)$$

$$W_{21} = N_2B_{21}\rho(\nu) + N_2A_{21}$$

where $\rho(\nu)$ is the Planck distribution function as modified above.

The composite system (matter and radiation) can be considered to be in thermal equilibrium as long as the intensity of the radiation is not too high. The ratio of the populations in the two levels is given by the Boltzmann formula (see Section 12.8).

$$\frac{N_2}{N_1} = \exp(-h\nu/k_BT)$$

where $h\nu$ is the energy difference between the two levels. The rate of the upward transitions must equal the sum of the rates of the downward transitions to maintain thermal equilibrium, giving

$$N_1B_{12}\rho(\nu) = N_2B_{21}\rho(\nu) + N_2A_{21} \qquad [20.17]$$

which we rearrange to get

$$\rho(\nu) = \frac{A_{21}N_2}{N_1B_{12} - N_2B_{21}} = \frac{A_{21}}{(N_1/N_2)B_{12} - B_{21}}$$

Substituting the Boltzmann formula for the ratios of the populations in the denominator gives

$$\rho(\nu) = \frac{A_{21}}{B_{12}\exp\left(-h\nu/k_BT\right) - B_{21}} \qquad [20.18]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The Planck distribution (see Section 4.2) is

$$\rho(\nu) = \frac{8\pi h\nu^3}{c^3}\frac{1}{e^{h\nu/k_BT} - 1}$$

which we substitute into the left hand side of Equation 20.18 and solve for the Einstein A and B coefficients to get

$$B_{21} = B_{12} \qquad [20.19]$$

and

$$\frac{A_{21}}{B_{21}} = \frac{8\pi h\nu^3}{c^3} \qquad [20.20]$$

These two conclusions have important and far-ranging consequences for nearly all areas of spectroscopy. Equation 20.19 asserts that the rate constants for stimulated absorption and stimulated emission between two energy levels must be equal to one another. The rate constants of the stimulated processes are the same in both directions, a conclusion that may seem obvious today, but recall that quantum mechanics had not been fully developed at the time. Equation 20.20 predicts that the ratio of the rate constants for spontaneous and stimulated emission increases strongly with increasing frequency. The spontaneous emission rate is equal to the rate constant itself, but the rate of stimulated emission is given by the product of the rate constant for stimulated emission and the radiation density. The ratio of these rates is $A_{21}/B_{21}\rho(\nu) = e^{h\nu/k_BT} - 1$. Spontaneous emission becomes greatly favored over stimulated emission only at higher frequencies, for which $h\nu/k_BT \gg 1$. This result has long since been confirmed experimentally and explains why emission spectroscopy is much more widely used in the ultraviolet and visible than in the infrared or microwave regions of the electromagnetic spectrum.

Einstein's A and B coefficients were developed for a system of atoms or molecules immersed in a bath of electromagnetic radiation. To analyze an absorption experiment using this approach, we first note that the intensity of the radiation (power per unit area) is just the energy density that is transferred across the sample at the speed of light c.

$$I = c\rho(\nu)$$

We then define a new set of Einstein coefficients for the rates of stimulated absorption and stimulated emission based on intensity as $B^I_{12} = B_{12}/c$ and $B^I_{21} = B_{21}/c$, and we now interpret N_1 and N_2 as the number of molecules in each state per unit volume. We calculate the *net* rate of absorption of energy from the beam causing transitions into the upper state as follows.

$$-dI = N_1 h\nu B^I_{12} I d\ell - N_2 h\nu B^I_{12} I d\ell$$

where $h\nu$ is the photon energy, I is the intensity of the radiation and $-dI$ is the intensity absorbed through a path length $d\ell$. The net rate is simply the difference between the rates of stimulated absorption and stimulated emission. Substituting and rearranging, we get

$$-dI = (N_2 - N_1)B^I_{12} h\nu I d\ell$$

which integrates to give

$$I(\ell) = I_0 \exp[-(N_1 - N_2)B^I_{12} h\nu\ell] \qquad [20.21]$$

where I_0 is the intensity of the incident radiation. Let's consider electronic absorption spectroscopy in which the energy level separations are much larger than k_BT at room temperature. We can set $N_2 = 0$ under these conditions to get

$$I(\ell) = I_0 \exp(-N_1 B^I_{12} h\nu\ell) \qquad [20.22]$$

Comparing Equation 20.22 with the second form of the Beer-Lambert law introduced in Section 20.1 gives

$$\sigma = B_{12}^{I} h\nu$$

which relates the measured absorption cross section to the Einstein coefficient for stimulated absorption which can, in principle, be calculated using quantum electrodynamics. A number of approximate relationships, like those introduced in Section 20.5, have proven to be very helpful in interpreting the electronic spectra of molecules and understanding their photophysics and photochemistry.

Lasers

Lasers are devices that produce very intense beams of collimated monochromatic light; they are the key elements in a number of important technologies with applications as diverse as machining, welding, communication, data storage and surgery, to name a few. Fiber optic networks transmit huge volumes of digitized voice, video, and data across and between continents at nearly the speed of light. Data stored on CDs and DVDs are written by "burning" submicron size holes in the disks using a solid state laser and read by measuring the reflectivity of the surface to locate the holes and smooth surfaces, which represent "ones" and "zeros", respectively. There is enough energy produced delivered by the 192 beams of the National Ignition Facility laser (see Section 19.7) to heat a mixture of hydrogen isotopes to a few million degrees and initiate fusion. Although Einstein almost certainly did not foresee this enormously diverse range of applications, the possibility of light amplification through stimulated emission of radiation (giving rise to the acronym *laser*) was implicit in his treatment of the matter-radiation interaction and he is reported to have suggested that excess energy could be released as light, under certain circumstances. Lasers have been constructed from many different materials and have a variety of different characteristics that make them suitable for particular applications. The lasing medium may be a gas, liquid, solid, or plasma, producing radiation from the far infrared to the X-ray region of the electromagnetic spectrum. Lasers may operate continuously, like laser pointers used in the classroom, or they may be pulsed for durations as short as 12 attoseconds (12×10^{-15} s). The basic principles of laser operation are the same for all lasers, however, and they follow directly from Equation 20.22, which shows how the intensity of a beam of radiation changes as it propagates through a medium.

The population of the excited state N_2 is always less than that of the ground state N_1 for systems in thermal equilibrium, as required by the Boltzmann distribution. A beam of light passing through a medium is attenuated exponentially under these conditions, as shown by Equation 20.22. Increasing the intensity of the incident radiation does, in fact, increase the population of the excited state but the rate of stimulated emission also increases, resulting in saturation, a steady state in which $N_2 = N_1 = N/2$, where N is the total number of atoms or molecules in the system. Suppose, however, that we are able to prepare a system in which $N_2 > N_1$, a condition known as a population inversion. This situation would result in exponential amplification instead of exponential attenuation, producing a beam of radiation very different from that of ordinary light; it would be highly collimated and the photons in the beam would be travelling in phase with each other. (Explanations for the last two assertions are beyond the scope of this textbook but are important characteristics of lasers to know about.) The trick, of course, is how to prepare a system that is not in thermal equilibrium. There are two general approaches. The first is to excite the system with a very short burst of intense radiation, intense enough to create the population inversion but short enough to preclude significant stimulated emission. The second is to use a medium with three or four states that provide a bottleneck that allows population to accumulate in the upper state. Two other conditions are required for sustaining laser emission. The

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

radiation must be confined in such a way to ensure that emitted photons stimulate emission from other excited atoms or molecules, creating the cascade or chain reaction that is analogous to that essential for a nuclear chain reaction (see Section 19.6). This is generally accomplished by housing the lasing medium in a resonant cavity, terminated by a pair of highly reflective mirrors that keep the radiation circulating in the cavity, as well as to ensure that all of the photons are travelling in the same direction. A practical laser, however, must extract some of the radiation from the cavity to be useful; a partially transmitting mirror is generally used for this purpose, with most of the radiation being reflected back into the cavity to sustain a population inversion while allowing some of the radiation to escape as a laser beam. Some of the more common lasers with which you may be familiar include the continuous red HeNe gas laser, used in supermarket scanners, or the green solid-state Nd:YAG laser used in laser pointers. Both of these lasers use multiple energy levels to achieve and maintain population inversions in the continuous mode of operation; the Nd:YAG laser can operate either in continuous or pulsed modes, the latter being used to generate the high powers necessary to initiate nuclear fusion.

Figure 20.59 shows the energy levels of a four-level system and the characteristics of the excitation and relaxation processes that lead to efficient laser action. Lasers are pumped by other lasers or by broadband emission from flash lamps or laser diodes; the lasing medium should have a large absorption coefficient at the pump wavelength(s) to create a significant population of excited states. Relaxation back to the ground state via emission or nonradiative processes must be slow. Nonradiative relaxation or energy transfer to the upper level of a second set of states must be fast, relaxation to the lower level must be slow, and relaxation back to the initial state must be fast; these conditions lead to the creation of a population inversion between the two levels on the right-hand side of the energy level diagram. Figure 20.60 shows the energy level diagram for the Nd:YAG laser in which the lasing medium consists of a particular yttrium aluminum garnet, $Y_3Al_5O_{12}$ in which

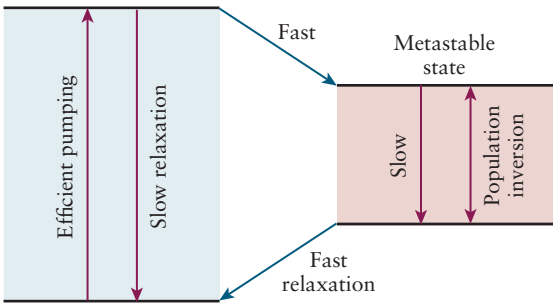

FIGURE 20.59 Mechanism of lasing. Peter Atkins, Julio de Paula. Physical Chemistry, W. H. Freeman and Company, New York 2010 p. 513.

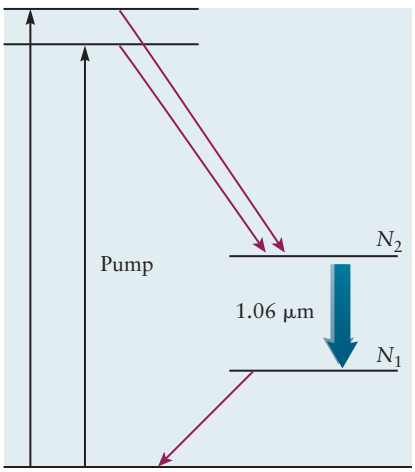

FIGURE 20.60 Nd:YAG laser operation. Peter Atkins, Julio de Paula. Physical Chemistry, W. H. Freeman and Company, New York 2010 p. 733.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

about 1% of the Y^{3+} ions have been replaced by Nd^{3+} ions. Two excited states lying relatively close in energy are pumped either by diode lasers at the appropriate wavelengths (808 nm is a popular choice) or by broadband diode lasers or flashlamps. Rapid nonradiative relaxation populates the N_2 level (with 3 unpaired electrons) creating the population inversion that results in lasing at 1.06 μm. Relaxation from the N_1 level back to the ground state of the system is rapid, as required to sustain the population inversion. Nd:YAG lasers are used in many of the applications cited earlier with the fundamental frequency (1.064 μm) multiplied in special crystals to produce radiation at shorter wavelengths. Frequency doubling produces the 532 nm green light of laser pointers whereas frequency tripling produces the 355 nm UV radiation used in the National Ignition Facility.

CHAPTER SUMMARY

Spectroscopy—understanding and exploiting the interactions between radiation and matter—has provided us with a suite of techniques with which to study the structures and reactions of molecules in environments that range from dilute gases in interstellar space to those in living cells. Each of the different kinds of motions of a molecule is quantized, and each can be selectively excited by the absorption of electromagnetic radiation of the appropriate frequency. The energies of the motions increase in the order: nuclear spin flips, molecular rotations, molecular vibrations, electronic excitations. They are excited by radiofrequency, microwave, infrared, and visible and ultraviolet radiation, respectively. We obtain bond lengths and angles, bond dissociation energies, and the energies of molecular orbitals from the spectra of molecules. Time-resolved methods allow us to follow molecular dynamics and chemical reactions on time scales as short as 10^{-14} seconds and imaging techniques provide molecularly specific information on length scales as short as 100 nm. Absorption of ultraviolet and visible radiation produces electronically excited states of molecules, the first step in a number of important processes in spectroscopy and photochemistry. Fluorescence spectroscopy is one of our most sensitive tools for detecting and imaging molecules. Energy and electron transfer are key steps in solar energy conversion processes, including photosynthesis. Understanding atmospheric photochemistry in greater detail will enable us to address problems of truly global scope—air pollution, ozone destruction, and climate change.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 20.1 – Introduction to Molecular Spectroscopy

Identify the different kinds of spectroscopic techniques based upon the information provided and the region of the electromagnetic spectrum involved. See Table 20.1.

State the Beer-Lambert law and use it to calculate the intensity of absorption, emission, or scattering (Problems 1, 2).

- The Beer-Lambert law is $I = I_o \exp[-(N/V)\sigma\ell]$ where (N/V) is the molecular number density, σ is a cross section measured in cm^2 $molecule^{-1}$ and ℓ is a path length measured in cm.

Use the Boltzmann distribution to calculate the population differences between two levels as a function of their energy difference and the temperature (Problems 3, 4).

- The Boltzmann distribution is $N_i/N \approx g_i \exp(-\varepsilon_i/k_BT)$ from which we calculate population differences using Equation 20.3.

Section 20.2 – Experimental Methods in Molecular Spectroscopy

Identify the essential components of a molecular spectroscopy experiment.

- Spectroscopy experiments require a source of electromagnetic radiation, an element that disperses the radiation spatially to select wavelengths, or an element that modulates the radiation in Fourier transform techniques, and a detector.

Section 20.3 – Rotational and Vibrational Spectroscopy

Calculate the energy levels and the separation between energy levels of a linear rigid rotor and predict the appearance of pure rotational spectra (Problems 5–8).

- The energy levels of a linear rigid rotor are given by

  $E_J = hc\tilde{B}J(J+1)$ where $\tilde{B}$ is a rotational constant in cm^{-1}.

  Only transitions for which $\Delta J = 1$ are allowed in absorption so the spectrum consists of a series of lines separated by $2\tilde{B}$ with relative intensities determined by the degeneracies of the two levels involved and the differences in their populations as given by the Boltzmann distribution.

Calculate bond lengths from rotational spectral data (Problems 5–8).

- The rotational constant, which is determined from the spacing between adjacent levels, is related to the moment of inertia by Equation 20.2b. The bond length is determined by substituting the reduced mass into the definition of the moment of inertia. See Example 20.2.

Describe rotational Raman spectroscopy and the appearance of a rotational Raman spectrum (Problems 8, 9).

- Only those transitions for which $\Delta J = 0, \pm 2$ are allowed in rotational Raman spectra of diatomic molecules. The appearance of the spectra depends upon the nuclear spins for homonuclear diatomic molecules as well as the relative populations of the levels that are determined by the degeneracies of the levels and the Boltzmann distribution.

Describe the harmonic oscillator model, calculate force constants from vibrational frequencies and reduced masses for diatomic molecules, and interpret vibrational frequencies in terms of force constants and reduced masses. (Problems 13–16).

- The harmonic oscillator model assumes that the potential energy function, $V(x) = \frac{1}{2}kx^2$, is given by Hooke's law.
- Solving the Schrödinger equation for this model problem gives a set of wave functions and a formula for calculating the quantized energy levels, which is $E_v = (v + \frac{1}{2}h\nu)$ where v is the vibrational quantum number and ν is the vibrational frequency of the oscillator. v can be 0, 1, 2, 3... and the term $\frac{1}{2}h\nu$ is the zero-point energy of the oscillator.
- The bond force constant is related to the vibrational frequency by $k = \mu(2\pi\nu)^2$.
- Vibrational frequencies are proportional to the square root of the force constant and inversely proportional to the square root of the reduced mass; they increase with increasing bond order, for a series of molecules with the same mass, such as C—C single, double and triple bonds, and decrease with increasing mass for a series of molecules with similar bond order and increasing mass, such as the hydrogen halides.

Describe the anharmonic oscillator model, the effects of anharmonicity on the appearance of infrared spectra, and how bond dissociation energies can be calculated from the spectra.

- The energy levels of an anharmonic oscillator are not equally spaced, they decrease with increasing v, and the harmonic oscillator selection rule $\Delta v = \pm 1$ is relaxed. A plot of the energy differences between adjacent levels as a function of the vibrational quantum number v is approximately a straight line; extrapolat-

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ing that straight line to the x intercept and taking the area under the curve gives the bond dissociation energy.

Describe the vibrational spectra of polyatomic molecules (Problems 23–26).

- A polyatomic molecule with N atoms has $3N - 5$ vibrational modes if the molecule is linear and $3N - 6$ vibrational modes if it is not. The vibrational frequencies of functional groups tend to be similar in many molecules and can be used for qualitative analysis.

20.4 – Nuclear Magnetic Resonance Spectroscopy

Describe the physical basis for NMR spectroscopy.

- Many nuclei have intrinsic magnetic moments that arise from their nuclear spin. The energy levels of a magnetic dipole in a magnetic field are quantized; they depend upon its orientation and the magnetic field strength.

Discuss what can be learned from NMR spectra (Problems 27–30).

- The chemical shift depends upon the charge density at the magnetic nucleus of interest as well as local fields induced by the interaction of the magnetic field with neighboring nuclei; it is characteristic of particular functional groups. The spin–spin splitting pattern identifies the number of protons on carbon atoms adjacent to the carbon atom to which the particular proton of interest is bound. Taken together, the chemical shifts and spin–spin splitting patterns allow chemists to locate functional groups within molecules and to determine molecular structures.

20.5 – Electronic Spectroscopy and Excited State Relaxation Processes

Use Beer's law to calculate concentration of an unknown solutions and determine molar extinction coefficients from absorption spectra (Problems 31–34).

- Beer's law is $A = \log(I/I_0) = \varepsilon c\ell$; the desired quantities can be determined from the available data by substitution.

Be able to identify the molecular orbitals of common chromophores, discuss the various kinds of transitions between them, and predict the wavelengths of maximum absorption for linear polyenes and aromatic compounds using particle-in-a-box models (Problems 54, 55 58–61).

- The frontier orbitals of organic chromophores include the $\sigma, \sigma^*, \pi, \pi^*$, and n orbitals. $\sigma \longrightarrow \sigma^*$ transitions occur in the UV, $\pi \longrightarrow \pi^*$ transitions for linear polyenes begin in the UV and shift toward the visible as the number of carbon atoms increases.

Describe how molecular photoelectron spectroscopy provides information about the bonding characteristics of molecular orbitals.

- The number and frequencies of the vibrational bands observed in the spectra provide information about the nature of the molecular ion, from which we can deduce the characteristics of the orbital from which the electron was removed. Few bands with frequencies close to that of the parent molecule indicate that the electron was ionized from a nonbonding orbital, many bands with frequencies lower than that of the parent molecule indicate that the electron came from a bonding orbital, and an intermediate number of bands with frequencies somewhat larger than that of the parent molecule indicate that the orbital was antibonding.

Identify and characterize the major radiative and nonradiative relaxation processes in molecules.

- Radiative processes include fluorescence, the emission of light resulting from transitions between states of the same spin, and phosphorescence, the emission of light resulting from transitions between states of different spin. Nonradiative

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

processes include internal conversion, relaxation between states of the same spin without emission and intersystem crossing, and relaxation between states of different spin. Energy is released in the form of heat in both cases.

Define the Franck–Condon principle and provide a physical interpretation.

- The Franck–Condon principle asserts that the most intense absorption band in a series that involves simultaneous electronic and vibrational excitation is the one in which the overlap of the vibrational wave functions in the ground and excited electronic states is the greatest. The principle is a consequence of the fact that nuclei move much more slowly than electrons and can be considered to be stationary during an electronic transition.

20.6 – Introduction to Atmospheric Chemistry

Identify the different regions of the atmosphere, current areas of concern and the physical processes involved (Problems 43–46).

- We are mostly concerned with the chemistry of the troposphere, the region of the atmosphere that extends from the surface of the Earth to an altitude of about 15 km, and the stratosphere, the region between 15 and 30 km. Air pollution is the chief area of concern in the troposphere, with the dominant sources being vehicle emissions and emissions from power plants and manufacturing. Oxides of nitrogen and sulfur are respiratory irritants and precursors to acid rain, which is damaging both to human health and physical structures like buildings, roads, and bridges. CFCs produced for use as refrigerants and propellants have depleted stratospheric ozone through a series of photochemical reactions that result in catalysis of the reaction $2O_3 \longrightarrow 3O_2$. Anthropogenic greenhouse gases, such as CO_2, CH_4, and N_2O are thought to be largely responsible for the increase in the temperature of the Earth that has been observed since the Industrial Revolution.

20.7 – Photosynthesis

Explain the mechanism by which photosynthetic bacteria and green plants convert light energy to chemical energy. (Problems 47–48).

- Visible light absorbed by chlorophyll molecules and accessory pigments is transferred to the photosynthetic reaction center where a series of light-driven and dark reactions produce carbohydrates and O_2 from CO_2 and H_2O.

20.8 – A Deeper Look . . . The Einstein Radiation Relations and Lasers

Explain the basis of the Einstein radiation relations and the chief conclusions of the analysis.

- Einstein assumed the existence of two kinds of processes, those that were stimulated by the presence of electromagnetic radiation and those that occurred independently of electromagnetic radiation. Considering the molecules and the radiation field to be in thermal equilibrium, with the relative populations of two levels being given by the Boltzmann distribution requires that the rates of stimulated absorption and emission be equal to one another and that the ratio of the rates of spontaneous emission to stimulated emission be given by $\frac{A_{21}}{B_{21}} = \frac{8\pi h\nu}{c^3}$.

CUMULATIVE EXERCISE

Bromine

Elemental bromine is a brownish-red liquid that was first isolated in 1826. It is currently produced by oxidation of bromide ion in natural brines with elemental chlorine.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) What is the ground-state configuration of the valence electrons of bromine molecules (Br_2)? Is bromine paramagnetic or diamagnetic?

(b) What is the electron configuration of the Br_2^+ molecular ion? Is its bond stronger or weaker than that in Br_2? What is its bond order?

(c) Bromine compounds have been known and used for centuries. The deep purple color that symbolized imperial power in ancient Rome originated with the compound dibromoindigo, which was extracted in tiny quantities from purple snails (about 8000 snails per gram of compound). What color and maximum wavelength of *absorbed* light would give a deep purple (violet) color?

(d) What excited electronic state is responsible for the brownish-red color of bromine? Refer to Figure 6.16.

(e) The two naturally occurring isotopes of bromine are ^{79}Br and ^{81}Br, with masses of 78.918 and 80.916 u, respectively. The wavelength of the $J = 0$ to $J = 1$ rotational transition in $^{79}Br^{81}Br$ is measured to be 6.18 cm. Use this information to calculate the bond length in the Br_2 molecule, and compare the result with that listed in Table 3.3.

(f) The wavelength of the vibrational transition in the $^{79}Br^{81}Br$ molecule is 3.09×10^{-5} m. Calculate the force constant for the bond in this molecule.

(g) The action of light on bromine compounds released into the air (such as by leaded gasoline) causes the formation of the BrO radical. Give the bond order of this species by comparing it with the related radical OF.

(h) There is concern that synthetic bromine-containing compounds, in addition to chlorofluorocarbons, are helping to destroy ozone in the stratosphere. The BrO [see part (g)] can take part with ClO in the following catalytic cycle:

$$Cl + O_3 \longrightarrow ClO + O_2$$

$$Br + O_3 \longrightarrow BrO + O_2$$

$$ClO + BrO \longrightarrow Cl + Br + O_2$$

Write the overall equation for this cycle.

Answers

(a) $(\sigma_{g4s})^2(\sigma^*_{u4s})^2(\sigma_{g4p_z})^2(\pi_{u4p})^4(\pi^*_{g4p})^4$; diamagnetic

(b) $(\sigma_{g4s})^2(\sigma^*_{u4s})^2(\sigma_{g4p_z})^2(\pi_{u4p})^4(\pi^*_{g4p})^3$; stronger; bond order is $\frac{3}{2}$ versus 1

(c) Yellow light, near 530 nm (see Figure 4.3)

(d) The lowest energy excited state, which arises from the excitation of an electron from the filled π^*_{g4p} orbital to the unfilled σ^*_{u4pz} orbital

(e) 2.28 Å (from Table 3.3: 2.286 Å)

(f) 247 J Nm^{-1}

(g) $\frac{3}{2}$ order

(h) Overall: $2\ O_3 \longrightarrow 3\ O_2$

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

1. Stratospheric ozone absorbs ultraviolet radiation (UVB) that is known to cause cancer in humans. The onset of the UVB region of the spectrum is 320 nm and the absorption cross section for ozone (O_3) that wavelength is about 5×10^{-20} cm^2 $molecule^{-1}$ (see Fig. 20.44). The average ozone number density in the stratosphere is about 5×10^{12} molecules cm^{-3}. What thickness of the ozone layer is required to absorb 90% of the UV radiation at 320 nm?

2. The absorption cross section for fluorescein, a dye that is used as a fluorescent probe for biological imaging (see the Chapter Opener figure on page 941), is 9.25×10^{-16} cm^2 $molecule^{-1}$ at 500 nm. How much light is transmitted through a 1-cm path length by a standard 10^{-6} M solution of fluorescein used to label biological samples?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

3. The vibrational frequency ν for H_2 is 4156 cm^{-1} and its rotational constant $\tilde{B}$ is 0.082 cm^{-1}. Calculate the relative populations of the $v = 1$ and $v = 0$ vibrational energy levels and the relative populations of the $J = 1$ and $J = 0$ rotational levels for H_2 at the operating temperature of the space shuttle's combustion chamber, which is 3300 °C. Comment on your results.

4. The vibrational frequency ν for Br_2 is 323 cm^{-1} and its rotational constant $\tilde{B}$ is 60.96 cm^{-1}. Calculate the relative populations of the $v = 1$ and $v = 0$ vibrational energy levels and the relative populations of the $J = 1$ and $J = 0$ rotational levels for Br_2 at 300 K. Comment on your results.

Rotational and Vibrational Spectroscopy

5. Use data from Tables 19.1 and 3.3 to predict the energy spacing between the ground state and the first excited rotational state of the $^{14}N^{16}O$ molecule.

6. Use data from Tables 19.1 and 3.3 to predict the energy spacing between the ground state and the first excited rotational state of the $^{1}H^{19}F$ molecule.

7. The first three absorption lines in the pure rotational spectrum of gaseous $^{12}C^{16}O$ are found to have the frequencies 1.15×10^{11}, 2.30×10^{11}, and 3.46×10^{11} s^{-1}. Calculate:
   (a) The moment of inertia I of CO (in kg m^2)
   (b) The energies of the $J = 1$, $J = 2$, and $J = 3$ rotational levels of CO, measured from the $J = 0$ state (in joules)
   (c) The C—O bond length (in angstroms)

8. Four consecutive absorption lines in the pure rotational spectrum of gaseous $^{1}H^{35}Cl$ are found to have the frequencies 2.50×10^{12}, 3.12×10^{12}, 3.74×10^{12}, and 4.37×10^{12} s^{-1}. Calculate:
   (a) The moment of inertia I of HCl (in kg m^2)
   (b) The energies of the $J = 1$, $J = 2$, and $J = 3$ rotational levels of HCl, measured from the $J = 0$ state (in joules)
   (c) The H—Cl bond length (in angstroms)
   (d) The initial and final J states for the observed absorption lines

9. The rotational constant $\tilde{B} = 1.45$ cm^{-1} for O_2. Calculate the O_2 bond length and predict the appearance of its rotational Raman spectrum, recalling that transitions between states with even J are forbidden due to nuclear spin statistics considerations.

10. The rotational constant $\tilde{B}$ of $^{7}Li_2$ is 0.6727 cm^{-1}. Calculate the $^{7}Li_2$ bond length and predict the appearance of its rotational Raman spectrum without the effect of nuclear spin statistics on the relative intensities of the lines. Compare your results with those of Example 20.4.

11. In Example 20.3, we determined that the moment of inertia of the NaH molecule is 5.70×10^{-47} kg m^2.
   (a) Calculate the relative population of the $J = 5$ level and the ground state at 25°C.
   (b) Calculate the relative population of the $J = 15$ level and the ground state at 25°C.
   (c) Calculate the relative population of the $J = 25$ level and the ground state at 25°C.

12. The rotational constant for $^{14}N_2$, measured for the first time using rotational Raman spectroscopy (see Fig. 20.8), is 1.99 cm^{-1}. Calculate (a) the moment of inertia I of N_2 in kg m^2 (b) The energies of the first three excited rotational levels, relative to that of the ground level, in wave numbers (c) The frequency of the $J = 0 \longrightarrow J = 1$ transition in GHz.

13. The Li_2 molecule (^{7}Li isotope) shows a very weak infrared line in its vibrational spectrum at a wavelength of 2.85×10^{-5} m. Calculate the force constant for the Li_2 molecule.

14. The Na_2 molecule (^{23}Na isotope) shows a very weak infrared line in its vibrational spectrum at a wavelength of 6.28×10^{-5} m. Calculate the force constant for the Na_2 molecule, and compare your result with that of problem 13. Give a reason for any difference.

15. The "signature" infrared absorption that indicates the presence of a C—H stretching motion in a molecule occurs at wavelengths near 3.4×10^{-6} m. Use this information to estimate the force constant of the C—H stretch. Take the reduced mass in this motion to be approximately equal to the mass of the hydrogen atom (a good approximation when the H atom is attached to a heavy group).

16. Repeat the calculation of the preceding problem for the N—H stretch, where absorption occurs near 2.9×10^{-6} m. Which bond is stiffer: N—H or C—H?

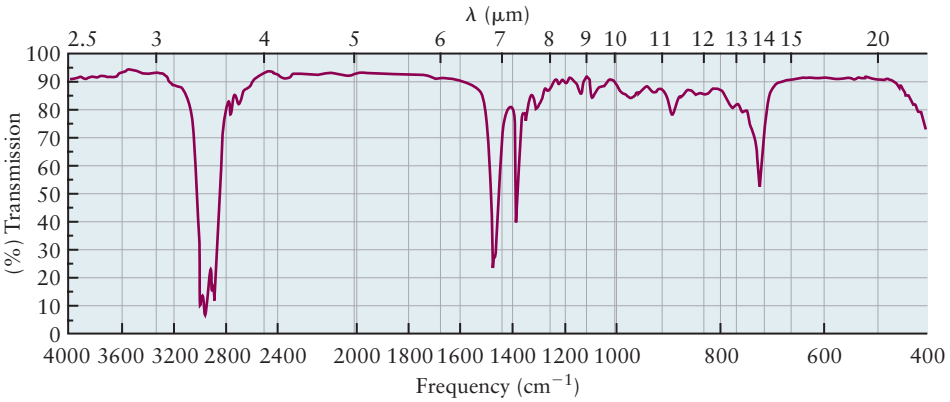
17. Estimate the ratio of the number of molecules in the first excited vibrational state of the molecule N_2 to the number in the ground state, at a temperature of 450 K. The vibrational frequency of N_2 is 7.07×10^{13} s^{-1}.

18. The vibrational frequency of the ICl molecule is 1.15×10^{13} s^{-1}. For every million (1.00×10^{6}) molecules in the ground vibrational state, how many will be in the first excited vibrational state at a temperature of 300 K?

19. The measured vibrational frequencies for the hydrogen halides given in Section 20.3 are: $^{1}H^{19}F$ (4139 cm^{-1}); $^{1}H^{35}Cl$ (2991 cm^{-1}); $^{1}H^{81}Br$ (2449 cm^{-1}); and $^{1}H^{127}I$ (2308 cm^{-1}). Calculate the force constants for each molecule, using the vibrational frequencies given and the atomic masses provided in Table 19.1. Which is the more important factor in determining the vibrational frequencies in this series of molecules, the force constants or the reduced masses?

20. The vibrational frequencies for the mixture of gases shown in the Chapter 3 *Connection to Instrumental Analysis* include: H_2 (4160 cm^{-1}) N_2 (2331 cm^{-1}) CO (2143 cm^{-1}), and O_2 (1550 cm^{-1}). What can you conclude about the bond orders by inspection? Calculate the force constants for each molecule to check the accuracy of your estimate.

21. Substitution of hydrogen by deuterium is a convenient way to label organic molecules at specific sites for the purpose of investigating reaction mechanisms. At what frequency would the C—D stretch of a phenyl ring appear if the frequency of the C—H stretch is 3062 cm^{-1}?



22. ^{13}C is also used as a label in organic chemistry. What is the frequency of a $^{12}C—^{13}C$ single bond stretch if the frequency of the corresponding $^{12}C—^{12}C$ stretch appears at 1053 cm^{-1}?

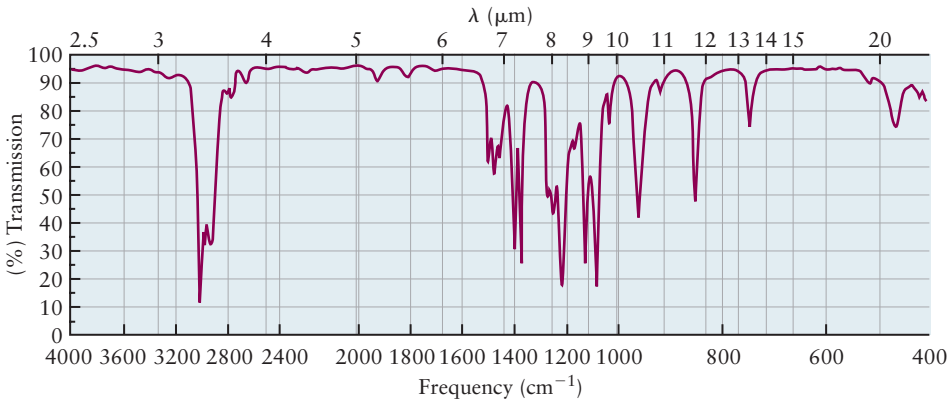
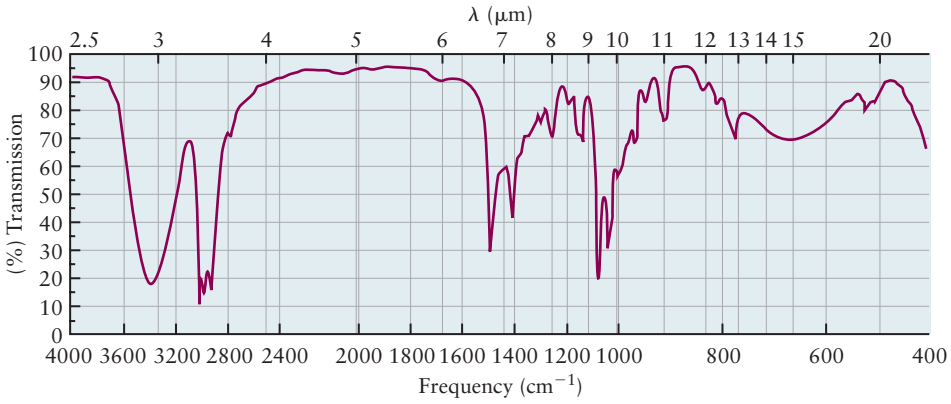
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

23. How many normal vibrational modes does each of the following molecules have?
(a) NH_3
(b) C_2H_4
(c) CCl_2F_2
(d) CH_3CH_2OH

24. Consider the vibrations of the molecules in the previous problem from a localized point of view, as the vibrations of individual bonds. Infrared absorption is proportional to the permanent dipole moment of each individual bond. Which of the molecules will absorb IR radiation most strongly and why?



25. The IR spectra of nonane (C_9H_{20}) and 1-hexanol ($C_6H_{13}OH$) are shown below. Assign each spectrum to the correct compound and identify the frequencies and the functional groups used to support your assignment.



26. The IR spectrum of 2-methyl-1-butanol ($H_3CCH_2CH_2(CH_3)CH_2OH$) and *tert*-butyl methyl ether [$(CH_3)_3OCH_3$] are shown on p. 1027. Assign each spectrum to the correct compound and identify the frequencies and the functional groups used to support your assignment.

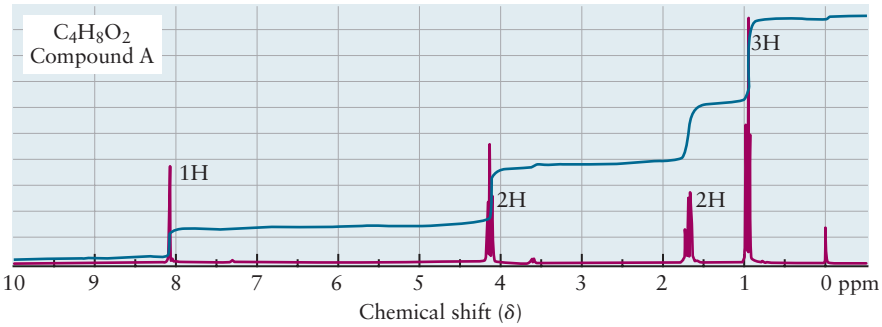
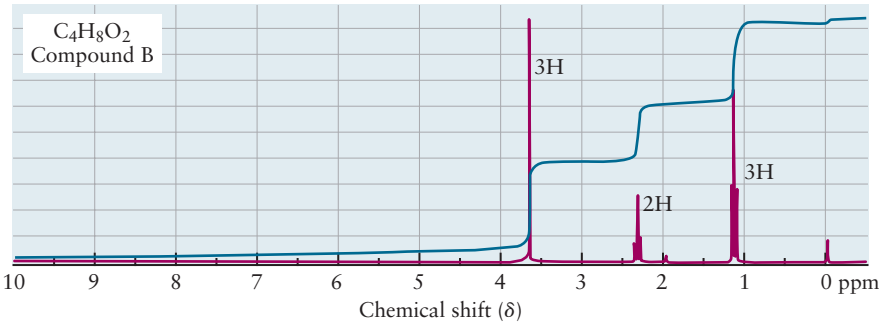
Nuclear Magnetic Resonance Spectroscopy

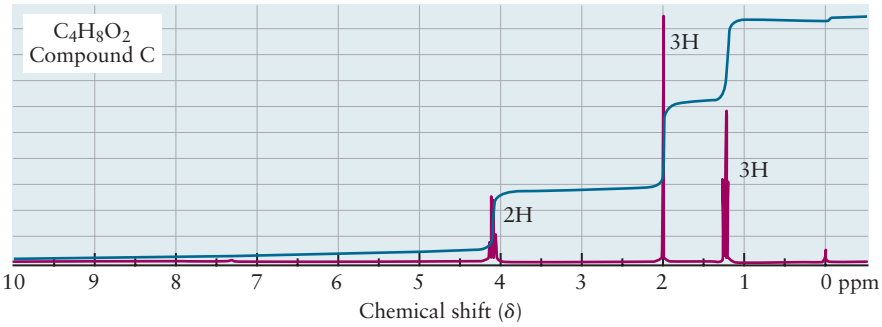
27. Give the number of peaks and the relative peak areas that should be observed in the low-resolution proton magnetic resonance spectra of the following molecules:



$CH_3CH_2CH_2CH_3$, CH_3OCH_3, CH_3NHCH_3.



28. The organic compound 1,4-dimethylbenzene (also known as *p*-xylene) has the formula $(CH_3)_2C_6H_4$. Its structure has two CH_3 (methyl) groups substituted at opposite positions on the benzene (C_6H_6) ring. Predict the number of peaks in the low-resolution proton NMR spectrum of this compound and the relative areas of the peaks.



29. The NMR spectrum of a molecule closely related to that discussed in Example 20.9 has the molecular formula $C_7H_{14}O$. The ^1H NMR spectrum shows three single peaks at $\delta = 1.01$, 2.11, and 2.32 with peak areas in the ratio 9:3:2, respectively. What is the structure of the molecule?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

30. Identify the three molecules with the molecular formula $C_4H_8O_2$ from their NMR spectrum shown below. Hint: they are all esters.

Introduction to Molecular Spectroscopy

31. The percentage transmittance of light at 250 nm through a certain aqueous solution is 20.0% at 25°C. The experimental cell length is 1.0 cm, and the concentration of the solution is 5×10^{-4} mol L^{-1}. Calculate the absorbance. Calculate the molar absorption coefficient.

32. Beer's law is used to measure the concentration of species in solutions, once a "standardization curve" has been prepared for that species. In one such experiment, percent transmission was measured for a series of solutions with known concentrations and the results were as follows:

Concentration μg mL^{-1}	1.0	2.0	3.0	4.0	5.0
Transmission, percent	66.8	44.7	29.2	19.9	13.3

Plot these results to obtain the standardization curve. An unknown concentration of the same species, measured in the same transmission cell, transmitted 35% of the incoming light. Calculate the concentration of the unknown solution.

33. Beer's law can be used to determine the concentration of two substances *A* and *B* in solution, provided they do not react or interact, so they absorb radiation independently. The following data were obtained for *A* and *B* in three different solutions:

	[A] mol L^{-1}	[B] mol L^{-1}	% Transmittance at λ = 400 nm	% Transmittance at λ = 500 nm
Solution 1	0.0010	0	10.0	60.0
Solution 2	0	0.0050	80.0	20.0
Solution 3	?	?	40.0	50.0

Calculate the concentrations of A and B in Solution 3.

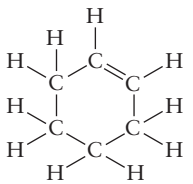
Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

34. The absorption of ultraviolet light by proteins at wavelength 280 nm is caused mostly by the amino acids tyrosine and tryptophan along the protein molecular chains. The molecular absorption coefficients for these two amino acids are:

$$\epsilon_{tryp}^{280} = 5690 \text{ L cm}^{-1} \text{ mol}^{-1}$$
$$\epsilon_{tyro}^{280} = 1280 \text{ L cm}^{-1} \text{ mol}^{-1}$$

Experiments are carried out on a protein with molecular weight 26,000, which contains two units of tryptophan and six units of tyrosine along the chain. The absorption is measured in a cell 1 cm long, and the protein concentration is 1.0 mg mL^{-1}. Calculate the absorbance and the percent transmission.

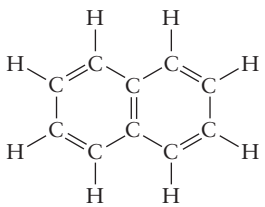
Electronic Spectroscopy and Excited State Relaxation Processes



35. Suppose that an ethylene molecule gains an additional electron to give the $C_2H_4^-$ ion. Will the bond order of the carbon–carbon bond increase or decrease? Explain.

36. Suppose that an ethylene molecule is ionized by a photon to give the $C_2H_4^+$ ion. Will the bond order of the carbon–carbon bond increase or decrease? Explain.

37. The color of the dye "indanthrene brilliant orange" is evident from its name. In what wavelength range would you expect to find the maximum in the absorption spectrum of this molecule? Refer to the color spectrum in Figure 4.3.



38. In what wavelength range would you expect to find the maximum in the absorption spectrum of the dye "crystal violet"?

39. The structure of the molecule cyclohexene is shown below:

Does the absorption of ultraviolet light by cyclohexene occur at shorter wavelengths than in benzene? Explain.

40. The naphthalene molecule has a structure that corresponds to two benzene molecules fused together:

The π-electrons in this molecule are delocalized over the entire molecule. The wavelength of maximum absorption in the UV-visible part of the spectrum in benzene is 255 nm. Is the corresponding wavelength shorter or longer than 255 nm for naphthalene?

41. Use data from Table 3.3 to give an upper bound on the wavelengths of light that are capable of dissociating a molecule of ClF.

42. Use data from Table 3.3 to give an upper bound on the wavelengths of light that are capable of dissociating a molecule of ICl.

Introduction to Atmospheric Chemistry

43. The bond dissociation energy of a typical C—F bond in a chlorofluorocarbon is approximately 440 kJ mol^{-1}. Calculate the maximum wavelength of light that can photodissociate a molecule of CCl_2F_2, breaking such a C—F bond.

44. The bond dissociation energy of a typical C—Cl bond in a chlorofluorocarbon is approximately 330 kJ mol^{-1}. Calculate the maximum wavelength of light that can photodissociate a molecule of CCl_2F_2, breaking such a C—Cl bond.

45. Draw a Lewis diagram(s) for the ozone molecule (O_3). Determine the steric number and hybridization of the central oxygen atom, and identify the molecular geometry. Describe the nature of the π bonds and give the bond order of the O—O bonds in ozone.

46. The compounds carbon dioxide (CO_2) and sulfur dioxide (SO_2) are formed by the burning of coal. Their apparently similar formulas mask underlying differences in molecular structure. Determine the shapes of these two types of molecules, identify the hybridization at the central atom of each, and compare the natures of their π bonds.

Photosynthesis

47. One way in which photosynthetic bacteria store chemical energy is through the conversion of a compound called adenosine diphosphate (ADP), together with hydrogen phosphate ion, to adenosine triphosphate (ATP):

$$ADP^{3-} + HPO_4^{2-} + H_3O^+ \longrightarrow ATP^{4-} + 2\ H_2O$$
$$\Delta G = +34.5 \text{ kJ (pH 7)}$$

Suppose some chlorophyll molecules absorb 1.00 mol of photons of blue light with wavelength 430 nm. If *all* this energy could be used to convert ADP to ATP at room conditions and pH 7, how many molecules of ATP would be produced per photon absorbed? (The actual number is smaller because the conversion is not 100% efficient.)

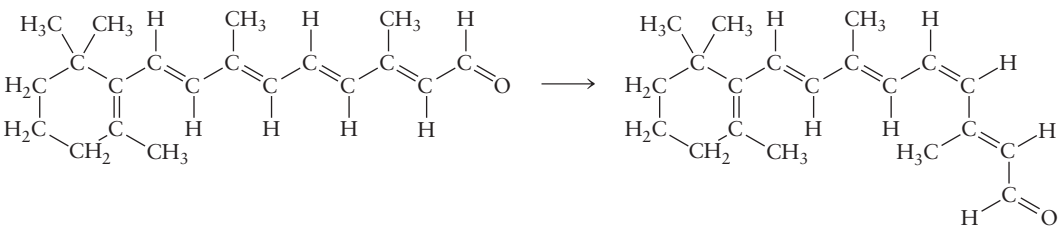
48. Repeat the calculation of the preceding problem for red light with wavelength 700 nm.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ADDITIONAL PROBLEMS

49. What are the moments of inertia of $^{1}H^{19}F$ and $^{1}H^{81}Br$, expressed in kg m^2? Compute the spacings $\nu = \Delta E/h$ of the rotational states, in s^{-1}, between $J = 0$ and 1 and between $J = 1$ and 2. Explain, in one sentence, why the large change in mass from 19 to 81 causes only a small change in rotational energy differences.

50. The average bond length of a molecule can change slightly with vibrational state. In $^{23}Na^{35}Cl$, the frequency of light absorbed in a change from the $J = 1$ to the $J = 2$ rotational state in the ground vibrational state ($n = 0$) was measured to be $\nu = 2.60511 \times 10^{10}$ s^{-1}, and that for a change from $J = 1$ to $J = 2$ in the first excited vibrational state ($n = 1$) was $\nu = 2.58576 \times 10^{10}$ s^{-1}. Calculate the average bond lengths of NaCl in these two vibrational states, taking the relative atomic mass of ^{23}Na to be 22.9898 and that of ^{35}Cl to be 34.9689.



51. The vibrational frequencies of $^{23}Na^{1}H$, $^{23}Na^{35}Cl$, and $^{23}Na^{127}I$ are 3.51×10^{13} s^{-1}, 1.10×10^{13} s^{-1}, and 0.773×10^{13} s^{-1}, respectively. Their bond lengths are 1.89 Å, 2.36 Å, and 2.71 Å. What are their reduced masses? What are their force constants? If NaH and NaD have the same force constant, what is the vibrational frequency of NaD? D is ^{2}H.

52. Recall that nuclear spin states in nuclear magnetic resonance are typically separated by energies of 2×10^{-5} kJ mol^{-1} to 2×10^{-4} kJ mol^{-1}. What are the ratios of occupation probability between a pair of such levels at thermal equilibrium and a temperature of 25°C?

53. The vibrational temperature of a molecule prepared in a supersonic jet can be estimated from the observed populations of its vibrational levels, assuming a Boltzmann distribution. The vibrational frequency of HgBr is 5.58×10^{12} s^{-1}, and the ratio of the number of molecules in the $n = 1$ state to the number in the $n = 0$ state is 0.127. Estimate the vibrational temperature under these conditions.

54. An electron in the π orbital of ethylene (C_2H_4) is excited by a photon to the π^* orbital. Do you expect the equilibrium bond length in the excited ethylene molecule to be greater or less than that in ground-state ethylene? Will the vibrational frequency in the excited state be higher or lower than in the ground state? Explain your reasoning.

55. One isomer of retinal is converted to a second isomer by the absorption of a photon:

This process is a key step in the chemistry of vision. Although free retinal (in the form shown to the left of the arrow) has an absorption maximum at 376 nm, in the ultraviolet region of the spectrum this absorption shifts into the visible range when the retinal is bound in a protein, as it is in the eye.

(a) How many of the C=C bonds are *cis* and how many are *trans* in each of the preceding structures? (When assigning labels, consider the relative positions of the two largest groups attached at each double bond.) Describe the motion that takes place upon absorption of a photon.

(b) If the ring and the −CHO group in retinal were replaced by $-CH_3$ groups, would the absorption maximum in the molecule shift to longer or shorter wavelengths?

* 56. The ground-state electron configuration of the H_2^+ molecular ion is $(\sigma_{g1s})^1$.

(a) A molecule of H_2^+ absorbs a photon and is excited to the σ^*_{u1s} molecular orbital. Predict what happens to the molecule.

(b) Another molecule of H_2^+ absorbs even more energy in an interaction with a photon and is excited to the σ_{g2s} molecular orbital. Predict what happens to this molecule.

* 57. (a) Draw a Lewis diagram for formaldehyde (H_2CO), and decide the hybridization of the central carbon atom.

(b) Formulate the molecular orbitals for the molecule.

(c) A strong absorption is observed in the ultraviolet region of the spectrum and is attributed to a $\pi \longrightarrow \pi^*$ transition. Another, weaker transition is observed at lower frequencies. What electronic excitation causes the weaker transition?

58. Write balanced chemical equations that describe the formation of nitric acid and sulfuric acid in rain, starting with the sulfur in coal and the oxygen, nitrogen, and water vapor in the atmosphere.

59. Compare and contrast the roles of ozone (O_3) and nitrogen dioxide (NO_2) in the stratosphere and in the troposphere.

60. Describe the greenhouse effect and its mechanism of operation. Give three examples of energy sources that contribute to increased CO_2 in the atmosphere and three that do not.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

61. Draw a schematic diagram of the steps in bacterial photosynthesis, numbering them in sequence and showing the approximate spatial relations of the involved molecules.

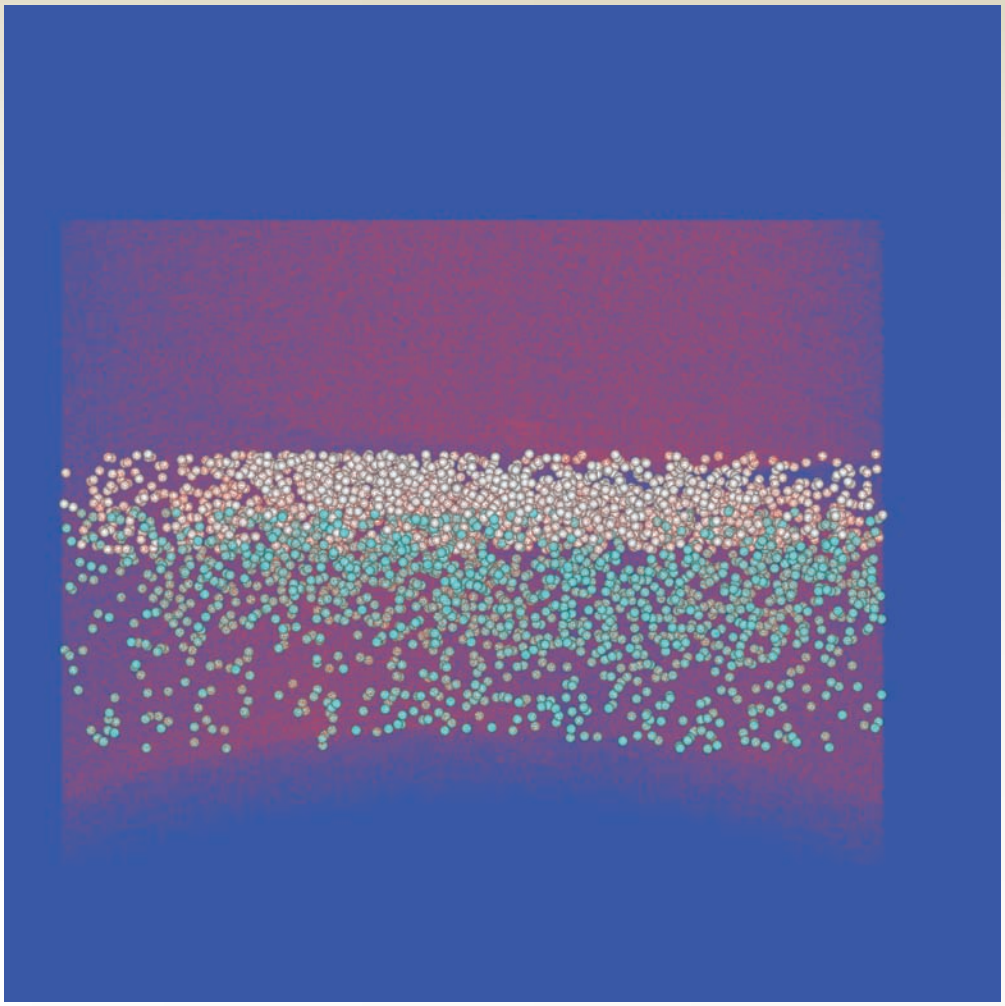
62. Do you expect the energy of the special pair of bacteriochlorophyll molecules to be higher or lower than the energy of an isolated bacteriochlorophyll? (*Hint:* Think about the analogy between the mixing of atomic orbitals to make molecular orbitals and the mixing of molecular orbitals on two nearby molecules.)

CUMULATIVE PROBLEMS

63. At thermal equilibrium, is the rate as a molecule is excited from $n = 0$ to the $n = 1$ level greater than or less than the rate for the reverse process? What is the ratio of the rate constants? (*Hint:* Think of the analogy with the chemical equilibrium between two species.)

* 64. It is important to know the dissociation constant of an indicator in order to use it properly in acid–base titrations. Spectrophotometry can be used to measure the concentration of these intensely colored species in acidic versus basic solutions, and from these data the equilibrium between the acidic and basic forms can be calculated. In one such study on the indicator *m*-nitrophenol, a 6.36×10^{-4} M solution was examined by spectrophotometry at 390 nm and 25°C in the following experiments. In highly acidic solution, where essentially all the indicator was in the form HIn, the absorbance was 0.142. In highly basic solution, where essentially all of the indicator was in the form In^-, the absorbance was 0.943. In a further series of experiments, the pH was adjusted using a buffer solution of ionic strength I, and absorbance was measured at each pH value. The following results were obtained:

pH	I	A
8.321	0.10	0.527
8.302	0.08	0.518
8.280	0.06	0.505
8.251	0.04	0.493
8.207	0.02	0.470



Calculate pK_a for the indicator at each value of ionic strength.

65. The hydroxyl radical has been referred to as the "chief clean-up agent in the troposphere." Its concentration is approximately zero at night and becomes as high as 1×10^7 molecules per cm^3 in highly polluted air.
   (a) Calculate the maximum mole fraction and partial pressure of OH in polluted air at 25°C and atmospheric pressure.
   (b) Write an equation for the reaction of HO with NO_2 in the atmosphere. How does the oxidation state of nitrogen change in this reaction? What is the ultimate fate of the product of this reaction?

66. In unpolluted air at 300 K, the hydroxyl radical OH reacts with CO with a bimolecular rate constant of 1.6×10^{11} L mol^{-1} s^{-1} and with CH_4 with a rate constant of 3.8×10^9 L mol^{-1} s^{-1}. Take the partial pressure of CO in air to be constant at 1.0×10^{-7} atm and that of CH_4 to be 1.7×10^{-6} atm, and assume that these are the primary mechanisms by which OH is consumed in the atmosphere. Calculate the half-life of OH under these conditions.

Throughout history, the discovery of new materials from which to fashion the structures, machines, and devices of everyday life has set off great change in human affairs. Modern science and engineering—with chemistry in the central role—provide routes for modifying properties of materials to meet specific applications and for synthesizing and processing new materials designed from the beginning to have specific properties. The mechanical, thermal, electrical, and optical properties of a material depend on the extended nano-structural arrangement of chemical bonds within it. This arrangement can be created, modified, and tailored through chemical reactions. The contemporary disciplines of materials chemistry, solid state chemistry, and materials science and engineering—among the most active branches of chemistry today—all rely on the "properties↔structure↔reactions" correlation to make the leap from chemical bonding in isolated molecules (Unit II) to engineering applications.

UNIT CHAPTERS

CHAPTER 21
Structure and Bonding in Solids

CHAPTER 22
Inorganic Materials

CHAPTER 23
Polymeric Materials and Soft Condensed Matter

UNIT GOALS

- To study the relationship between crystal symmetry and atomic-level structure as revealed by X-ray diffraction experiments
- To survey chemical bonding in classes of solids and correlate bonding with the properties of solids
- To explore three essential classes of materials—ceramics, optical and electronic materials, and polymers
- To illustrate the role of modern chemistry in measuring properties and identifying applications for both natural and manufactured materials

Pairs of silicon atoms separated by only 0.78 Å are clearly resolved in this ultrahigh-resolution electron microscope image.

In this chapter we begin a radical departure from the emphasis on the single molecule that permeates the previous twenty chapters. Unit II describes the chemical bonding and structure of single, isolated molecules. Unit III explains the macroscopic properties of gases and liquids through intermolecular forces that originate in the structures of individual molecules. While the behavior of many molecules contributes to these properties, the mechanism of their contribution is essentially that a few molecules come close enough to a "target" molecule to experience the intermolecular forces it sets up. Units IV and V deal with the equilibrium and rate aspects of chemical reactions as consequences of collisions between individual molecules.

Charles D. Winters

FIGURE 21.1 Calcite.

The behavior of solids is a different story altogether. Chapter 10 identifies *rigidity* as the unique characteristic of solids, in dramatic contrast to the fluidity of gases and liquids. A rigid material retains its shape when an external mechanical force, called stress, is applied. A rigid material shows structural strength by not flowing under stress. All classes of solids behave this way because—with one exception—they are not collections of molecules held together by intermolecular forces. Rather, solids are extended arrays of strong chemical bonds between atoms, almost as if they were "super-molecules." These arrays extend over macroscopic distances, and it is the *collective behavior* of this set of chemical bonds that imparts strength and rigidity to solids.

Solids whose structures are highly ordered and symmetrical over macroscopic distances are called **crystals.** Although the symmetry and beauty of crystals have always excited curiosity and wonder, the science of **crystallography** began only in the latter part of the 18th century. In those closing days of the Age of Enlightenment—while Lavoisier led the modern approach to chemistry—another brilliant French thinker established the fundamental laws of crystallography. René-Just Haüy was struck by the observation that when he accidentally dropped a crystal of calcite (a form of calcium carbonate), it fractured into smaller crystals with the same interfacial angles between their planar surfaces as in the original crystal. The statement that constant interfacial angles are observed when crystals are cleaved is now known as **Haüy's law.** Haüy concluded that the outward symmetry of crystals (Fig. 21.1) implies a highly regular internal structure and the existence of a smallest crystal unit. His inferences were correct. What distinguishes the crystalline state from the gaseous and liquid states is the nearly perfect positional order of the atoms, ions, or molecules in crystals. This crystalline order has been confirmed experimentally by X-ray diffraction and explained theoretically by the quantum theory of solids.

We begin this chapter with a look at the microscopic structure of a perfect crystal, and establish the methods for determining structure and the language for describing it. We then examine the types of chemical bonding in solids, identifying the forces that hold together different kinds of solids. The perfect crystal is the idealized model for investigations in solid state science, just as the ideal gas is the starting point for studies of fluid behavior. We use it as the point of reference for describing less ordered condensed phases of matter—defective crystals and amorphous solids—in terms of their deviations from perfect order and the consequent changes in properties. We end the chapter with a brief introduction to diffusion in solids, the mechanism by which a free atom migrates through an extended solid state structure. Diffusion has great influence on the rate and equilibrium of chemical reactions in the solid state and on tailoring the properties of the solids through carefully controlled incorporation of impurities.

21.1 CRYSTAL SYMMETRY AND THE UNIT CELL

The unifying aspect of crystal structure is the repetition, over long distances, of the same basic structural features in the arrangement of the atoms. The most fundamental way to characterize and classify these structures is based on the numbers and kinds of their **symmetry elements.** When the result of rotation, reflection, or inversion of an object can be exactly superimposed on the original object—that is, matched point for point to the original object—the structure is said to contain the corresponding symmetry element. Examples include an axis of rotation, a plane of reflection (mirror plane), or a central point (inversion center), as shown in Figure 21.2. These symmetry operations can be applied to geometrical shapes, to physical objects, and to molecular structures.

Consider a cube as an example. Suppose the center of the cube is placed at the origin of its coordinate system and the symmetry operations that transform it into

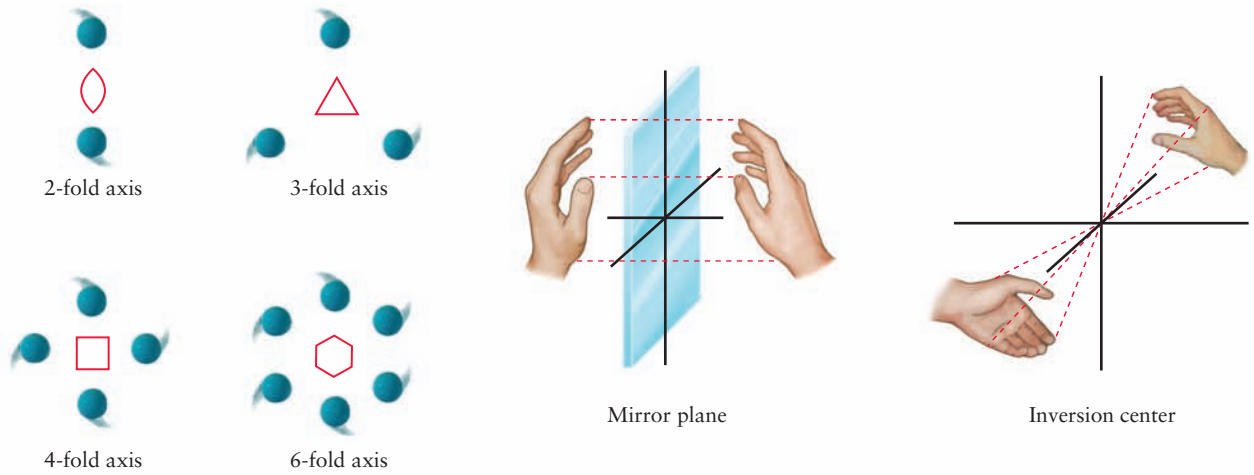

FIGURE 21.2 Three types of symmetry operation: rotation about an *n*-fold axis, reflection in a plane, and inversion through a point.

identity with itself are counted (Fig. 21.3). The *x*, *y*, and *z* coordinate axes are 4-fold axes of rotational symmetry, denoted by C_4, because a cube that is rotated through a multiple of 90° (= 360°/4) about any one of these axes is indistinguishable from the original cube. Similarly, a cube has four 3-fold axes of rotational symmetry, designated C_3, that are the body diagonals of the cube, connecting opposite vertices. In addition, a cube has six 2-fold rotational axes of symmetry, defined by the six axes that pass through the centers of edges and through the coordinate origin. Next, the cube has nine mirror planes of symmetry (designated by the symbol *m*), which reflect any point in one half of the cube into an equivalent point in the other half. Finally, a cube has a center of inversion (reflection through a point, designated *i*).

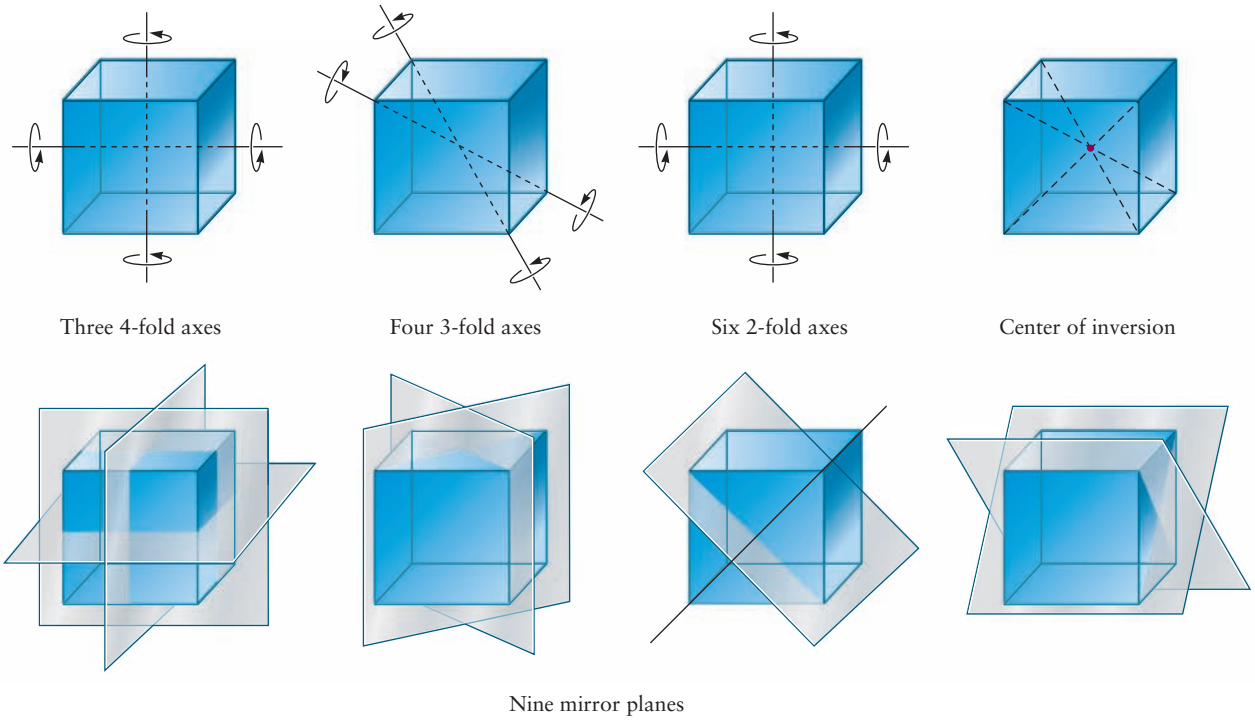

FIGURE 21.3 Symmetry operations on a cube. There are three 4-fold axes, only two of which are shown, four 3-fold axes, only two of which are shown, and six 2-fold axes, only two of which are shown. The rest can be determined by connecting equivalent pairs of points by inspection.

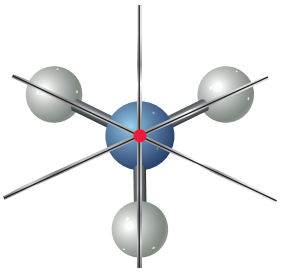

FIGURE 21.4 An ammonia molecule has a 3-fold axis rotation axis and three mirror planes. The rotation axis is represented by the red dot, which indicates that the rotation occurs around an axis perpendicular to the plane of the page. The three mirror planes are also oriented perpendicular to the plane of the page.

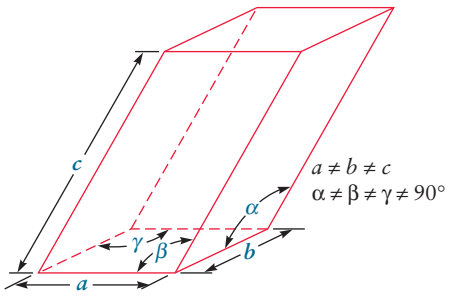
EXAMPLE 21.1

Identify the symmetry elements of the ammonia molecule (NH_3).

Solution

If the ammonia molecule is drawn as a pyramid with the nitrogen atom at the top (Fig. 21.4), then the only axis of rotational symmetry is a 3-fold axis passing downward through the N atom. Three mirror planes intersect at this 3-fold axis.



Related Problems: 3, 4

Unit Cells in Crystals

The symmetry operations just described can be applied to crystals as well as to individual molecules or shapes. Identical sites within a crystal recur regularly because of long-range order in the organization of the atoms. The three-dimensional array made up of all the points within a crystal that have the same environment in the same orientation is a **crystal lattice.** Such a lattice is an abstraction "lifted away" from a real crystal, embodying the scheme of repetition at work in that crystal. The lattice of highest possible symmetry is that of the **cubic system.** This lattice is obtained by filling space with a series of identical cubes, which are the **unit cells** in the system. A single unit cell contains all structural information about its crystal, because in principle the crystal could be constructed by making a great many copies of a single original unit cell and stacking them in a three-dimensional array. Unit cells fill space.

Other crystal systems besides cubic can be defined by their own unique unit cells. Constraints of symmetry permit only seven types of three-dimensional lattices. Each type has a unit cell with the shape of a parallelepiped (Fig. 21.5), whose size and shape are fully described by three edge lengths (*a*, *b*, and *c*) and the three angles between those edges (α, β, and γ). These lengths and angles are the **cell constants.** The symmetry that defines each of the seven crystal systems imposes conditions on the shape of the unit cell summarized in relations among the cell constants (Table 21.1, Fig. 21.6). The unit cell chosen is the smallest unit that has all the symmetry elements of the crystal lattice; there is no benefit in using large cells once all the symmetry elements have been included. A unit cell of the minimum size is **primitive** and shares each of the eight **lattice points** at its corners with seven other unit cells, giving one lattice point per unit cell.

Other possible unit cells with the same volume (an infinite number, in fact) could be constructed, and each could generate the macroscopic crystal by repeated elementary translations, but only those shown in Figure 21.6 possess the symmetry

Triclinic

FIGURE 21.5 Unit cells always have three pairs of mutually parallel faces. Only six pieces of information are required to construct a scale model of a unit cell: the three cell edges (*a, b,* and *c*) and the three angles between the edges (α, β, and γ). By convention, γ is the angle between edges *a* and *b*, α the angle between *b* and *c*, and β the angle between *a* and *c*.

TABLE 21.1

The Seven Crystal Systems

Crystal System	Minimum Essential Symmetry	Conditions on Unit-Cell Edges and Angles
Hexagonal	One 6-fold rotation	$a = b$; $\alpha = \beta = 90°$, $\gamma = 120°$
Cubic	Four independent 3-fold rotations†	$a = b = c$; $\alpha = \beta = \gamma = 90°$
Tetragonal	One 4-fold rotation	$a = b$; $\alpha = \beta = \gamma = 90°$
Trigonal	One 3-fold rotation	$a = b = c$; $\alpha = \beta = \gamma \neq 90°$
Orthorhombic	Three mutually perpendicular 2-fold rotations	$\alpha = \beta = \gamma = 90°$
Monoclinic	One 2-fold rotation	$\alpha = \beta = 90°$
Triclinic	No symmetry required	None

†Each of these axes makes 70.53° angles with the other three.

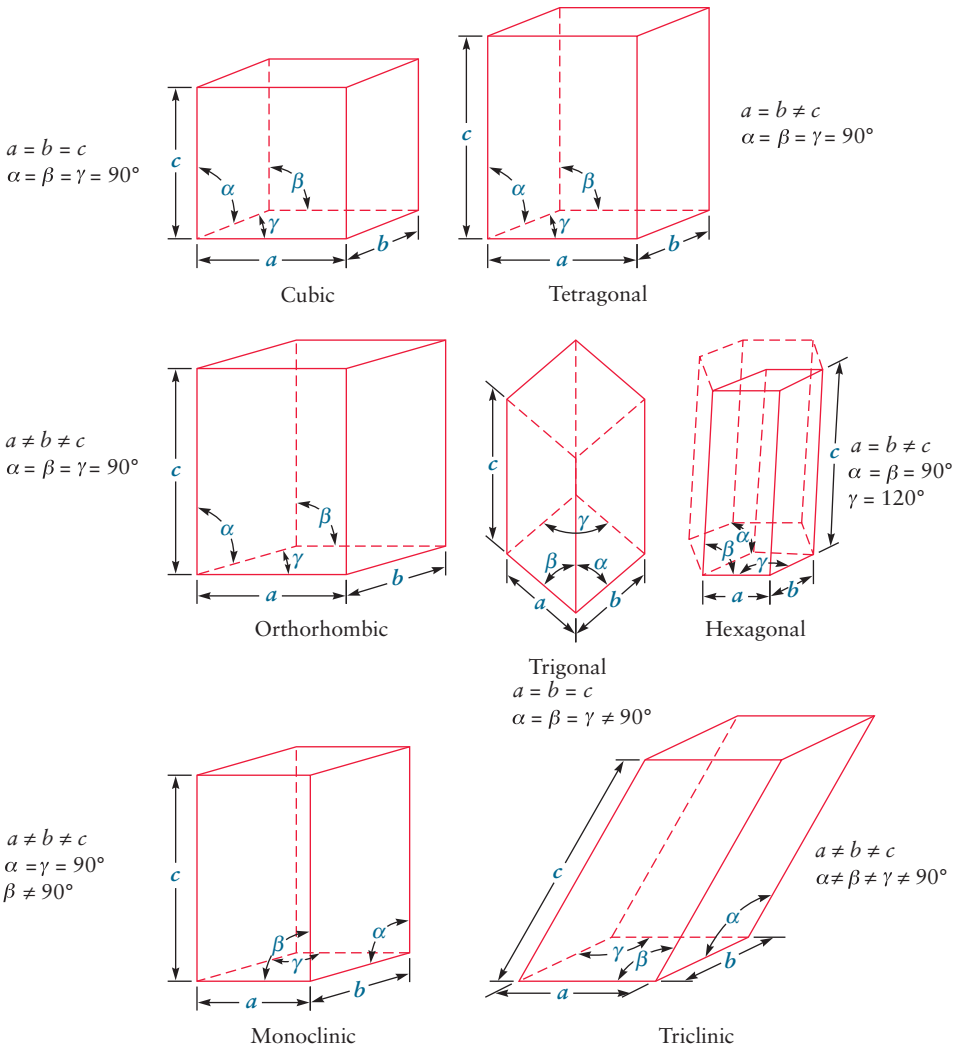

FIGURE 21.6 Shapes of the unit cells in the seven crystal systems. The more symmetric crystal systems have more symmetric cells.

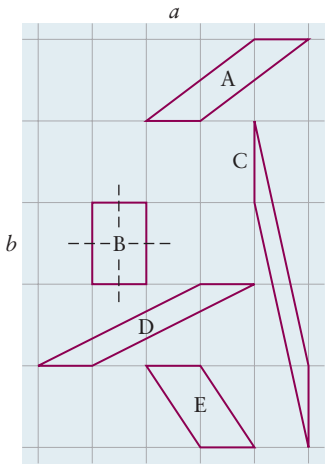

FIGURE 21.7 Cells with and without mirror planes in a two-dimensional lattice. Each cell has the same area, but only cell B possesses mirror planes in addition to the 2-fold rotation axes required by the lattice.

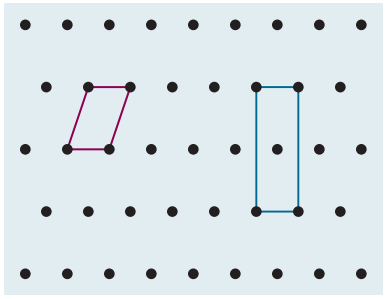

FIGURE 21.8 In this two-dimensional lattice, every lattice point is at the intersection of a horizontal mirror line and a vertical mirror line. It is possible to draw a primitive unit cell (red), but the larger, centered unit cell (blue) is preferred because it also has two mirror lines, the full symmetry of the lattice. A similar argument applies to the choice of unit cells on three-dimensional lattices.

elements of their crystal systems. Figure 21.7 illustrates a few of the infinite number of cells that can be constructed for a two-dimensional rectangular lattice. Only the rectangular cell B in the figure has three 2-fold rotation axes and two mirror planes. Although the other cells all have the same area, each of them has only one 2-fold axis and no mirror planes; they are therefore not acceptable unit cells.

Sometimes the smallest, or primitive, unit cell does not have the full symmetry of the crystal lattice. If so, a larger *nonprimitive* unit cell that does have the characteristic symmetry is deliberately chosen (Fig. 21.8). Only three types of nonprimitive cells are commonly used in the description of crystals: **body-centered, face-centered,** and **side-centered.** They are shown in Figure 21.9.

Scattering of X-Rays by Crystals

In the 19th century, crystallographers could classify crystals into the seven crystal systems only on the basis of their external symmetries. They could not measure the dimensions of unit cells or the positions of atoms within them. Several developments by German physicists changed this situation at the turn of the century. Wilhelm Roentgen's discovery of X-rays in 1895 provided a tool of enormous power for determining the structures of crystals. Max von Laue suggested that crystals might serve as three-dimensional gratings for the diffraction of electromagnetic radiation with a wavelength comparable to the distance between planes of atoms. Friedrich and Knipping demonstrated experimentally in 1912 that this was indeed the case, and von Laue was awarded the Nobel Prize in physics in 1914 for

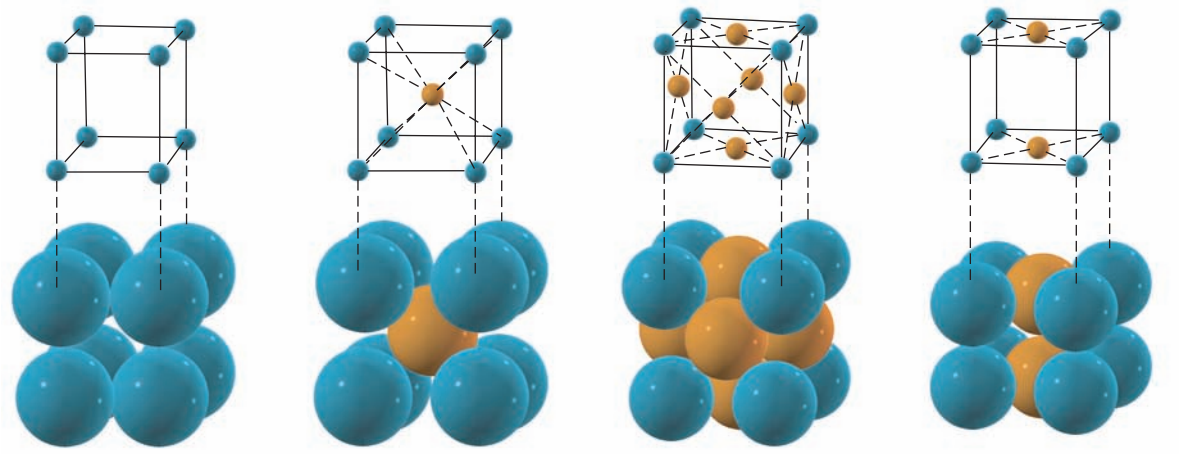

FIGURE 21.9 Centered lattices, like all lattices, have lattice points at the eight corners of the unit cell. A body-centered lattice has an additional lattice point at the center of the cell, a face-centered lattice has additional points at the centers of the six faces, and a side-centered lattice has points at the centers of two parallel sides of the unit cell. (**Note:** The colored dots in the lattice diagrams represent lattice points, not atoms.)

his theory of the diffraction of X-rays by crystals. At about the same time, W. H. Bragg and W. L. Bragg (father and son) at Cambridge University in England also demonstrated the diffraction of X-rays by crystals and shared the Nobel Prize in physics the following year. (W. L. Bragg was 22 years old and still a student at Cambridge when he discovered the diffraction law.) The formulation of the diffraction law proposed by the Braggs is equivalent to von Laue's suggestion and somewhat simpler to visualize. So we will follow an approach similar to theirs.

When electromagnetic radiation passes through matter, it interacts with the electrons in atoms, and some of it is scattered as spherical waves going out from the atoms in the solid. Suppose that X-radiation strikes two neighboring scattering centers. The expanding spheres of scattered waves soon encounter each other and interfere. In some directions, the waves are in phase and reinforce each other, or interfere *constructively* (Fig. 21.10a); in others they are out of phase and cancel each other out, or interfere *destructively* (see Fig. 21.10b). Constructive interference occurs when the paths traversed by two waves differ in length by a whole number of wavelengths. The amplitudes of waves that interfere constructively add

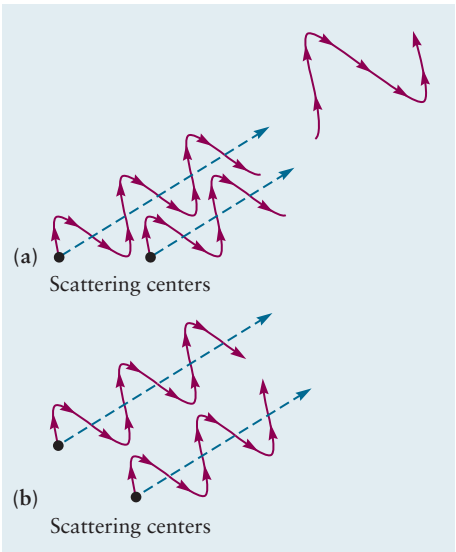

FIGURE 21.10 A beam of X-rays (not shown) is striking two scattering centers, which emit scattered radiation. The difference in the lengths of the paths followed by the scattered waves determines whether they interfere (a) constructively or (b) destructively. This path difference depends on both the distance between the centers and the direction in which the scattered waves are moving.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

to one another, and the intensity of the scattered radiation in that direction is proportional to the square of the total amplitude.

Figure 21.11 illustrates the constructive interference of X-rays scattered by the electrons in atoms in equally spaced planes separated by the distance d. A parallel bundle of coherent X-rays of a single known wavelength is allowed to fall on the surface of a crystal, making an angle θ with a set of parallel planes of atoms in the crystal. The scattering angle 2θ is then varied by rotating the crystal about an axis perpendicular to the plane of the figure. Line AD in Figure 21.11 represents a wave front of waves that are in phase as they approach the crystal. The wave that is scattered at B follows the path ABC, and the one that is scattered at F follows the path DFH. The second wave travels a greater distance than the first, and the difference in path length is the sum of the two segments EF and FG. To achieve constructive interference in the scattered waves (that is, for the phases to be the same along the wave front CH), this additional distance traveled by the second wave must be an integral multiple of the X-ray wavelength λ:

$$\text{EF} + \text{FG} = n\lambda \qquad n = 1, 2, 3, \ \ldots$$

From trigonometry, the lengths of these two segments are equal to each other and to $d \sin \theta$, where d is the interplanar spacing. Therefore, constructive interference occurs only when

$$n\lambda = 2d \sin \theta \qquad n = 1, 2, 3, \ \ldots \qquad [21.1]$$

It is easy to verify that for angles that meet this condition, the waves scattered from the third and subsequent planes are also in phase with the waves scattered from the first two planes.

The preceding condition on allowed wavelengths is called the **Bragg law,** and the corresponding angles are called **Bragg angles** for that particular set of parallel planes of atoms. It appears as though the beam of X-rays has been reflected symmetrically from those crystal planes, and we often speak colloquially of the "Bragg reflection" of X-rays. The X-rays have not been reflected, however, but have undergone constructive interference, more commonly called diffraction. The case $n = 1$ is called first-order Bragg diffraction, $n = 2$ is second-order, and so forth.

We now possess a tool of immense value for determining the interplanar spacings of crystals. If a crystal is turned through different directions, other parallel sets of planes with different separations are brought into the Bragg condition. The symmetry of the resulting diffraction pattern identifies the crystal system, and the Bragg angles determine the cell constants. Moreover, the *intensities* of the diffracted beams permit the locations of the atoms in the unit cell to be determined.

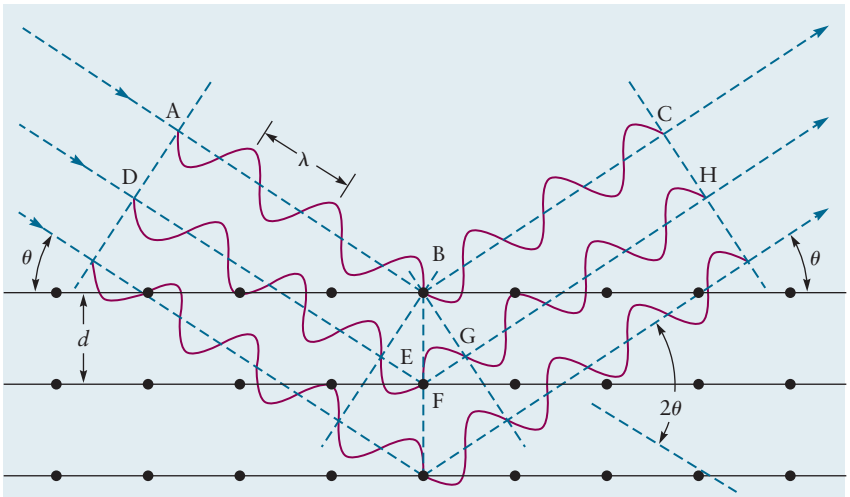

FIGURE 21.11 Constructive interference of X-rays scattered by atoms in lattice planes. Three beams of X-rays, scattered by atoms in three successive layers of a simple cubic crystal, are shown. Note that the phases of the waves are the same along the line CH, indicating constructive interference at this scattering angle 2θ.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Analogous scattering techniques use beams of neutrons. In that case the scattering interaction is between the magnetic moments of the incident neutrons and nuclei in the solid, but the principles are the same as for X-ray diffraction. Of course, it is the wave character of neutrons (in particular, their de Broglie wavelength; see Chapter 4) that is responsible for neutron diffraction. Recall that the de Broglie wavelength and neutron momentum are related by $\lambda = h/p$.

EXAMPLE 21.2

A diffraction pattern of aluminum is obtained by using X-rays with wavelength $\lambda = 0.709$ Å. The second-order Bragg diffraction from the parallel faces of the cubic unit cells is observed at the angle $2\theta = 20.2°$. Calculate the lattice parameter a.

Solution

From the Bragg condition for $n = 2$,

$$2\lambda = 2d \sin \theta$$

the spacing between planes, which is the lattice parameter, is

$$d = \frac{\lambda}{\sin \theta} = \frac{0.709\text{Å}}{\sin (10.1°)} = 4.04 \text{ Å} = a$$

Related Problems: 5, 6

21.2 CRYSTAL STRUCTURE

The crystal lattice is an abstract construction whose points of intersection describe the underlying symmetry of a crystal. To flesh out the description of a particular solid state structure, we must identify some structural elements that are "pinned" to the lattice points. These structural elements can be atoms, ions, or even groups of atoms as we see in this and the next chapter. We begin with some illustrative simple cases. Some of the chemical elements crystallize in particularly simple solid structures, in which a single atom is situated at each point of the lattice.

Polonium is the only element known to crystallize in the **simple cubic lattice,** with its atoms at the intersections of three sets of equally spaced planes that meet at right angles. Each unit cell contains one Po atom, separated from each of its six nearest neighbors by 3.35 Å.

The alkali metals crystallize in the **body-centered cubic (bcc) structure** at atmospheric pressure (Fig. 21.12). A unit cell of this structure contains two lattice points, one at the center of the cube and the other at any one of the eight corners. A single alkali-metal atom is associated with each lattice point. An alternative way to visualize this is to realize that each of the eight atoms that lie at the corners of a bcc unit cell is shared by the eight unit cells that meet at those corners. The contribution of the atoms to one unit cell is therefore $8 \times \frac{1}{8} = 1$ atom, to which is added the atom that lies wholly within that cell at its center.

The metals aluminum, nickel, copper, and silver, among others, crystallize in the **face-centered cubic (fcc) structure** shown in Figure 21.13. This unit cell contains four lattice points, with a single atom associated with each point. No atom lies wholly within the unit cell; there are atoms at the centers of its six faces, each of which is shared with another cell (contributing $6 \times \frac{1}{2} = 3$ atoms), and an atom at each corner of the cell (contributing $8 \times \frac{1}{8} = 1$ atom), for a total of four atoms per unit cell.

The volume of a unit cell is given by the formula

$$V_c = abc \sqrt{1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2 \cos \alpha \cos \beta \cos \gamma} \qquad [21.2]$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. FIGURE 21.12 The bcc structure. An atom is located at the center of each cubic cell (orange) as well as at each corner of the cube (blue). The atoms are reduced slightly in size to make positions clear.

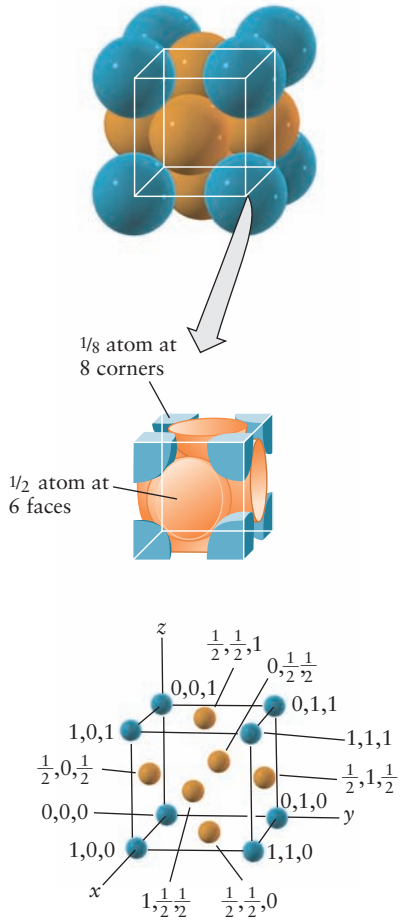

FIGURE 21.13 The fcc structure. Atoms are located at the centers of the faces (orange) as well as at the corners of the cube (blue). The atoms are reduced slightly in size to make positions clear.

When the angles are all 90° (so that their cosines are 0), this formula reduces to the simple result $V = abc$ for the volume of a rectangular box. If the mass of the unit cell contents is known, the theoretical cell density can be computed. This density must come close to the measured density of the crystal, a quantity that can be determined by entirely independent experiments. For an *element* whose crystal contains n_c atoms per unit cell, the calculated cell density is

$$\text{density} = \rho = \frac{\text{mass}}{\text{volume}} = \frac{n_c\left(\dfrac{\mathcal{M}}{N_A}\right)}{V_c} = \frac{n_c\mathcal{M}}{N_A V_c}$$

where we have used the fact that the molar mass $\mathcal{M}$ of the element divided by Avogadro's number N_A is the mass of a single atom. This equation can also be used to calculate Avogadro's number from the measured density and cell constants, as the following example illustrates.

EXAMPLE 21.3

Sodium has a density of $\rho = 0.9700$ g cm^{-3} at 20°C, and its lattice parameter is $a = 4.2856$ Å. What is the value of Avogadro's number, given that the molar mass of sodium is 22.9898 g mol^{-1}?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solution
Sodium has two atoms per unit cell because its structure is bcc, and the volume of the unit cell is a^3. Solve the foregoing equation for Avogadro's number:

$$N_A = \frac{n_c \mathcal{M}}{\rho a^3} = \frac{(2)(22.9898 \text{ g mol}^{-1})}{(0.9700 \text{ g cm}^{-3})(4.2856 \times 10^{-8} \text{ cm})^3} = 6.022 \times 10^{23} \text{ mol}^{-1}$$

Related Problems: 15, 16

It is useful to define the locations of atoms in the unit cell with a set of three numbers measured in units of the lattice parameter(s). For this purpose, one corner of the unit cell is taken to be at the origin of the coordinate axes appropriate to the crystal system, and an atom at that lattice point has the coordinates (0, 0, 0). Equivalent atoms at the seven remaining corners of the cell then have the coordinates (1, 0, 0), (0, 1, 0), (0, 0, 1), (1, 0, 1), (1, 1, 0), (0, 1, 1), and (1, 1, 1). These atom positions are generated from an atom at (0, 0, 0) by successive translations through unit distances along the three axes. An atom in a body-centered site has coordinates $\left(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right)$ and the prescription for locating it is to proceed from the coordinate origin at (0, 0, 0) a distance $a/2$ along a, then a distance $b/2$ along b, and finally $c/2$ along c. In the same way, an atom in a face-centered site has coordinates such as $\left(\frac{1}{2}, \frac{1}{2}, 0\right)$, $\left(\frac{1}{2}, 0, \frac{1}{2}\right)$, or $\left(0, \frac{1}{2}, \frac{1}{2}\right)$.

So far, we have considered only cubic metals in which one atom corresponds to each lattice point. More complicated structures also occur, even for the elements, in which atoms occupy positions that are not lattice points. Diamond has an fcc structure with eight atoms (not four) per unit cell (see Fig. 21.22). Boron has a tetragonal structure with a very complex unit cell that contains 50 atoms. In molecular crystals the number of atoms per unit cell can be still greater; in a protein with a molecular mass of 10^5, there may be tens of thousands of atoms per unit cell. The computer-generated model of the protein myoglobin shown in Figure 23.21 is representative of the kinds of complex structures that are now routinely determined using modern X-ray crystallography.

Atomic Packing in Crystals

As we begin to add structural features like atoms onto crystal lattice sites, we have to pay attention to the size of the features. How efficiently can we pack atoms onto a lattice? We have already discussed two measures of the "size" of an atom or molecule. In Section 9.6, the van der Waals parameter b was related to the volume excluded per mole of molecules, so b/N_A is one measure of molecular size. In Section 5.5, we defined an approximate radius of an atom as the distance at which the electron density had fallen off to a particular value, or as the radius of a sphere containing a certain fraction of the total electron density. A third related measure of atomic size is based on the interatomic separations in a crystal. The radius of a noble-gas or metallic atom can be approximated as half the distance between the center of an atom and the center of its nearest neighbor in the crystal. We picture crystal structures as resulting from packing spheres in which nearest neighbors are in contact.

The nearest neighbor separation in a simple cubic crystal is equal to the lattice parameter a, so the atomic radius in that case is $a/2$. For the bcc lattice, the central atom in the unit cell "touches" each of the eight atoms at the corners of the cube, but those at the corners do not touch one another, as Figure 21.12 shows. The nearest-neighbor-distance is calculated from the Cartesian coordinates of the atom at the origin (0, 0, 0) and that at the cell center $(a/2, a/2, a/2)$. By the Pythagorean theorem, the distance between these points is $\sqrt{(a/2)^2 + (a/2)^2 + (a/2)^2} = a\sqrt{3}/2$, so the atomic

TABLE 21.2

Structural Properties of Cubic Lattices

	Simple Cubic	Body-Centered Cubic	Face-Centered Cubic
Lattice points per cell	1	2	4
Number of nearest neighbors	6	8	12
Nearest-neighbor distance	A	$a\sqrt{3}/2 = 0.866a$	$a\sqrt{2}/2 = 0.707a$
Atomic radius	$a/2$	$a\sqrt{3}/4 = 0.433a$	$a\sqrt{2}/4 = 0.354a$
Packing fraction	$\frac{\pi}{6} = 0.524$	$\frac{\sqrt{3\pi}}{8} = 0.680$	$\frac{\sqrt{2\pi}}{6} = 0.740$

radius is $a\sqrt{3}/4$. Figure 21.13 shows that in an fcc crystal the atom at the center of a face [such as at $(0, a/2, a/2)$] touches each of the neighboring corner atoms [such as at $(0, 0, 0)$], so the nearest-neighbor distance is $\sqrt{(a/2)^2 + (a/2)^2} = a\sqrt{2}/2$ and the atomic radius is $a\sqrt{2}/4$. Table 21.2 summarizes the results for cubic lattices.

What is the most dense crystal packing that can be achieved? To answer this question, construct a crystal by first putting down a plane of atoms with the highest possible density, shown in Figure 21.14a. Each sphere is in contact with six other spheres in the plane. Then put down a second close-packed plane on top of the first one (see Fig. 21.14b) in such a way that each sphere in the second plane is in contact with three spheres in the plane below it; that is, each sphere in the second plane forms a tetrahedron with three spheres beneath. When the third plane is laid down, there are two possibilities. In Figure 21.14c, the atoms in the third plane lie on sites not directly over those in the first layer, whereas in Figure 21.14d the third-plane atoms are directly over the first-plane atoms.

Clearly, there are two choices for placing each plane, and an infinite number of crystal structures can be generated that have the same atomic packing density. The two simplest such structures correspond to the periodic layer sequences *abcabcab* . . . and *abababa*. . . . The first of these is the fcc structure already discussed, and the second is a close-packed structure in the hexagonal crystal system termed **hexagonal close-packed (hcp).** In each of these simple structures, atoms occupy 74.0% of the unit cell volume, as the following example shows. (Atoms that crystallize in the bcc structure occupy only 68.0% of the crystal volume, and the packing fraction for a simple cubic array is only 52.4%.)

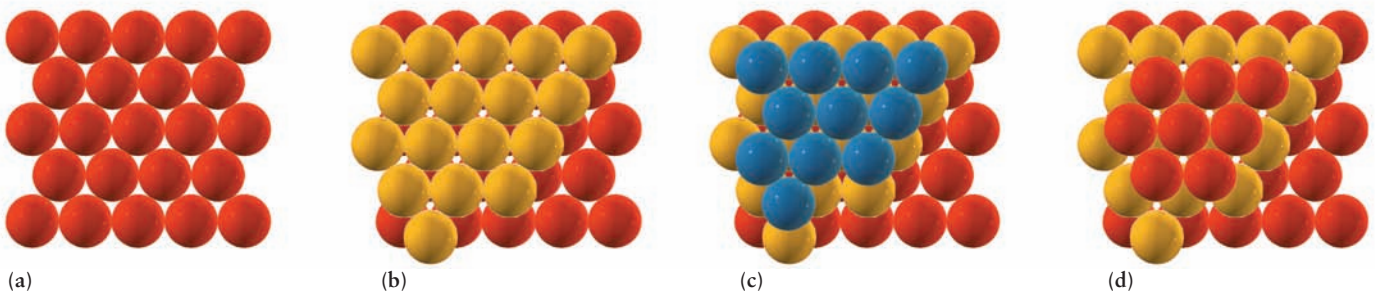

FIGURE 21.14 Close-packing of spheres. (a) One layer, with each atom surrounded by six nearest neighbors. (b) Two layers, with the atoms of the second layer centered on top of indentations in the layer below. (c) The third layer can be placed on sites that are not directly above the sites in the first layer (note that the red spheres show through). If this pattern is repeated as *abcabc* . . . it gives cubic close-packing. (d) Alternatively, the third layer can be placed directly over the sites in the first layer (note that the white triangular spaces show through). The repeated pattern *ababab* . . . gives hexagonal close-packing.

EXAMPLE 21.4

Calculate (**a**) the atomic radius of an aluminum atom and (**b**) the fraction of the volume of aluminum that is occupied by its atoms.

Solution

(**a**) Aluminum crystallizes in the fcc crystal system, and its unit cell therefore contains four atoms. Because a face-centered atom touches each of the atoms at the corners of its face, the atomic radius r_1 (see the triangle in Fig. 21.15) can be expressed by

$$4r_1 = a\sqrt{2}$$

Using the value $a = 4.04$ Å derived from X-ray diffraction (see Example 21.2) and solving for r_1 gives

$$r_1 = 1.43\ Å$$

(**b**) The fraction of the volume of an aluminum single crystral that is occupied by its atoms is

$$f = \frac{4\left[\frac{4}{3}\pi r_1^3\right]}{a^3} = \frac{4\frac{4}{3}\pi\left[\frac{a\sqrt{2}}{4}\right]^3}{a^3} = 0.740$$

Related Problem: 23

Interstitial Sites

The ways in which the empty volume is distributed in a crystal are both interesting and important. For the close-packed fcc structure, two types of **interstitial sites,** upon which the free volume in the unit cell is centered, are identifiable. An **octahedral site** is surrounded at equal distances by six nearest-neighbor atoms. Figure 21.15 shows that such sites lie at the midpoints of the edges of the fcc unit cell. A cell has twelve edges, each of which is shared by four unit cells, so the edges contribute three octahedral interstitial sites per cell. In addition, the site at the center of the unit cell is also octahedral, so the total number of octahedral sites per fcc unit cell is four, the same as the number of atoms in the unit cell.

With a bit of simple geometry, we can calculate the size of an octahedral site in an fcc structure or, more precisely, the radius r_2 of a smaller atom that would fit in the site without overlapping its neighboring atoms. Figure 21.15 represents a cell face in which the length of the diagonal is $4r_1$ and the length of the cell edge is $2r_1 + 2r_2$, where r_1 is the radius of the host atoms and r_2 is the radius of the octahedral site. From the figure,

$$r_1 = a\frac{\sqrt{2}}{4}$$

$$a = 2r_2 + 2r_1 = 2r_2 + 2a\frac{\sqrt{2}}{4}$$

$$r_2 = \frac{a}{2} - a\frac{\sqrt{2}}{4} = 0.146a$$

and the ratio of the octahedral-site radius to the host-atom radius is

$$\frac{r_2}{r_1} = \frac{0.146a}{a\sqrt{2/4}} = 0.414$$

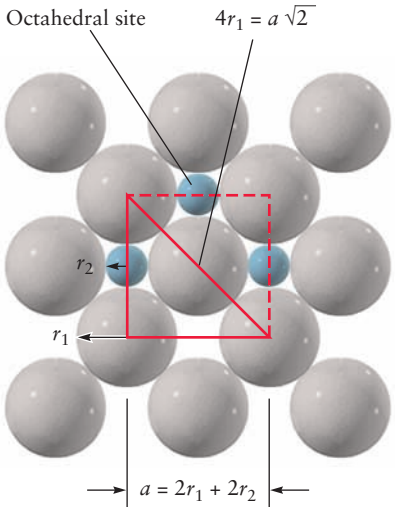

FIGURE 21.15 Octahedral sites in an fcc lattice. The geometric procedure for relating the site radius r_2 to the atom radius r_1 is shown.

The second type of interstitial site, known as a **tetrahedral site,** lies at the center of the space defined by four touching spheres. In an fcc cell, a tetrahedral site oc-

curs in the volume between a corner atom and the three face-centered atoms nearest to it. Geometrical reasoning like that used for the octahedral site gives the following ratio of the radius of a tetrahedral site to that of a host atom:

$$\frac{r_2}{r_1} = 0.225$$

The fcc unit cell contains eight tetrahedral sites, twice the number of atoms in the cell.

Interstitial sites are important when a crystal contains atoms of several kinds with considerably different radii. We will return to this shortly when we consider the structures of ionic crystals.

21.3 COHESION IN SOLIDS

In addition to symmetry, the nature of the bonding forces between atoms provides a useful way to classify solids. This classification does indeed lead to an understanding of the remarkable differences in the chemical and physical properties of different materials. We now consider crystals held together through ionic, metallic, or covalent bonding interactions, and the one class of solids held together by intermolecular forces.

Ionic Crystals

Compounds formed by atoms with significantly different electronegativities are largely ionic, and to a first approximation the ions can be treated as hard, charged spheres that occupy positions on the crystal lattice (see the ionic radii in Appendix F). All the elements of Groups I and II of the periodic table react with Group VI and VII elements to form ionic compounds, the great majority of which crystallize in the cubic system. The alkali-metal halides (except for the cesium halides), the ammonium halides, and the oxides and sulfides of the alkaline-earth metals all crystallize in the **rock-salt,** or **sodium chloride, structure** shown in Figure 21.16. It may be viewed as an fcc lattice of anions whose octahedral sites are all occupied by cations or, equivalently, as an fcc lattice of cations whose octahedral sites are all occupied by anions. Either way, each ion is surrounded by six equidistant ions of the opposite charge. The rock-salt structure is a stable crystal structure when the cation-anion radius ratio lies between 0.414 and 0.732, if cations and anions are assumed to behave as incompressible charged spheres.

When the hard-sphere cation-anion radius ratio exceeds 0.732, as it does for the cesium halides, a different crystal structure called the **cesium chloride structure,**

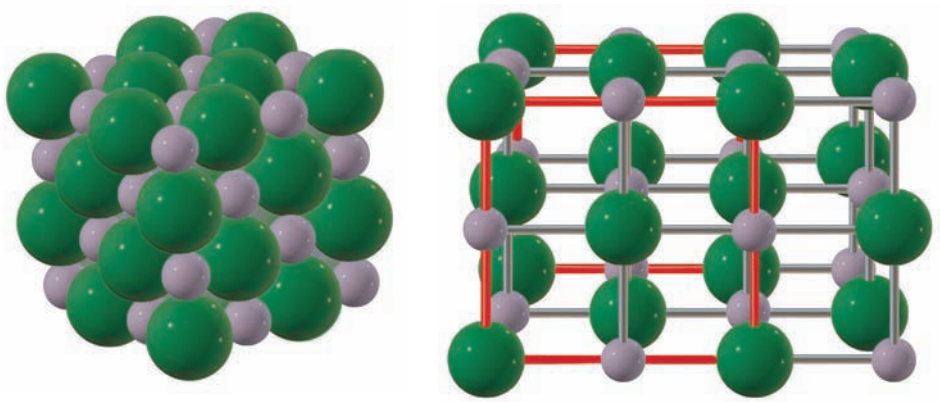

FIGURE 21.16 The sodium chloride, or rock-salt, structure. On the left, the sizes of the Na^+ ions (purple) and the Cl^- ions (green) are drawn to scale. On the right, the ions are reduced in size to allow a unit cell (shown by red lines) to be outlined clearly.

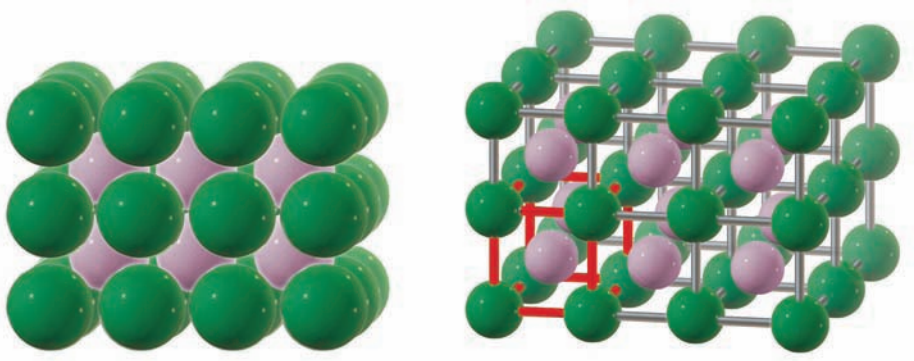

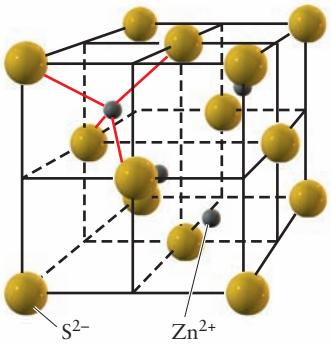

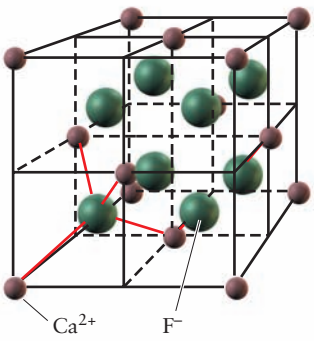

FIGURE 21.17 The structure of cesium chloride. On the left, the sizes of the Cs^+ ions (purplish pink) and the Cl^- ions (green) are drawn to scale. On the right, they are reduced in size to allow a unit cell (shown by red lines) to be outlined clearly. Note that the lattice in this structure is simple cubic, with one Cs^+ ion and one Cl^- ion per unit cell.

is more stable. It may be viewed as two interpenetrating simple cubic lattices, one of anions and the other of cations, as shown in Figure 21.17. When the cation–anion radius ratio is less than 0.414, the **zinc blende,** or **sphalerite, structure** (named after the structure of ZnS) results. This crystal consists of an fcc lattice of S^{2-} ions, with Zn^{2+} ions occupying half of the available tetrahedral sites in alternation, as Figure 21.18a illustrates. **Fluorite** (CaF_2) has yet another structure; the unit cell is based on an fcc lattice of Ca^{2+} ions. The F^- ions occupy all eight of the tetrahedral sites, so the unit cell contains four Ca^{2+} and eight F^- ions (see Fig. 21.18b). The radius ratios (0.414 and 0.732) at which crossovers from one type of crystal to another occur are not accidental numbers. Recall from Section 21.2 that 0.414 is the ratio of the octahedral-site radius to the host-atom radius for an fcc lattice; only when this size ratio is exceeded does the ion inserted into that site come into contact with ions of the opposite sign in the rock-salt structure. The number 0.732 comes from a corresponding calculation of the radius ratio of the interstitial site at the center of a simple cubic unit cell (see problem 25). It is important to realize that the radius-ratio criterion for the stability limits of the structures of binary ionic compounds assumes that the ions are incompressible and that the wave functions do not overlap. The criterion fails when these approximations are not met.

The strength and range of the electrostatic attractions make ionic crystals hard, high-melting, brittle solids that are electrical insulators. Melting an ionic crystal, however, disrupts the lattice and sets the ions free to move, so ionic liquids are good electrical conductors.

Metallic Crystals

The type of bonding found in metals is quite different from that in other crystals. As we compare the various main group and transition metals in the periodic table we see only small differences in electronegativity. So, there is little tendency for ionic bonding in metals. The electronic configurations of metal atoms, even in the transition metals, do not have nearly-filled subshells, so there is little tendency to form covalent bonds by sharing electrons to achieve a stable octet. The familiar classical models of chemical bonding (see Chapter 3) do not extend to metals.

Prior to quantum mechanics, bonding in metals was described by the Drude model, named for the German physicist Paul Drude. The solid was viewed as a fixed array of positively charged metal ions, each localized at a site of the crystal lattice. These fixed ions were surrounded by a sea of mobile electrons, one contributed by each of the atoms in the solid. The number density of electrons was equal to the number density of positively charged ions, so the metal was electrically neutral. The sea of delocalized electrons would interact with the stable ions to give a strong cohesive force keeping the metal bound together. The Drude model accounts for the malleability (deformation in response to mechanical force, like hammering) and ductility (ease of drawing into a fine wire) of metals. As some ions move to new positions in response to these mechanical disturbances, delocalized electrons can

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

rapidly adjust to maintain metallic bonding in the deformed or drawn solid. The ease with which metals conduct electricity is explained because these delocalized electrons can respond to any applied electric fields.

The delocalized sea of electrons picture of metal bonding survives in the quantum theory of solids, which is an extension of the molecular orbital description of molecular bonding (see Chapter 6). The valence electrons in a metal are delocalized in huge molecular orbitals that extend over the entire crystal and provide the "glue" that holds together the positively charged ion cores of the metal atoms. To understand the origin of these molecular orbitals, suppose just two sodium atoms are brought together, each in its electronic ground state with the configuration $1s^2 2s^2 2p^6 3s^1$. As the atoms approach each other, the wave functions of their 3*s* electrons combine to form two molecular orbitals—one in which their phases are symmetric (σ_{3s}) and another in which they are antisymmetric (σ^*_{3s}). Solving the Schrödinger equation yields two energy states, one above and the other below the energy of the atomic 3*s* levels, analogous to the formation of a hydrogen molecule from two hydrogen atoms described in Chapter 6. If both valence electrons are put into the level of lower energy with spins opposed, the result is a Na_2 molecule. If a third sodium atom is added, the 3*s* atomic levels of the atoms split into three sublevels (Fig. 21.19). Two electrons occupy the lowest level with their spins opposed, and the third electron occupies the middle level. The three energy levels and the three electrons belong collectively to the three sodium atoms. A fourth sodium atom could be added so that there would be four closely spaced energy sublevels, and this process could be carried on without limit.

The foregoing is not a mere "thought experiment." Sodium vapor contains about 17% Na_2 molecules at its normal boiling point. Larger sodium clusters have

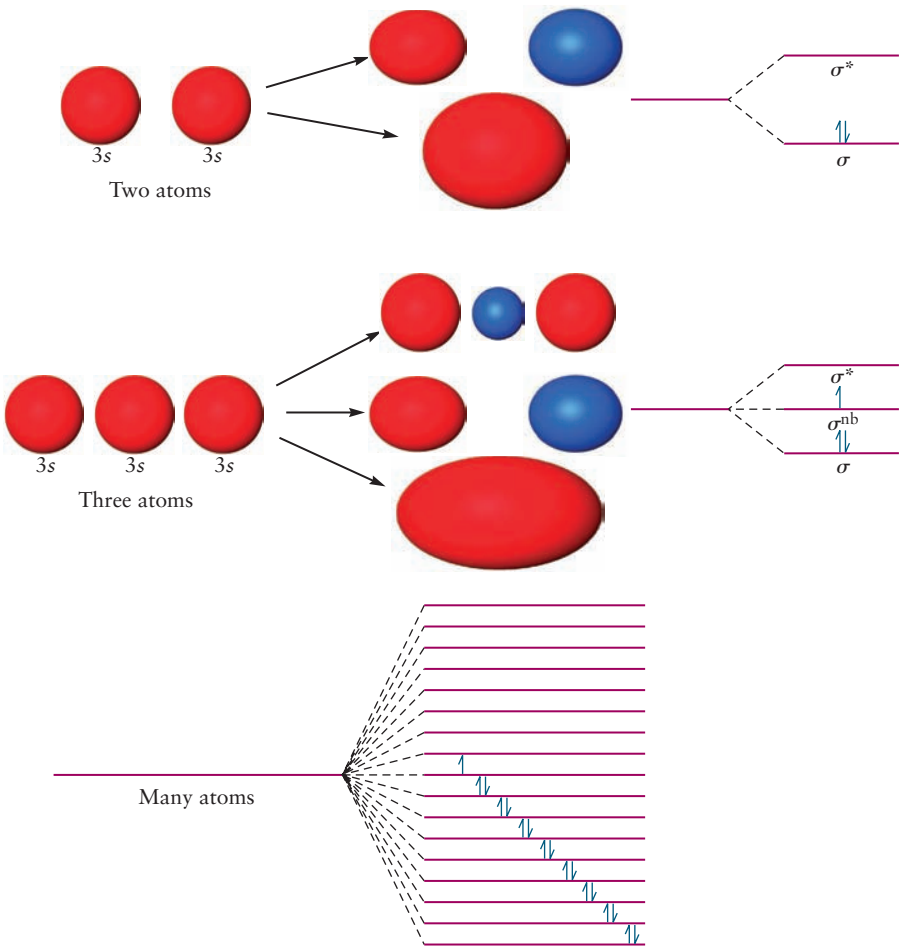

FIGURE 21.19 As sodium atoms are brought together, the molecular orbitals formed from their 3*s* atomic orbitals spread out into a band of levels, half occupied by electrons.

FIGURE 21.21 Solid gallium has a low melting point, low enough to melt from the heat of the body.

been produced in molecular beam experiments, and mass spectrometry shows that such clusters can contain any desired number of atoms. For each added Na atom, another energy sublevel is added. Because the sublevels are so very closely spaced in a solid (with, say, 10^{23} atoms), the collection of sublevels can be regarded as an **energy band.** Figure 21.19 depicts the formation of bands of sublevels that broaden (become delocalized) as the spacing between the nuclear centers decreases, and the 3*s* electrons go into these bands. The electrons that belong to the 1*s,* 2*s,* and 2*p* atomic levels of sodium are only very slightly broadened at the equilibrium internuclear separation of the crystal, so they retain their distinct, localized character as the core levels of the ions at the lattice sites. Chapter 22 explores the electrical properties of metals, which arise from this band structure.

Most metals have crystal structures of high symmetry and crystallize in bcc, fcc, or hcp lattices (Fig. 21.20). Relatively few metals (Ga, In, Sn, Sb, Bi, and Hg) have more complex crystal structures. Many metals undergo phase transitions to other structures when the temperature or pressure is changed. Both liquid and crystal phases can be metals; in fact, the conductivity usually drops by only a small amount when a metal melts. The electron sea provides very strong binding in most metals, as shown by their high boiling points. Metals have a very large range of melting points. Gallium melts at 29.78°C (Fig. 21.21), and mercury stays liquid at temperatures that freeze water. Many transition metals require temperatures in excess of 1000°C to melt, and tungsten, the highest melting elemental metal, melts at 3410°C (see Section 8.1).

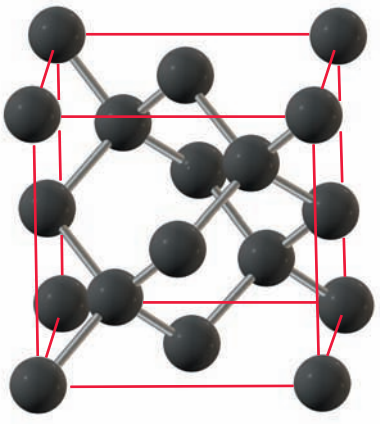

FIGURE 21.22 The structure of diamond. Each carbon atom has four nearest neighbors surrounding it at the corners of a tetrahedron.

Covalent Crystals

We turn finally to a class of crystalline solids whose atoms are linked by covalent bonds rather than by the electrostatic attractions of ions or the valence electron "glue" in a metal. The archetype of the covalent crystal is diamond, which belongs to the cubic system. The ground-state electron configuration of a carbon atom is $1s^2 2s^2 2p^2$, and as shown in Section 6.9, its bonding is described by four hybrid sp^3 orbitals directed to the four corners of a regular tetrahedron. Each of the equivalent hybrid orbitals contains one electron that can spin-pair with the electron in one of the sp^3 orbitals of another carbon atom. Each carbon atom can thus link covalently to four others to yield the space-filling network shown in Figure 21.22. Covalent crystals are also called "network crystals," for obvious reasons. In a sense, every atom in a covalent crystal is part of one giant molecule that is the crystal itself. These crystals have very high melting points because of the strong attractions between covalently bound atoms. They are hard and brittle. Chapter 22 describes the electrical properties of covalent crystals.

Molecular Crystals

Molecular crystals include the noble gases; oxygen; nitrogen; the halogens; compounds such as carbon dioxide; metal halides of low ionicity such as Al_2Cl_6, $FeCl_3$, and $BiCl_3$; and the vast majority of organic compounds. All these molecules are held in their lattice sites by the intermolecular forces discussed in Sections 9.6 and 10.2. The trade-off between attractive and repulsive forces among even small molecules in a molecular crystal is complex because so many atoms are involved. A useful simplification is to picture a molecule as a set of fused spheres centered at each nucleus. The radius of each sphere is the van der Waals radius of the element involved. In molecular crystals, such shapes pack together so that no molecules overlap but empty space is minimized. Figure 21.23 depicts such a "space-filling model" of cyanuric triazide (C_3N_{12}), showing how nature solves the problem of efficiently packing many copies of the rather complicated molecular shape of C_3N_{12} in a single layer. In the three-dimensional molecular

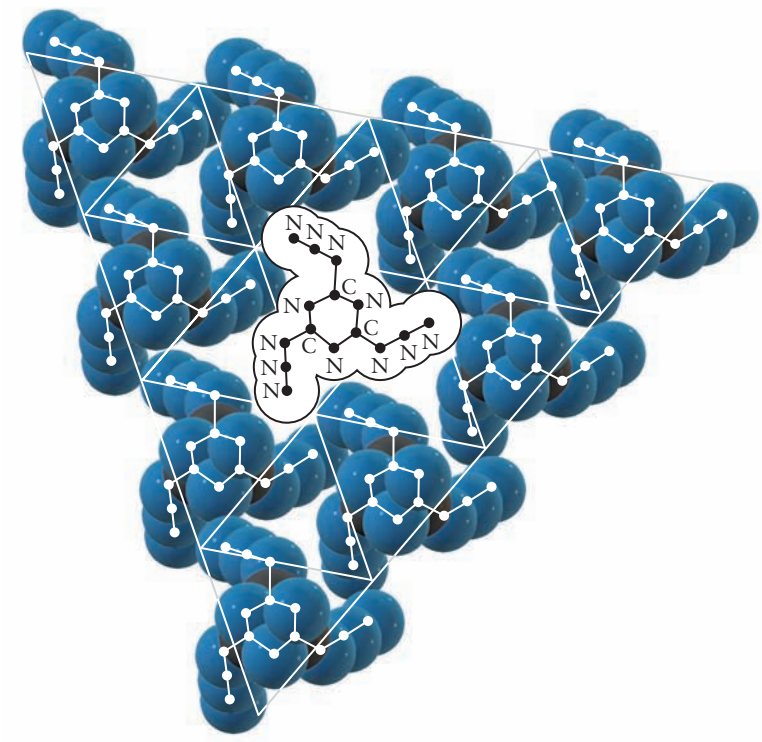

FIGURE 21.23 The van der Waals radii of the carbon and nitrogen atoms superimposed on an outline of the molecular structure of cyanuric triazide, C_3N_{12}, to show the volume of space from which each molecule excludes the others. Van der Waals forces in the molecular crystal hold the molecules in contact in a pattern that minimizes empty space. The thin white lines emphasize the 3-fold symmetry of the pattern.

crystal of C_3N_{12}, many such layers stack up with a slight offset that minimizes unfilled space between layers.

Van der Waals forces are much weaker than the forces that operate in ionic, metallic, and covalent crystals. Consequently, molecular crystals typically have low melting points and are soft and easily deformed. Although at atmospheric pressure the noble-gas elements crystallize in the highly symmetric fcc lattice shown in Figure 21.13, molecules (especially those with complex geometries) more often form crystals of low symmetry in the monoclinic or triclinic systems. Molecular crystals are of great scientific value. If proteins and other macromolecules are obtained in the crystalline state, their structures can be determined by X-ray diffraction. Knowing the three-dimensional structures of biological molecules is the starting point for understanding their functions.

Crystal Structures of the Elements

The chemical elements provide examples of three of the four classes of crystalline solids described in this section. Only ionic solids are excluded, because a single element cannot have the two types of atoms of different electronegativities needed to form an ionic material. We have already discussed some of the structures formed by metallic elements, which are sufficiently electropositive that their atoms readily give up electrons to form the electron sea of metallic bonding. The nonmetallic elements are more complex in their structures, reflecting a competition between intermolecular and intramolecular bonding and producing molecular or covalent solids with varied properties.

Each halogen atom has seven valence electrons and can react with one other halogen atom to form a diatomic molecule. Once this single bond forms, there is no further bonding capacity; the halogen diatomic molecules interact with one another only through relatively weak van der Waals forces and form molecular solids with low melting and boiling points.

The Group VI elements oxygen, sulfur, and selenium display dissimilar structures in the solid state. Each oxygen atom (with six valence electrons) can form one double or two single bonds. Except in ozone, its high-free-energy form, oxygen uses up all its bonding capacity with an intramolecular double bond, forming a molecular liquid and a molecular solid that are only weakly bound. In contrast, diatomic sulfur molecules (S=S) are relatively rare, being encountered only in high-temperature vapors. The favored forms of sulfur involve the bonding of every atom to two other sulfur atoms. This leads to either rings or chains, and both are observed. The stable form of sulfur at room temperature consists of S_8 molecules, with eight sulfur atoms arranged in a puckered ring (Fig. 21.24). The weak interactions between S_8 molecules make elemental sulfur a rather soft molecular solid. Above 160°C the rings in molten sulfur break open and relink to form long, tangled chains, producing a highly viscous liquid. An unstable ring form of selenium (Se_8) is known, but the thermodynamically stable form of this element is a gray crystal of metallic appearance that consists of very long spiral chains with weak interchain interaction. Crystalline tellurium has a similar structure. The Group VI elements thus show a trend (moving down the periodic table) from the formation of multiple bonds toward the chains and rings characteristic of atoms that each form two single bonds.

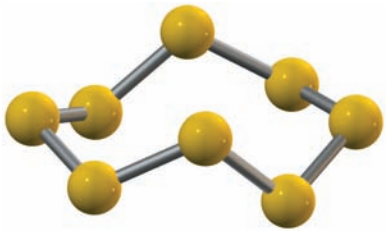

FIGURE 21.24 The structure of the S_8 sulfur molecule. The orthorhombic unit cell of rhombic sulfur, the most stable form of elemental sulfur at room temperature, is large and contains 16 of these S_8 molecules for a total of 128 atoms of sulfur.

A similar trend is evident in Group V. Only nitrogen forms diatomic molecules with triple bonds, in which all the bonding capacity is used between pairs of atoms. Elemental phosphorus exists in three forms, in all of which each phosphorus atom forms three single bonds rather than one triple bond. White phosphorus (Fig. 21.25a) consists of tetrahedral P_4 molecules, which interact with each other through weak van der Waals forces. Black phosphorus and red phosphorus (see Figs. 21.25b, c) are higher melting network solids in which the three bonds formed by each atom connect it directly or indirectly with all the other atoms in the sample. Unstable solid forms of arsenic and antimony that consist of As_4 or Sb_4 tetrahedra like those in white

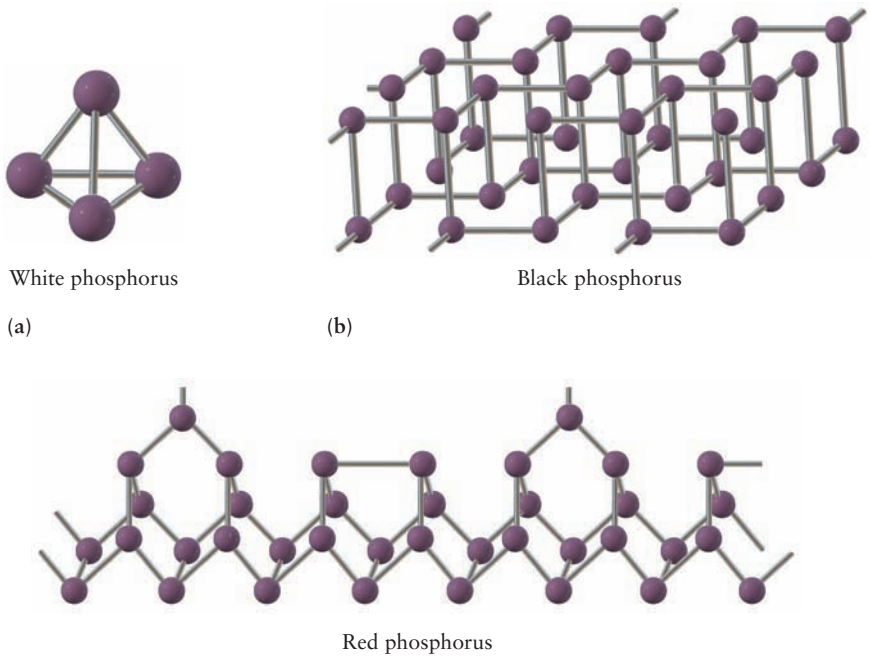

FIGURE 21.25 Structures of elemental phosphorus.

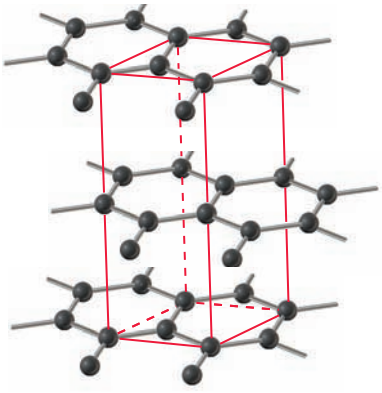

FIGURE 21.26 The structure of graphite.

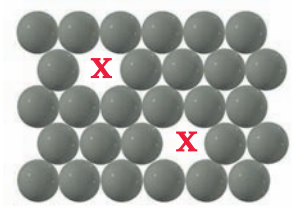
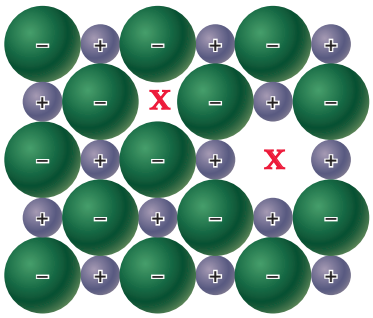
phosphorus can be prepared by rapid cooling of the vapor. The stable forms of these elements have structures related to that of black phosphorus.



The elements considered so far lie on the border between covalent and molecular solids. Other elements, those of intermediate electronegativity, exist as solids on the border between metallic and covalent; these are called **metalloids.** Antimony has a metallic luster, for example, but is a rather poor conductor of electricity and heat. Silicon and germanium are **semiconductors,** with electrical conductivities far lower than those of metals but still significantly higher than those of true insulators such as diamond. Section 22.7 examines the special properties of these materials more closely.

Some elements of intermediate electronegativity exist in two crystalline forms with very different properties. White tin has a tetragonal crystal structure and is a metallic conductor. Below 13°C it crumbles slowly to form a powder of gray tin (with the diamond structure) that is a poor conductor. Its formation at low temperature is known as the "tin disease" and can be prevented by the addition of small amounts of bismuth or antimony. The thermodynamically stable form of carbon at room conditions is not the insulator diamond, but graphite. Graphite consists of sheets of fused hexagonal rings with only rather weak interactions between layers (Fig. 21.26). Each carbon atom shows sp^2 hybridization, with its remaining p orbital (perpendicular to the graphite layers) taking part in extended π-bonding interactions over the whole plane. Graphite can be pictured as a series of interlocked benzene rings, with π-electron delocalization contributing significantly to its stability. The delocalized electrons give graphite a significant value for conductivity in the planes of fused hexagons approaching that of the metallic elements. The conductivity and relative chemical inertness of graphite make it useful for electrodes in electrochemistry.

21.4 DEFECTS AND AMORPHOUS SOLIDS



Although real crystals display beautiful symmetries to the eye, they are not perfect. As a practical matter, it is impossible to rid a crystal of all impurities or to ensure that it contains perfect periodic ordering. So, we describe real crystals as "perfect crystals with defects," and define means to characterize these defects. If so many

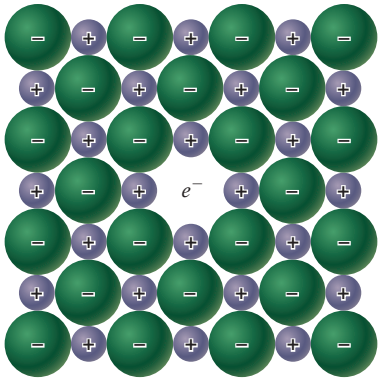

FIGURE 21.28 An F-center in a crystal.

defects are present that crystalline order is destroyed, we describe the material as an **amorphous solid.**

Point Defects

Point defects in a pure crystalline substance include **vacancies,** in which atoms are missing from lattice sites, and **interstitials,** in which atoms are inserted in sites different from their normal sites. In real crystals, a small fraction of the normal atom sites remain unoccupied. Such vacancies are called **Schottky defects,** and their concentration depends on temperature:

$$N = N_s \exp(-\Delta G/RT)$$

where N is the number of lattice vacancies per unit volume, N_s is the number of atom sites per unit volume, and ΔG is the molar free energy of formation of vacancies. Figure 21.27a illustrates Schottky defects in the crystal structure of a metal or noble gas. Schottky defects also occur in ionic crystals but with the restriction that the imperfect crystals remain electrically neutral. Thus, in sodium chloride, for every missing Na^+ ion there must also be a missing Cl^- ion (see Fig. 21.27b).

In certain kinds of crystals, atoms or ions are displaced from their regular lattice sites to interstitial sites, and the crystal defect consists of the lattice vacancy plus the interstitial atom or ion. Figure 21.27c illustrates this type of lattice imperfection, known as a **Frenkel defect.** The silver halides (AgCl, AgBr, AgI) are examples of crystals in which Frenkel disorder is extreme. The crystal structures of these compounds are established primarily by the anion lattice, and the silver ions occupy highly disordered, almost random, sites. The rate of diffusion of silver ions in these solids is exceptionally high, as studies using radioactive isotopes of silver have shown. Both Frenkel and Schottky defects in crystals are mobile, jumping from one lattice site to a neighboring site with frequencies that depend on the temperature and the strengths of the atomic forces. Diffusion in crystalline solids is due largely to the presence and mobility of point defects; it is a thermally activated process, just like the rates of chemical reactions considered in Chapter 18. The coefficient of self-diffusion has the form

$$D = D_0 \exp[-\Delta G/RT] \qquad [21.3]$$

where E_a is the activation energy. The rates of diffusive motion in crystalline solids vary enormously from one substance to another. In a crystal of a low-melting metal such as sodium, an average atom undergoes about 10^8 diffusive jumps per second at 50°C, whereas in a metal such as tungsten that melts at 3410°C, an average atom jumps to another lattice site less than once per year at 1000°C!

If an alkali halide crystal such as NaCl is irradiated with X-rays, ultraviolet radiation, or high-energy electrons, some Cl^- ions may lose an electron:

$$Cl^- + h\nu \longrightarrow Cl + e^-$$

The resulting Cl atom, being uncharged and much smaller than a Cl^- ion, is no longer strongly bound in the crystal and can diffuse to the surface and escape. The electron can migrate through the crystal quite freely until it encounters an anion vacancy and is trapped in the Coulomb field of the surrounding cations (Fig. 21.28). This crystal defect is called an **F-center** (from the German word *Farbenzentrum,* meaning **color center**). It is the simplest of a family of electronic crystal defects. As the name suggests, it imparts a color to ionic crystals (Fig. 21.29).

Nonstoichiometric Compounds

As Chapter 1 emphasizes, the law of definite proportions was one of the principal pieces of evidence that led to the acceptance of Dalton's atomic theory. It is now recognized that a great many solid-state binary compounds do *not* have fixed and

FIGURE 21.29 Pure calcium fluoride, CaF2, is white but the natural sample of calcium fluoride (fluorite) shown here is a rich purple because F-centers are present. These are lattice sites where the F^- anion is replaced by an electron only.

unvarying compositions but exist over a range of compositions in a single phase. Thus, FeO (wüstite) has the composition range $Fe_{0.85}O_{1.00}$ to $Fe_{0.95}O_{1.00}$ and is never found with its nominal 1:1 composition. The compounds NiO and Cu_2S also deviate considerably from their nominal stoichiometries.

The explanation depends on the existence of more than one oxidation state for the metal. In wüstite, iron can exist in either the +2 or the +3 oxidation state. Suppose a solid were to begin at the hypothetical composition of $Fe_{1.00}O_{1.00}$, with iron entirely in the +2 oxidation state. For every two Fe^{3+} ions introduced, three Fe^{2+} ions must be removed to maintain overall charge neutrality. The total number of moles of iron is then less than that in the ideal FeO stoichiometry. The departure from the nominal stoichiometry can be far more extreme than that found in wüstite. The composition of "TiO" ranges from $Ti_{0.75}O$ to $Ti_{1.45}O$. Nickel oxide varies only from $Ni_{0.97}O$ to NiO in composition, but the variation is accompanied by a dramatic change in properties. When the compound is prepared in the 1:1 composition, it is pale green and is an electrical insulator. When it is prepared in an excess of oxygen, it is black and conducts electricity fairly well. In the black material, a small fraction of Ni^{2+} ions are replaced by Ni^{3+} ions, and compensating vacancies occur at some nickel atom sites in the crystal.

EXAMPLE 21.5

The composition of a sample of wüstite is $Fe_{0.930}O_{1.00}$. What percentage of the iron is in the form of iron(III)?

Solution

For every 1.00 mol of oxygen atoms in this sample, there is 0.930 mol of iron atoms. Suppose y mol of the iron is in the +3 oxidation state and $0.930 - y$ is in the +2 oxidation state. Then the total positive charge from the iron (in moles of electron charge) is

$$+3y + 2(0.930 - y)$$

This positive charge must exactly balance the 2 mol of negative charge carried by the mole of oxygen atoms (recall that each oxygen atom has oxidation number −2). We conclude that

$$3y + 2(0.930 - y) = +2$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Solving this equation for y gives

$$y = 0.140$$

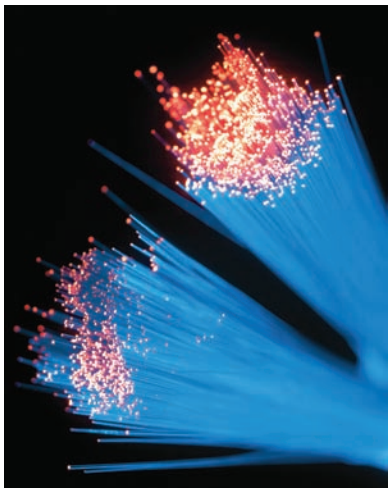
The percentage of iron in the form of Fe^{3+} is then the ratio of this number to the total number of moles of iron, 0.930, multiplied by 100%:

$$\%\ \text{iron in form of } Fe^{3+} = \frac{0.140}{0.930} * 100\% = 15.1\%$$

Related Problems: 37, 38

Alloys

The nonstoichiometric compounds just described are ionic materials with compositional disorder. A related type of disorder is exhibited by an **alloy,** a mixture of elements that displays metallic properties.



There are two types of alloys. In a **substitutional alloy,** some of the metal atoms in a crystal lattice are replaced by other atoms (usually of comparable size). Examples are brass, in which approximately one third of the atoms in a copper crystal are replaced by zinc atoms, and pewter, an alloy of tin that contains 7% copper, 6% bismuth, and 2% antimony. In an **interstitial alloy,** atoms of one or more additional elements enter the interstitial sites of the host metal lattice. An example is steel, in which carbon atoms occupy interstitial sites of an iron crystal, making the material stronger and harder than pure iron. Mild steel contains less than 0.2% C and is used for nails, whereas high-carbon steels can contain up to 1.5% C and are used in specialty applications such as tools and springs. *Alloy steels* are both substitutional and interstitial; atoms from metals such as chromium and vanadium substitute for iron atoms, with carbon remaining in interstitial sites. Alloy steels have a variety of specialized purposes, ranging from cutlery to bicycle frames.

Amorphous Solids and Glasses

The arrangements of atoms, ions, or molecules in crystalline solids exhibit high degrees of spatial order. Now let us briefly consider solids that lack this characteristic. **Amorphous solids,** commonly called **glasses,** resemble crystalline solids in many respects. They may have chemical compositions, mechanical properties such as hardness and elasticity, and electrical and magnetic properties that are similar to those of crystals. Like crystals, glasses may have molecular, ionic, covalent, or metallic bonding. On an atomic scale, however, amorphous solids lack the regular periodic structure of crystals. They are states of matter in which so many defects are present that crystalline order is destroyed.

Some substances have a strong tendency to solidify as glasses. The best example is the material used in common window panes, with the approximate chemical formula $Na_2O{\cdot}CaO{\cdot}(SiO_2)_6$. This is a partly ionic, partly covalent material with Na^+ and Ca^{2+} ions distributed through a covalently bonded Si—O network. Glass-forming ability is not restricted to a few special materials, however. If a substance can be liquefied, it can almost certainly be prepared in an amorphous state. Even metals, which are known primarily in the crystalline state, have been made into amorphous solids. The trick is to bypass crystallization by cooling molten material very fast. One technique involves shooting a jet of liquid metal at a rapidly rotating cold cylinder, which produces a continuous ribbon of amorphous metal at a rate up to 2 km per minute.

FIGURE 21.30 Optical fibers (extremely thin glass fibers of specialized composition) carry information in the form of light waves.

On the molecular level, a strong tendency to form glasses is associated with the presence of long or irregularly shaped molecules that can easily become tangled and disordered. Even slowly cooling a liquid assembly of such molecules may not afford enough time for them to organize into a crystalline lattice before solidification. Instead of a sharp liquid-to-crystal transition, such glass-formers transform continuously, over a range of temperature, into amorphous solids. They lend themselves to fabrication into articles of every conceivable shape, because the flow properties of the work piece can be managed by controlling its temperature. This plasticity is the reason that glass has played an indispensable role in science, industry, and the arts.

One of the most exciting new uses of a glass is the transmission of voice messages, television images, and data as light pulses. Tens of thousands of audio messages can be transmitted simultaneously through glass fibers no greater in diameter than a human hair. This is done by encoding the audio signal into electronic impulses that modulate light from a laser source. The light then passes down the glass fiber as though it were a tube. Chemical control of the glass composition reduces light loss and permits messages to travel many kilometers without amplification (Fig. 21.30).

A DEEPER LOOK

21.5 LATTICE ENERGIES OF CRYSTALS

The **lattice energy** of a crystal is the energy required to separate the crystal into its component atoms, molecules, or ions at 0 K. In this section we examine the calculation and measurement of lattice energies for molecular and ionic crystals.

Lattice Energy of a Molecular Crystal

The lattice energy of a molecular crystal can be estimated by using the simple Lennard-Jones potential of Section 9.6:

$$V_{LJ}(R) = 4\varepsilon\left[\left(\frac{\sigma}{R}\right)^{12} - \left(\frac{\sigma}{R}\right)^{6}\right]$$

Table 9.4 lists the values of ε and σ for various atoms and molecules. To obtain the total potential energy for 1 mol, sum over all pairs of atoms or molecules:

$$V_{tot} = \tfrac{1}{2}\sum_{i=1}^{N_A}\sum_{j=1}^{N_A} V_{LJ}(R_{ij})$$

where R_{ij} is the distance between atom i and atom j. The factor $\frac{1}{2}$ arises because each interaction between a pair of atoms should be counted only once, not twice. For a crystal of macroscopic size, this can be rewritten as

$$V_{tot} = \frac{N_A}{2}\sum_{j=1}^{N_A} V_{LJ}(R_{ij})$$

where i is taken to be some atom in the middle of the crystal. Taking the nearest neighbor distance to be R_0, we define a ratio of distances $p_{ij} = R_{ij}/R_0$ and rewrite V_{tot} for the Lennard-Jones potential as

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

$$V_{\text{tot}} = \frac{N_A}{2}\ (4\varepsilon)\left[\sum_j \left(\frac{\sigma}{p_{ij}R_0}\right)^{12} - \sum_j \left(\frac{\sigma}{p_{ij}R_0}\right)^{6}\right]$$

$$= 2\varepsilon N_A\left[\left(\frac{\sigma}{R_0}\right)^{12}\sum_j (p_{ij})^{-12} - \left(\frac{\sigma}{R_0}\right)^{6}\sum_j (p_{ij})^{-6}\right]$$

The two summations are dimensionless properties of the lattice structure, and accurate values can be obtained by summing over the first few sets of nearest neighbors (Table 21.3). The resulting total energy for the fcc lattice is

$$V_{\text{tot}} = 2\varepsilon N_A\left[12.132\left(\frac{\sigma}{R_0}\right)^{12} - 14.454\left(\frac{\sigma}{R_0}\right)^{6}\right]$$

The equilibrium atomic spacing at $T = 0$ K should be close to the one that gives a minimum in V_{tot}, which can be calculated by differentiating the preceding expression with respect to R_0 and setting the derivative to 0. The result is

$$R_0 = 1.09\sigma$$

and the value of V_{tot} at this value of R_0 is

$$V_{\text{tot}} = -8.61\varepsilon N_A$$

The corresponding potential energy when the atoms or molecules are completely separated from one another is zero. The lattice energy is the difference between these quantities and is a positive number:

$$\text{lattice energy} = -V_{\text{tot}} = 8.61\varepsilon N_A$$

This overestimates the true lattice energy because of the quantum effect of zero-point energy (see Section 4.6). When a quantum correction is applied, the binding energy is reduced by 28%, 10%, 6%, and 4% for Ne, Ar, Kr, and Xe, respectively. Table 21.4 shows the resulting predictions for crystal lattice energies and nearest neighbor distances. The agreement with experiment is quite reasonable, considering the approximations inherent in the use of a Lennard-Jones potential derived entirely from gas-phase data. For helium the amplitude of zero-point motion is so great that if a crystal did form, it would immediately melt. Consequently, helium remains liquid down to absolute zero at atmospheric pressure.

Lattice Energy of an Ionic Crystal

In Section 3.8, we calculated the potential energy of a gaseous diatomic ionic molecule relative to the separated ions by means of Coulomb's law:

$$\text{V} = \frac{q_1 q_2}{4\pi\epsilon_0 R_0}$$

where R_0 is the equilibrium internuclear separation. Coulomb's law can also be used to calculate the lattice energies of ionic compounds in the crystalline state.

For simplicity, consider a hypothetical one-dimensional crystal (Fig. 21.31), in which ions of charge $+e$ and $-e$ alternate with an internuclear separation of R_0. One ion, selected to occupy an arbitrary origin, will interact attractively with all ions of opposite sign to make the following contribution to the crystal energy:

$$V_{\text{attraction}} = -\frac{e^2}{4\pi\epsilon_0 R_0}\ [2(1) + 2(\tfrac{1}{3}) + 2(\tfrac{1}{5}) + \dots]$$

Here the factors of 2 come from the fact that there are *two* ions of opposite sign at a distance R_0 from a given ion, two at a distance $3R_0$, two at $5R_0$, and so forth. The

TABLE 21.4

Properties of Noble-Gas Crystals[†]

	R_0 (Å)		Lattice Energy (kJ mol^{-1})	
	Predicted	Observed	Predicted	Observed
Ne	3.00	3.13	1.83	1.88
Ar	3.71	3.76	7.72	7.74
Kr	3.92	4.01	11.50	11.20
Xe	4.47	4.35	15.20	16.00

[†]All data are extrapolated to 0 K and zero pressure.

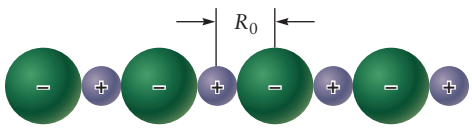

FIGURE 21.31 Lattice energy for a one-dimensional ionic crystal.

negative sign occurs because the ions that occupy odd-numbered sites have a charge opposite that of the ion at the origin, and their interaction with the ion at the origin is attractive. The ion at the origin also interacts repulsively with all ions of the same sign to make the following contribution to the crystal energy:

$$V_{\text{repulsion}} = +\frac{e^2}{4\pi\epsilon_0 R_0}\,[2(\tfrac{1}{2}) + 2(\tfrac{1}{4}) + 2(\tfrac{1}{6}) + \ldots]$$

The net interaction of N_A such ions of each sign with one another is:

$$V_{\text{net}} = -\frac{N_A e^2}{4\pi\epsilon_0 R_0}\left[2 - \frac{2}{2} + \frac{2}{3} - \frac{2}{4} + \frac{2}{5} - \frac{2}{6} + \ldots\right]$$

We must be very careful with factors of 2. To obtain the potential energy for the interaction of N_A positive ions with N_A negative ions, it is necessary to multiply the total potential energy of a given ion due to all others by $2N_A$ and then divide by 2 to avoid counting the interaction of a given pair of ions twice. This gives the preceding result.

If such a calculation is carried out for a real three-dimensional crystal, the result is a series (such as that just given in brackets) whose value sums to a dimensionless number that depends upon the crystal structure. That number is called the **Madelung constant,** M, and its value is independent of the unit-cell dimensions. Table 21.5 lists the values of the Madelung constant for several crystal structures. The lattice

TABLE 21.5

Madelung Constants

Lattice	M
Rock salt	1.7476

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

energy is again the opposite of the total potential energy. Expressed in terms of the Madelung constant, it is

$$\text{lattice energy} = \frac{N_A e^2}{4\pi\epsilon_0 R_0} = M \qquad [21.4]$$

EXAMPLE 21.6

Calculate the electrostatic part of the lattice energy of sodium chloride, given that the internuclear separation between Na^+ and Cl^- ions is 2.82 Å.

Solution

Using the Madelung constant of 1.7476 for this structure gives

$$\frac{(6.02\times10^{23}\ \text{mol}^{-1})(1.602\times10^{-19}\ \text{C})^2(1.7476)}{(4\pi)(8.854\times10^{-12}\ \text{C}^2\ \text{J}^{-1}\ \text{m}^{-1})(2.82\times10^{-10}\ \text{m})} = 8.61\times10^5\ \text{J mol}^{-1} = 861\ \text{kJ mol}^{-1}$$

Related Problems: 39, 40

Ionic lattice energies are measured experimentally by means of a thermodynamic cycle developed by Max Born and Fritz Haber. The **Born–Haber cycle** is an application of Hess's law (the first law of thermodynamics). It is illustrated by a determination of the lattice energy of sodium chloride, which is ΔU for the reaction

$$NaCl(s) \longrightarrow Na^+(g) + Cl^-(g) \qquad \Delta U = ?$$

This reaction can be represented as a series of steps, each with a measurable energy or enthalpy change. In the first step, the ionic solid is converted to the elements in their standard states:

$$NaCl(s) \longrightarrow Na(s) + \tfrac{1}{2}Cl_2(g)$$
$$\Delta U_1 \approx \Delta H = -\Delta H_f^\circ(NaCl(s)) = +411.2\ \text{kJ}$$

In the second step, the elements are transformed into gas-phase atoms:

$$Na(s) \longrightarrow Na(g) \qquad \Delta U \approx \Delta H = \Delta H_f^\circ(Na(g)) = +107.3\ \text{kJ}$$
$$\tfrac{1}{2}\ Cl_2(g) \longrightarrow Cl(g) \qquad \Delta U \approx \Delta H = \Delta H_f^\circ(Cl(g)) = +121.7\ \text{kJ}$$
$$Na(s) + \tfrac{1}{2}\ Cl_2(g) \longrightarrow Na(g) + Cl(g) \qquad \Delta U_2 = +229.0\ \text{kJ}$$

Finally, in the third step, electrons are transferred from the sodium atoms to the chlorine atoms to give ions:

$$Na(g) \longrightarrow Na^+(g) + e^- \qquad \Delta U = IE_1(Na) = 496\ \text{kJ}$$
$$Cl(g) + e^- \longrightarrow Cl^-(g) \qquad \Delta U = -EA(Cl) = -349\ \text{kJ}$$
$$Na(g) + Cl(g) \longrightarrow Na^+(g) + Cl^-(g) \qquad \Delta U_3 = +147\ \text{kJ}$$

Here $EA(Cl)$ is the electron affinity of Cl, and $IE_1(Na)$ is the first ionization energy of Na. The total energy change is

$$\Delta U = \Delta U_1 + \Delta U_2 + \Delta U_3 = 411 + 229 + 147 = +787\ \text{kJ}$$

The small differences between ΔU and ΔH were neglected in this calculation. If their difference is taken into account (using $\Delta H = \Delta U + RT\Delta n_g$, where Δn_g is the change in the number of moles of gas molecules in each step of the reaction), then

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ΔU_2 is decreased by $\frac{3}{2}RT$ and ΔU_1 by $\frac{1}{2}RT$, giving a net decrease of $2RT$ and changing ΔU to $+782$ kJ mol^{-1}. Comparing this experimental lattice energy with the energy calculated in Example 21.6 shows that the latter is approximately 10% greater, presumably because short-range repulsive interactions and zero-point energy were not taken into account in the lattice energy calculation.

CHAPTER SUMMARY

This chapter describes the distinctive properties of solids as the consequences of the collective behavior of an extended array of chemical bonds. The chemical bonds involved are already familiar in the context of isolated molecules. What is new here is the extended array of these bonds in the solid state. We can determine the array experimentally by X-ray diffraction. To describe the array we introduce the concepts of local symmetry and repetitive, long-range order; together, these define the unit cell and the crystal lattice. By placing structural elements at the points of the lattice, we complete the description of the structure of a perfect crystal. The number of atoms per unit cell depends on packing density of the atoms in the lattice. The properties of different classes of solids depend on the type of bonding involved: ionic, covalent, metallic, or molecular. The perfect crystal is the fundamental starting point for investigations in the solid state. Practical materials can be described and categorized by the nature and extent of their deviations from perfect crystal structure.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 21.1 – Crystal Symmetry and the Unit Cell

Relate the general properties of solids to the nature of the bonds between atoms and to the spatial arrangement of atoms in a solid.

- Solids differ from gases and liquids because they are rigid objects that retain their shapes even when external forces are applied. The rigidity and mechanical strength of solids are due to strong, directional bonds between atoms.
- Solids whose structures are highly ordered and symmetrical over macroscopic distances are called crystals with structures that are defined mathematically and measured experimentally.
- Crystal structure is defined in terms of the crystal lattice, a mathematical abstraction that represents the ordered and repetitive nature of the structure. A crystal lattice is constructed from a set of specific displacements along different directions. Each individual displacement generates a new lattice point; repeating this process many times generates the crystal lattice.

Identify the symmetry elements of different crystal systems (Problems 1–4).

- A symmetry element is an operation of rotation, reflection, or inversion which produces a new orientation of an object that can be exactly superimposed on the original orientation.
- The lattice embodies all the symmetry in the structure. Lattice points are identified by the fundamental symmetry operations of rotation, reflection, and inversion.
- The unit cell is the smallest region of a crystal lattice that contains all the structural information about the crystal. Each unit cell has characteristic lengths and angles. There are seven types of crystal structures (the seven crystal systems—see Table 21.1), each defined by the properties of its unit cell: hexagonal, cubic, tetragonal, trigonal, orthorhombic, monoclinic, and triclinic. The crystal lattice may be visualized as a three-dimensional stack of unit cells.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Section 21.2 – Crystal Structure

Explain how X-rays and neutrons are diffracted by crystals, and use information from such experiments to calculate lattice spacings (Problems 5–10).

- X-rays and neutrons have wavelengths comparable to the distance d between lattice planes in solids. Waves scattered from atoms in the solid experience constructive and destructive interference to produce a diffraction pattern in which peaks in the diffracted intensity appear at angles θ that satisfy the diffraction condition.

$$n\lambda = 2d \sin\theta \qquad n = 1, 2, 3, \ldots$$

- The distance d between planes in a crystal can be measured experimentally by X-ray diffraction once the diffraction angle *(* and *n,* the order of diffraction, are known.

Describe the packing of atoms in simple crystal lattices (Problems 11–24).

- Once the crystal lattice has been identified, description of the structure is completed by specifying the structural elements that are located at lattice points. The resulting structures are named by characteristics of the unit cell. Three examples are displayed by the elemental metals.

Simple cubic (one atom per unit cell)	Po
Body-centered cubic (two atoms per unit cell)	alkali metals
Face-centered cubic (four atoms per unit cell)	Al, Ni, Cu, Ag

- The volume of a unit cell is given by

$$V_c = abc\sqrt{1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cos\beta\cos\gamma}$$

The efficiency of packing atoms onto lattice sites is determined by the size of the atom and the dimensions of the unit cell. Table 21.2 lists the fractional volume occupied by the atoms (packing fraction) for cubic lattices.

Section 21.3 – Cohesion in Solids

Compare the natures of the forces that hold atoms or molecules in their lattice sites in ionic, metallic, covalent, and molecular crystals (Problems 27–32).

- Different types of chemical bonding appear in solids and are responsible for the differences in mechanical and structural properties of different types of solids.
- Because electrostatic forces are strong and operate over large distances, ionic crystals are hard, brittle solids that have high melting points and are poor conductors of heat and electricity. They crystallize in structures determined primarily by atomic packing density.
  - Zinc blende structure for cation–anion radius ratio smaller than 0.414
  - Rock-salt structure for cation–anion radius ratio between 0.414 and 0.732
  - Cesium chloride structure for cation–anion radius ratio greater than 0.732
- Bonding in metallic crystals is explained as a sea of delocalized electrons around positively charged ions located at the lattice sites. The number density of electrons is equal to the number density of positive ions, so the metal is electrically neutral. The bonds are quite strong, evidenced by the high melting and boiling points of metals. Metals are malleable and ductile because the highly mobile electrons can rapidly adjust when lattice ions are pushed to new locations by external mechanical forces. Metals are good conductors of heat and electricity because the delocalized electrons respond easily to applied external fields.

- Covalent crystals are held together by strong, highly directional bonds usually described by the valence bond hybrid orbital method. Because of the nature of their bonds, covalent crystals have very high melting points and are hard and brittle.
- Molecular crystals are held together by van der Waals forces, the same as the intermolecular forces in gases and liquids. Because these are much weaker than ionic, metallic, and covalent bonds, the molecular crystals are usually soft, easily deformed, and have low melting points.

Section 21.4 – Defects and Amorphous Solids

Describe the kinds of equilibrium defects that are present in crystalline solids and the properties of amorphous solids (Problems 35–36). Real-world crystals do not have perfect symmetry and order. It is useful to characterize practical materials by the ways in which they deviate from the structure of the perfect crystal models described earlier.

- Point defects where atoms are missing from lattice sites are called vacancies, or Schottky defects. Their number density depends on the temperature and on the Gibbs free energy of formation of defects.
- Point defects where atoms are located between lattice sites are called interstitials. If a lattice atom is displaced to an interstitial site, the combination of the vacancy and the interstitial is called a Frenkel defect.
- Diffusion in solids occurs as Schottky or Frenkel defects hop from one lattice site to another by a thermally activated process akin to chemical reactions. The diffusion constant is given by

$$D = D_0 \exp\left[-E_a/RT\right]$$

- Amorphous solids, or glasses, may have chemical compositions and mechanical properties similar to crystalline materials, and they may have ionic, metallic, covalent, or molecular bonding. But at the microscopic level they lack crystalline order. This arises from kinetic effects during solidification that reduce the mobility of atoms or molecules and prevent them from achieving ordered structures. Long or irregularly shaped molecules that are easily entangled lead to glass formation.

Determine the amount of different oxidation states present in nonstoichiometric solids (Problems 37–38).

- Determine the empirical formula for a nonstoichiometric metal oxide. Assuming the mixed oxide was initially 1:1, let y be the number of moles of metal ions in the +2 state that must be removed in order to accommodate each metal ion of the other oxidation state; the remaining metal ions must be in the +2 state. Enforce charge balance between the two states of metal and the total negative charge in the oxide anions to evaluate y. The method is illustrated in Example 21.5.

Section 21.5 – A Deeper Look . . . Lattice Energies of Crystals

Calculate lattice energies of molecular and ionic crystals (Problems 39–42).

- The lattice energy of a crystal is the energy required to separate the crystal into its component ions, atoms, or molecules at 0 K. The lattice energy is the negative of the total potential energy in the lattice. The total potential energy in an ionic crystal is calculated by adding up the pairwise Coulomb interactions among a mole of positive and negative ions separated by distance R_0 throughout the crystal. The geometry of the lattice is accounted for by the Madelung constant M, which multiples the pairwise interaction.

$$\text{lattice energy} = \frac{N_A e^2}{4\pi\epsilon_0 R_0} M$$

Two forms of elemental phosphorus: white and red.

The Many States of Phosphorus

Solid elemental phosphorus appears in a rich variety of forms, with crystals in all seven crystal systems reported under various conditions of temperature, pressure, and sample preparation.

(a) The thermodynamically stable form of phosphorus under room conditions is black phosphorus. Its unit cell is orthorhombic with edges of lengths 3.314, 4.376, and 10.48 Å. Calculate the volume of one unit cell, and determine the number of phosphorus atoms per unit cell, if the density of this form of phosphorus is 2.69 g cm^{-3}.

(b) The form of phosphorus that is easiest to prepare from the liquid or gaseous state is white phosphorus, which consists of P_4 molecules in a cubic lattice. When X-rays of wavelength 2.29 Å are scattered from the parallel faces of its unit cells, the first-order Bragg diffraction is observed at an angle 2θ of 7.10°. Calculate the length of the unit-cell edge for white phosphorus. At what angle will third-order Bragg diffraction be seen?

(c) Amorphous red phosphorus has been reported to convert to monoclinic, triclinic, tetragonal, and cubic red forms with different heat treatments. Identify the changes in the shape of the unit cell as a cubic lattice is converted first to tetragonal, then monoclinic, then triclinic.

(d) A monoclinic form of red phosphorus has been studied that has cell edge lengths 9.21, 9.15, and 22.60 Å, with an angle β of 106.1°. Each unit cell contains 84 atoms of phosphorus. Estimate the density of this form of phosphorus.

(e) Phosphorus forms many compounds with other elements. Describe the nature of the bonding in the solids white elemental phosphorus (P_4), black elemental phosphorus, sodium phosphate (Na_3PO_4), and phosphorus trichloride (PCl_3).

Answers

(a) Volume is 152.0 $Å^3$; eight atoms per unit cell

(b) 18.5 Å; angle $2\theta = 21.4°$

(c) Cubic to tetragonal: One cell edge is stretched or shrunk. Tetragonal to monoclinic: A second cell edge is stretched or shrunk, and the angles between two adjacent faces (and their opposite faces) are changed from 90°. Monoclinic to triclinic: The remaining two angles between faces are deformed from 90°.

(d) 2.36 g cm^{-3}

(e) P_4(white) and PCl_3 are molecular solids; P(black) is covalent; Na_3PO_4 is ionic.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

Crystal Symmetry and the Unit Cell

1. Which of the following has 3-fold rotational symmetry? Explain.
(a) An isosceles triangle
(b) An equilateral triangle
(c) A tetrahedron
(d) A cube

2. Which of the following has 4-fold rotational symmetry? Explain.
(a) A cereal box (exclusive of the writing on the sides)
(b) A stop sign (not counting the writing)
(c) A tetrahedron
(d) A cube

3. Identify the symmetry elements of the CCl_2F_2 molecule (see Fig. 12.18).

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Identify the symmetry elements of the PF_5 molecule (see Fig. 3.23a).

5. The second-order Bragg diffraction of X-rays with λ = 1.660 Å from a set of parallel planes in copper occurs at an angle 2θ = 54.70°. Calculate the distance between the scattering planes in the crystal.

6. The second-order Bragg diffraction of X-rays with λ = 1.237 Å from a set of parallel planes in aluminum occurs at an angle 2θ = 35.58°. Calculate the distance between the scattering planes in the crystal.

7. The distance between members of a set of equally spaced planes of atoms in crystalline lead is 4.950 Å. If X-rays with λ = 1.936 Å are diffracted by this set of parallel planes, calculate the angle 2θ at which fourth-order Bragg diffraction will be observed.

8. The distance between members of a set of equally spaced planes of atoms in crystalline sodium is 4.28 Å. If X-rays with λ = 1.539 Å are diffracted by this set of parallel planes, calculate the angle 2θ at which second-order Bragg diffraction will be observed.

9. The members of a series of equally spaced parallel planes of ions in crystalline LiCl are separated by 2.570 Å. Calculate all the angles 2θ at which diffracted beams of various orders may be seen, if the X-ray wavelength used is 2.167 Å.

10. The members of a series of equally spaced parallel planes in crystalline vitamin B_{12} are separated by 16.02 Å. Calculate all the angles 2θ at which diffracted beams of various orders may be seen, if the X-ray wavelength used is 2.294 Å.

Crystal Structure

11. A crucial protein at the photosynthetic reaction center of the purple bacterium *Rhodopseudomonas viridis* (see Section 20.7) has been separated from the organism, crystallized, and studied by X-ray diffraction. This substance crystallizes with a primitive unit cell in the tetragonal system. The cell dimensions are $a = b$ = 223.5 Å and c = 113.6 Å.
    (a) Determine the volume, in cubic angstroms, of this cell.
    (b) One of the crystals in this experiment was box-shaped, with dimensions 1 × 1 × 3 mm. Compute the number of unit cells in this crystal.

12. Compute the volume (in cubic angstroms) of the unit cell of potassium hexacyanoferrate(III) ($K_3Fe(CN)_6$), a substance that crystallizes in the monoclinic system with a = 8.40 Å, b = 10.44 Å, and c = 7.04 Å and with β = 107.5°.

13. The compound $Pb_4In_3B_{17}S_{18}$ crystallizes in the monoclinic system with a unit cell having a = 21.021 Å, b = 4.014 Å, c = 18.898 Å, and the only non-90° angle equal to 97.07°. There are two molecules in every unit cell. Compute the density of this substance.

14. Strontium chloride hexahydrate ($SrCl_2 \cdot 6H_2O$) crystallizes in the trigonal system in a unit cell with a = 8.9649 Å and α = 100.576°. The unit cell contains three formula units. Compute the density of this substance.

15. At room temperature, the edge length of the cubic unit cell in elemental silicon is 5.431 Å, and the density of silicon at the same temperature is 2.328 g cm^{-3}. Each cubic unit cell contains eight silicon atoms. Using only these facts, perform the following operations.
    (a) Calculate the volume (in cubic centimeters) of one unit cell.
    (b) Calculate the mass (in grams) of silicon present in a unit cell.
    (c) Calculate the mass (in grams) of an atom of silicon.
    (d) The mass of an atom of silicon is 28.0855 u. Estimate Avogadro's number to four significant figures.

16. One form of crystalline iron has a bcc lattice with an iron atom at every lattice point. Its density at 25°C is 7.86 g cm^{-3}. The length of the edge of the cubic unit cell is 2.87 Å. Use these facts to estimate Avogadro's number.

17. Sodium sulfate (Na_2SO_4) crystallizes in the orthorhombic system in a unit cell with a = 5.863 Å, b = 12.304 Å, and c = 9.821 Å. The density of these crystals is 2.663 g cm^{-3}. Determine how many Na_2SO_4 formula units are present in the unit cell.

18. The density of turquoise, $CuAl_6(PO_4)_4(OH)_8(H_2O)_4$, is 2.927 g cm^{-3}. This gemstone crystallizes in the triclinic system with cell constants a = 7.424 Å, b = 7.629 Å, c = 9.910 Å, α = 68.61°, β = 69.71°, and γ = 65.08°. Calculate the volume of the unit cell, and determine how many copper atoms are present in each unit cell of turquoise.

19. An oxide of rhenium has a structure with a Re atom at each corner of the cubic unit cell and an O atom at the center of each edge of the cell. What is the chemical formula of this compound?

20. The mineral perovskite has a calcium atom at each corner of the unit cell, a titanium atom at the center of the unit cell, and an oxygen atom at the center of each face. What is the chemical formula of this compound?

21. Iron has a body-centered cubic structure with a density of 7.86 g cm^{-3}.
    (a) Calculate the nearest neighbor distance in crystalline iron.
    (b) What is the lattice parameter for the cubic unit cell of iron?
    (c) What is the atomic radius of iron?

22. The structure of aluminum is fcc and its density is ρ = 2.70 g cm^{-3}.
    (a) How many Al atoms belong to a unit cell?
    (b) Calculate a, the lattice parameter, and d, the nearest neighbor distance.

23. Sodium has the body-centered cubic structure, and its lattice parameter is 4.28 Å.
    (a) How many Na atoms does a unit cell contain?
    (b) What fraction of the volume of the unit cell is occupied by Na atoms, if they are represented by spheres in contact with one another?

24. Nickel has an fcc structure with a density of 8.90 g cm^{-3}.
    (a) Calculate the nearest neighbor distance in crystalline nickel.
    (b) What is the atomic radius of nickel?
    (c) What is the radius of the largest atom that could fit into the interstices of a nickel lattice, approximating the atoms as spheres?

25. Calculate the ratio of the maximum radius of an interstitial atom at the center of a simple cubic unit cell to the radius of the host atom.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

26. Calculate the ratio of the maximum radius of an interstitial atom at the center of each face of a bcc unit cell to the radius of the host atom.

Cohesion in Solids

27. Classify each of the following solids as molecular, ionic, metallic, or covalent.
(a) $BaCl_2$ (b) SiC
(c) CO (d) Co

28. Classify each of the following solids as molecular, ionic, metallic, or covalent.
(a) Rb (b) C_5H_{12}
(c) B (d) Na_2HPO_4

29. The melting point of cobalt is 1495°C, and that of barium chloride is 963°C. Rank the four substances in problem 27 from lowest to highest in melting point.

30. The boiling point of pentane (C_5H_{12}) is slightly less than the melting point of rubidium. Rank the four substances in problem 28 from lowest to highest in melting point.

31. Explain the relationship between the number of bonds that can be formed by a typical atom in a crystal and the possibility of forming linear, two-dimensional, and three-dimensional network structures.

32. Although large crystals of sugar (rock candy) and large crystals of salt (rock salt) have different geometric shapes, they look much the same to the untrained observer. What physical tests other than taste might be performed to distinguish between these two crystalline substances?

33. By examining Figure 21.17, determine the number of nearest neighbors, second nearest neighbors, and third nearest neighbors of a Cs^+ ion in crystalline CsCl. The nearest neighbors of the Cs^+ ion are Cl^- ions, and the second nearest neighbors are Cs^+ ions.

34. Repeat the determinations of the preceding problem for the NaCl crystal, referring to Figure 21.16.

Defects and Amorphous Solids

35. Will the presence of Frenkel defects change the measured density of a crystal?

36. What effect will the (unavoidable) presence of Schottky defects have on the determination of Avogadro's number via the method described in problems 15 and 16?

37. Iron(II) oxide is nonstoichiometric. A particular sample was found to contain 76.55% iron and 23.45% oxygen by mass.
(a) Calculate the empirical formula of the compound (four significant figures).
(b) What percentage of the iron in this sample is in the +3 oxidation state?

38. A sample of nickel oxide contains 78.23% Ni by mass.
(a) What is the empirical formula of the nickel oxide to four significant figures?
(b) What fraction of the nickel in this sample is in the +3 oxidation state?

A Deeper Look . . . Lattice Energies of Crystals

39. Calculate the energy needed to dissociate 1.00 mol of crystalline RbCl into its gaseous ions if the Madelung constant for its structure is 1.7476 and the radii of Rb^+ and Cl^- are 1.48 Å and 1.81 Å, respectively. Assume that the repulsive energy reduces the lattice energy by 10% from the pure Coulomb energy.

40. Repeat the calculation of problem 39 for CsCl, taking the Madelung constant from Table 21.5 and taking the radii of Cs^+ and Cl^- to be 1.67 Å and 1.81 Å.

41. (a) Use the Born–Haber cycle, with data from Appendices D and F, to calculate the lattice energy of LiF.
(b) Compare the result of part (a) with the Coulomb energy calculated by using an Li—F separation of 2.014 Å in the LiF crystal, which has the rock-salt structure.

42. Repeat the calculations of problem 41 for crystalline KBr, which has the rock-salt structure with a K—Br separation of 3.298 Å.

ADDITIONAL PROBLEMS

43. Some water waves with a wavelength of 3.0 m are diffracted by an array of evenly spaced posts in the water. If the rows of posts are separated by 5.0 m, calculate the angle 2θ at which the first-order "Bragg diffraction" of these water waves will be seen.

44. A crystal scatters X-rays of wavelength $\lambda = 1.54$ Å at an angle 2θ of 32.15°. Calculate the wavelength of the X-rays in another experiment if this same diffracted beam from the same crystal is observed at an angle 2θ of 34.46°.

45. The number of beams diffracted by a single crystal depends on the wavelength λ of the X-rays used and on the volume associated with one lattice point in the crystal—that is, on the volume V_p of a primitive unit cell. An approximate formula is

$$\text{number of diffracted beams} = \frac{4}{3}\pi\left(\frac{2}{\lambda}\right)^3 V_p$$

(a) Compute the volume of the conventional unit cell of crystalline sodium chloride. This cell is cubic and has an edge length of 5.6402 Å.
(b) The NaCl unit cell contains four lattice points. Compute the volume of a primitive unit cell for NaCl.
(c) Use the formula given in this problem to estimate the number of diffracted rays that will be observed if NaCl is irradiated with X-rays of wavelength 2.2896 Å.
(d) Use the formula to estimate the number of diffracted rays that will be observed if NaCl is irradiated with X-rays having the shorter wavelength 0.7093 Å.

46. If the wavelength λ of the X-rays is too large relative to the spacing of planes in the crystal, no Bragg diffraction will be seen because $\sin\theta$ would be larger than 1 in the Bragg equation, even for $n = 1$. Calculate the longest wavelength of X-rays that can give Bragg diffraction from a set of planes separated by 4.20 Å.

47. The crystal structure of diamond is fcc, and the atom coordinates in the unit cell are (0, 0, 0), $\left(\frac{1}{2}, \frac{1}{2}, 0\right)$, $\left(\frac{1}{2}, 0, \frac{1}{2}\right)$, $\left(0, \frac{1}{2}, v\right)$, $\left(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}\right)$, $\left(\frac{3}{4}, \frac{1}{4}, \frac{3}{4}\right)$, $\left(\frac{3}{4}, \frac{3}{4}, \frac{1}{4}\right)$, and $\left(\frac{1}{4}, \frac{3}{4}, \frac{3}{4}\right)$. The lattice parameter is $a = 3.57$ Å. What is the C—C bond distance in diamond?

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

48. Polonium is the only element known to crystallize in the simple cubic lattice.
    (a) What is the distance between nearest neighbor polonium atoms if the first-order diffraction of X-rays with $\lambda = 1.785$ Å from the parallel faces of its unit cells appears at an angle of $2\theta = 30.96°$ from these planes?
    (b) What is the density of polonium in this crystal (in g cm^{-3})?

49. At room temperature, monoclinic sulfur has the unit-cell dimensions $a = 11.04$ Å, $b = 10.98$ Å, $c = 10.92$ Å, and $\beta = 96.73°$. Each cell contains 48 atoms of sulfur.
    (a) Explain why it is not necessary to give the values of the angles α and γ in this cell.
    (b) Compute the density of monoclinic sulfur (in g cm^{-3}).

50. A compound contains three elements: sodium, oxygen, and chlorine. It crystallizes in a cubic lattice. The oxygen atoms are at the corners of the unit cells, the chlorine atoms are at the centers of the unit cells, and the sodium atoms are at the centers of the faces of the unit cells. What is the formula of the compound?

* 51. Show that the radius of the largest sphere that can be placed in a tetrahedral interstitial site in an fcc lattice is $0.225r_1$, where r_1 is the radius of the atoms making up the lattice. (*Hint:* Consider a cube with the centers of four spheres placed at alternate corners, and visualize the tetrahedral site at the center of the cube. What is the relationship between r_1 and the length of a diagonal of a face? The length of a body diagonal?)

52. What is the closest packing arrangement possible for a set of thin circular discs lying in a plane? What fraction of the area of the plane is occupied by the discs? Show how the same reasoning can be applied to the packing of infinitely long, straight cylindrical fibers.

53. Name two elements that form molecular crystals, two that form metallic crystals, and two that form covalent crystals. What generalizations can you make about the portions of the periodic table where each type is found?

54. The nearest-neighbor distance in crystalline LiCl (rock-salt structure) is 2.570 Å; the bond length in a gaseous LiCl molecule is significantly shorter, 2.027 Å. Explain.

55. (a) Using the data of Table 9.4, estimate the lattice energy and intermolecular separation of nitrogen in its solid state, assuming an fcc structure for the solid lattice.
    (b) The density of cubic nitrogen is 1.026 g cm^{-3}. Calculate the lattice parameter a and the nearest neighbor distance. Compare your answer with that from part (a).

* 56. Solid CuI_2 is unstable relative to CuI at room temperature, but $CuBr_2$, $CuCl_2$, and CuF_2 are all stable relative to the copper(I) halides. Explain by considering the steps in the Born–Haber cycle for these compounds.

57. A crystal of sodium chloride has a density of 2.165 g cm^{-3} in the absence of defects. Suppose a crystal of NaCl is grown in which 0.15% of the sodium ions and 0.15% of the chloride ions are missing. What is the density in this case?

58. The activation energy for the diffusion of sodium atoms in the crystalline state is 42.22 kJ mol^{-1}, and $D_0 = 0.145$ cm^2 s^{-1}.
    (a) Calculate the diffusion constant $D = D_0 \exp(-E_a/RT)$ of sodium in the solid at its melting point (97.8°C).
    (b) What is the root-mean-square displacement of an average sodium atom from an arbitrary origin after the lapse of 1.0 hour at $t = 97.8$°C? (*Hint:* Use Equation 9.28 in Chapter 9.)

59. A compound of titanium and oxygen contains 28.31% oxygen by mass.
    (a) If the compound's empirical formula is Ti_xO, calculate x to four significant figures.
    (b) The nonstoichiometric compounds Ti_xO can be described as having a $Ti^{2+}—O^{2-}$ lattice in which certain Ti^{2+} ions are missing or are replaced by Ti^{3+} ions. Calculate the fraction of Ti^{2+} sites in the nonstoichiometric compound that are vacant and the fraction that are occupied by Ti^{3+} ions.

60. Classify the bonding in the following amorphous solids as molecular, ionic, metallic, or covalent.
    (a) Amorphous silicon, used in photocells to collect light energy from the sun
    (b) Polyvinyl chloride, a plastic of long-chain molecules composed of $—CH_2CHCl—$ repeating units, used in pipes and siding
    (c) Soda-lime-silica glass, used in windows
    (d) Copper-zirconium glass, an alloy of the two elements with approximate formula Cu_3Zr_2, used for its high strength and good conductivity

CUMULATIVE PROBLEMS

61. Sodium hydride (NaH) crystallizes in the rock-salt structure, with four formula units of NaH per cubic unit cell. A beam of monoenergetic neutrons, selected to have a velocity of 2.639×10^3 m s^{-1}, is scattered in second order through an angle of $2\theta = 36.26°$ by the parallel faces of the unit cells of a sodium hydride crystal.
    (a) Calculate the wavelength of the neutrons.
    (b) Calculate the edge length of the cubic unit cell.
    (c) Calculate the distance from the center of an Na^+ ion to the center of a neighboring H^- ion.
    (d) If the radius of an Na^+ ion is 0.98 Å, what is the radius of an H^- ion, assuming the two ions are in contact?

62. Chromium(III) oxide has a structure in which chromium ions occupy two-thirds of the octahedral interstitial sites in a hexagonal close-packed lattice of oxygen ions. What is the *d*-electron configuration on the chromium ion?

63. A useful rule of thumb is that in crystalline compounds every nonhydrogen atom occupies 18 $Å^3$, and the volume occupied by hydrogen atoms can be neglected. Using this rule, estimate the density of ice (in g cm^{-3}). Explain why the answer is so different from the observed density of ice.

64. Estimate, for the F-centers in CaF_2, the wavelength of maximum absorption in the visible region of the spectrum that will give rise to the color shown in Figure 21.29.

Azurite is a basic copper carbonate with chemical formula $Cu_3(CO_3)_2(OH)_2$.

Having laid the conceptual foundation for relating properties of solids to chemical bonding in Chapter 21, we turn now to applications of these concepts to three important classes of materials: ceramics, electronic materials, and optical materials. All of these are synthetic materials fashioned from inorganic, nonmetallic substances by chemical methods of synthesis and processing.

Ceramics are one of the oldest classes of materials prepared by humankind. New discoveries in ceramics are occurring at a startling rate, and major new technologic advances will certainly come from these discoveries. Ceramics have value both as structural materials—the role emphasized in this chapter—and for their wide range of electronic and optical properties.

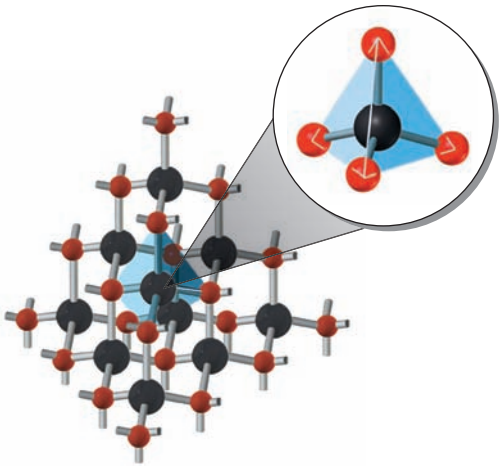
High-speed computing, fast communication, and rapid display of information were major technologic achievements in the second half of the 20th century. These developments will grow even more rapidly in the 21st century, when every home will be digitally connected to the Internet and every cell phone will display images requiring broadband transmission. These developments were made possible by the "microelectronics revolution," beginning with the first integrated circuits fabricated on microchips by Jack Kilby at Texas Instruments and Robert Noyce at Fairchild in 1958 to 1959.[1] The speed of computers increased dramatically through advances in transistor design; advances in the solid-state laser enabled high-speed communication via fiber optics. All these advances in device design relied critically on equally dramatic accomplishments in the growth and processing of materials, which in every case involved making and breaking chemical bonds in solid-state materials. Our goals in this chapter are to introduce the optical and electronic properties of materials and to show how they depend on chemical structure.

Electronic properties describe the movement of charged particles in a material in response to an applied electric field. If the charges are free to move throughout the material, the process is *electrical conduction,* measured by the *electrical conductivity* of the material. Differences in the magnitude of the conductivity distinguish metals, semiconductors, and insulators. If the charges can move only limited distances and are then halted by opposing binding forces, separation of positive and negative charges leads to *electric polarization* of the material, measured by its *dielectric constant*. Conduction involves dissipation of energy as heat, whereas polarization involves storage of potential energy in the material.

Optical properties describe the response of a material to electromagnetic radiation, particularly visible light. The list of optical properties is long, including reflection of light from a surface, refraction (bending the direction) of light as it passes from one medium into another, absorption, and transmission. We limit the discussion here to the generation and detection of light in solid materials, as extensions of the molecular processes of emission and excitation already described in Chapter 20. The absorption of light creates the bright colors of inorganic pigments and the conversion of solar energy into electrical energy in solar cells.

In this survey of mechanical, electrical, and optical properties, keep two questions in mind: (1) How does a material respond on an atomic level to applied mechanical stress and to electrical and optical fields? (2) If the chemical structure is modified, how does this change influence the response of the material to these forces?

22.1 MINERALS: NATURALLY OCCURRING INORGANIC MATERIALS



This chapter begins with a survey of the naturally occurring inorganic, nonmetallic minerals that are the starting materials for synthesis and processing of inorganic materials.

Silicates

Silicon and oxygen make up most of the earth's crust, with oxygen accounting for 47% and silicon for 28% of its mass. The silicon–oxygen bond is strong and partially ionic. It forms the basis for a class of minerals called **silicates,** which make up the bulk of the rocks, clays, sand, and soils in the earth's crust. From time immemorial, silicates have provided the ingredients for building materials such as bricks, cement, concrete, and glass (which are considered later in this chapter).

[1]Kilby was awarded the Nobel Prize in Physics in 2000, but Noyce, who had died, did not share the award. The Nobel Prize is not awarded posthumously.

Each SiO_2 unit shares O—Si—O bonds with other SiO_2 units arranged in a lattice of tetrahedra. Si atoms are shown in yellow and O atoms in red.

TABLE 22.1

Silicate Structures

Structure	Figure Number	Corners Shared at Each Si atom	Repeat Unit	Si:O Ratio	Example
Tetrahedra	22.1a	0	SiO_4^{4-}	1:4	Olivines
Pairs of tetrahedra	22.1b	1	$Si_2O_7^{6-}$	1:3 $\frac{1}{2}$	Thortveitite
Closed rings	22.1c	2	SiO_3^{2-}	1:3	Beryl
Infinite single chains	22.1d	2	SiO_3^{2-}	1:3	Pyroxenes
Infinite double chains	22.1e	2 $\frac{1}{2}$	$Si_4O_{11}^{6-}$	1:2 $\frac{3}{4}$	Amphiboles
Infinite sheets	22.1f	3	$Si_2O_5^{2-}$	1:2 $\frac{1}{2}$	Talc
Infinite network	22.1g	4	SiO_2	1:2	Quartz

The structure-building properties of silicates (Table 22.1) originate in the tetrahedral orthosilicate anion (SiO_4^{4-}), in which the negative charge of the silicate ion is balanced by the compensating charge of one or more cations. The simplest silicates consist of individual SiO_4^{4-} anions (Fig. 22.1a), with cations arranged around them on a regular crystalline lattice. Such silicates are properly called **orthosilicates.** Examples are forsterite (Mg_2SiO_4) and fayalite (Fe_2SiO_4), which are the extreme members of a class of minerals called **olivines,** $[Mg,Fe]_2SiO_4$. There is a continuous range of proportions of magnesium and iron in the olivines.

Other silicate structures form when two or more SiO_4^{4-} tetrahedra link and share oxygen vertices. The simplest such minerals are the **disilicates,** such as thort-

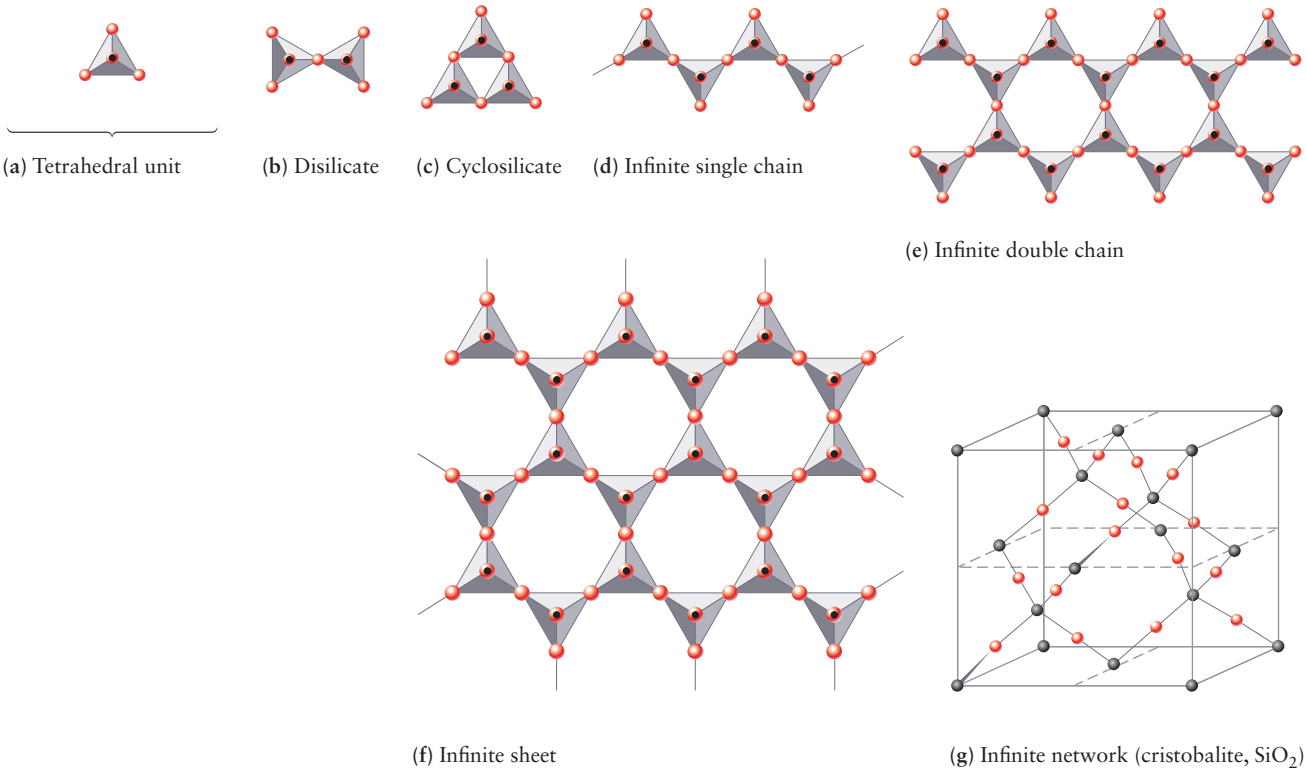

FIGURE 22.1 Classes of silicate structures. (a) Symbol used for the SiO_4^{4-} tetrahedron. This top view of the symbol shows a red circle to represent the fourth oxygen atom at the top of the tetrahedron. The black dot represents the silicon atom at the center of the tetrahedron. Bear in mind that all of these structures are actually three-dimensional. Planar projections are used here for convenience of representation. (b) Disilicate. (c) Cyclosilicate. (d) Infinite single chain. (e) Infinite double chain. (f) Infinite sheet. (g) Infinite network (cristobalite, SiO_2).

veitite, $Sc_2(Si_2O_7)$, in which two tetrahedra are linked (see Fig. 22.1b). Additional linkages of tetrahedra create the ring, chain, sheet, and network structures shown in Figure 22.1 and listed in Table 22.1. In each of these, the fundamental tetrahedron is readily identified, but the Si:O ratio is no longer 4 because oxygen (O) atoms are shared at the linkages.

EXAMPLE 22.1

By referring to Table 22.1, predict the structural class in which the mineral Egyptian blue ($CaCuSi_4O_{10}$) belongs. Give the oxidation state of each of its atoms.

Solution

Because the silicon/oxygen (Si:O) ratio is 4:10, or $1:2\frac{1}{2}$, this mineral should have an infinite sheet structure with the repeating unit $Si_2O_5^{2-}$. The oxidation states of Si and O are +4 and −2, as usual, and that of calcium (Ca) is +2. For the total oxidation number per formula unit to sum to 0, the oxidation state of copper (Cu) must be +2.

FIGURE 22.2 The mineral quartz is one form of silica, SiO_2.

The physical properties of the silicates correlate closely with their structures. Talc, $Mg_3(Si_4O_{10})(OH)_2$, is an example of an infinite layered structure (see Fig. 22.1f). In talc, all of the bonding interactions among the atoms occur in a single layer. Layers of talc sheets are attracted to one another only by van der Waals interactions, which (being weak) permit one layer to slip easily across another. This accounts for the slippery feel of talc (called talcum powder). When all four vertices of each tetrahedron are linked to other tetrahedra, three-dimensional network structures such as cristobalite (see Fig. 22.1g) or quartz (Fig. 22.2) result. Note that the quartz network carries no charge; consequently, there are no cations in its structure. Three-dimensional network silicates such as quartz are much stiffer and harder than the linear and layered silicates, and they resist deformation well.

Asbestos is a generic term for a group of naturally occurring, hydrated silicates that can be processed mechanically into long fibers (Fig. 22.3). Some of these silicates, such as tremolite, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$, show the infinite double-chain structure of Figure 22.1e. Another kind of asbestos mineral is chrysotile, $Mg_3(Si_2O_5)(OH)_4$. As the formula indicates, this mineral has a sheet structure (see Fig. 22.1f), but the sheets are rolled into long tubes. Asbestos minerals are fibrous because the bonds along the strandlike tubes are stronger than those that hold different tubes together. Asbestos is an excellent thermal insulator that does not burn, resists acids, and is strong. For many years, it was used in cement for pipes and ducts and woven into fabric to make fire-resistant roofing paper and floor tiles. Its use has decreased significantly in recent years because inhalation of its small fibers can cause the lung disease asbestosis. The risk comes with breathing asbestos dust that is raised during mining and manufacturing processes or that is released in buildings in which asbestos-containing materials are fraying, crumbling, or being removed.

FIGURE 22.3 The fibrous structure of asbestos is apparent in this sample.

Aluminosilicates

An important class of minerals called **aluminosilicates** results from the replacement of some of the Si atoms in silicates with aluminum (Al) atoms. Aluminum is the third most abundant element in the earth's crust (8% by mass), where it occurs largely in the form of aluminosilicates. Aluminum in minerals can be a simple cation (Al^{3+}), or it can replace silicon in tetrahedral coordination. When it replaces silicon, it contributes only three electrons to the bonding framework in place of the four electrons of Si atoms. The additional required electron is supplied by the ionization of a metal atom such as sodium (Na) or potassium (K); the resulting alkali-metal ions occupy nearby sites in the aluminosilicate structure.

FIGURE 22.4 Naturally occurring muscovite mica. The mechanical properties of crystals of mica are quite anisotropic. Thin sheets can be peeled off a crystal of mica by hand, but the sheets resist stresses in other directions more strongly. Transparent, thin sheets of mica, sometimes called isinglass, have been used for heat-resistant windows in stoves or in place of window glass.

The most abundant and important of the aluminosilicate minerals in the earth's surface are the **feldspars,** which result from the substitution of aluminum for silicon in three-dimensional silicate networks such as quartz. The Al ions must be accompanied by other cations such as sodium, potassium, or calcium to maintain overall charge neutrality. Albite is a feldspar with the chemical formula $NaAlSi_3O_8$. In the high-temperature form of this mineral, the Al and Si atoms are distributed at random (in 1 : 3 proportion) over the tetrahedral sites available to them. At lower temperatures, other crystal structures become thermodynamically stable, with partial ordering of the Al and Si sites.

If one of the four Si atoms in the structural unit of talc, $Mg_3(Si_4O_{10})(OH)_2$, is replaced by an Al atom and a K atom is furnished to supply the fourth electron needed for bonding in the tetrahedral silicate framework, the result is the composition $KMg_3(AlSi_3O_{10})(OH)_2$, which belongs to the family of **micas** (Fig. 22.4). Mica is harder than talc, and its layers slide less readily over one another, although the crystals still cleave easily into sheets. The cations occupy sites between the infinite sheets, and the van der Waals bonding that holds adjacent sheets together in talc is augmented by an ionic contribution. The further replacement of the three Mg^{2+} ions in $KMg_3(AlSi_3O_{10})(OH)_2$ with two Al^{3+} ions gives the mineral muscovite, $KAl_2(AlSi_3O_{10})(OH)_2$. Writing its formula in this way indicates that there are Al atoms in two kinds of sites in the structure: One Al atom per formula unit occupies a tetrahedral site, substituting for one Si atom, and the other two Al atoms are between the two adjacent layers. The formulas that mineralogists and crystallographers use convey more information than the usual empirical chemical formula of a compound.

Clay Minerals

Clays are minerals produced by the weathering action of water and heat on primary minerals. Their compositions can vary widely as a result of the replacement of one element with another. Invariably, they are microcrystalline or powdered in form and are usually hydrated. Often, they are used as supports for catalysts, as fillers in paint, and as ion-exchange vehicles. The clays that readily absorb water and swell are used as lubricants and bore-hole sealers in the drilling of oil wells.

The derivation of clays from talcs and micas provides a direct way to understand the structures of the clays. The infinite-sheet mica pyrophyllite, $Al_2(Si_4O_{10})(OH)_2$, serves as an example. If one of six Al^{3+} ions in the pyrophyllite structure is replaced by one Mg^{2+} ion and one Na^+ ion (which together carry the same charge), a type of clay called montmorillonite, $MgNaAl_5(Si_4O_{10})_3(OH)_6$, results. This clay readily absorbs water, which infiltrates between the infinite sheets and hydrates the Mg^{2+} and Na^+ ions there, causing the montmorillonite to swell (Fig. 22.5).

A different clay derives from the layered mineral talc, $Mg_3(Si_4O_{10})(OH)_2$. If iron(II) and aluminum replace magnesium and silicon in varying proportions and

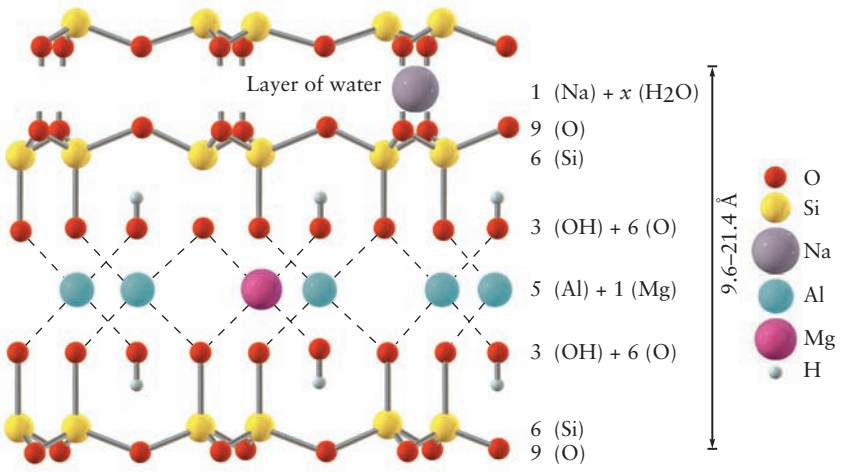

FIGURE 22.5 Structure of the clay mineral montmorillonite. Insertion of variable amounts of water causes the distance between layers to swell from 9.6 Å to more than 20 Å. When 1 Al^{3+} ion is replaced by an Mg^{2+} ion, an additional ion such as Na^+ is introduced into the water layers to maintain overall charge neutrality.

water molecules are allowed to take up positions between the layers, the swelling clay vermiculite results. When heated, vermiculite pops like popcorn, as the steam generated by the vaporization of water between the layers puffs the flakes up into a light, fluffy material with air inclusions. Because of its porous structure, vermiculite is used for thermal insulation or as an additive to loosen soils.

Zeolites

Zeolites are a class of three-dimensional aluminosilicates. Like the feldspars, they carry a negative charge on the aluminosilicate framework that is compensated by neighboring alkali-metal or alkaline-earth cations. Zeolites differ from feldspars in having much more open structures that consist of polyhedral cavities connected by tunnels (Fig. 22.6). Many zeolites are found in nature, but they can also be synthesized under conditions controlled to favor cavities of uniform size and shape. Most zeolites accommodate water molecules in their cavities, where they provide a mobile phase for the migration of the charge-compensating cations. This enables zeolites to serve as ion-exchange materials (in which one kind of positive ion can be readily exchanged for another) and is the key to their ability to soften water. Water "hardness" arises from soluble calcium and magnesium salts such as $Ca(HCO_3)_2$ and $Mg(HCO_3)_2$. Such salts are converted to insoluble carbonates (boiler scale) when the water is heated and form objectionable precipitates (bathtub ring) with soaps. When hard water is passed through a column packed with a zeolite that has Na ions in its structure, the Ca and Mg ions exchange with the Na ions and are removed from the water phase:

$$2\ NaZ(s) + Ca^{2+}(aq) \rightleftharpoons CaZ_2(s) + 2\ Na^{+}(aq)$$

When the ion-exchange capacity of the zeolite is exhausted, this reaction can be reversed by passing a concentrated solution of sodium chloride through the zeolite to regenerate it in the sodium form.

A second use of zeolites derives from the ease with which they adsorb small molecules. Their spongelike affinity for water makes them useful as drying agents; they are put between the panes of double-pane glass windows to prevent moisture from condensing on the inner surfaces. The pore size of zeolites can be selected to allow molecules that are smaller than a certain size to pass through but hold back larger molecules. Such zeolites serve as "molecular sieves"; they have been used to capture nitrogen molecules in a gas stream while permitting oxygen molecules to pass through.

Perhaps the most exciting use of zeolites is as catalysts. Molecules of varying sizes and shapes have different rates of diffusion through a zeolite; this feature enables chemists to enhance the rates and yields of desired reactions and suppress unwanted reactions. The most extensive applications of zeolites currently are in the catalytic cracking of crude oil, a process that involves breaking down long-chain hydrocarbons and re-forming them into branched-chain molecules of lower molecular mass for use in high-octane unleaded gasoline. A relatively new process uses "shape-selective" zeolite catalysts to convert methanol (CH_3OH) to high-quality gasoline. Plants have been built to make gasoline by this process, using methanol derived from coal or from natural gas.

22.2 PROPERTIES OF CERAMICS

The term ***ceramics*** covers synthetic materials that have as their essential components inorganic, nonmetallic materials. This broad definition includes cement, concrete, and glass, in addition to the more traditional fired clay products such as bricks, roof tiles, pottery, and porcelain. The use of ceramics predates recorded history; the emergence of civilization from a primitive state is chronicled in fragments of pottery. No one knows when small vessels were first shaped by human hands from moist clay and left to harden in the heat of the sun. Such containers held nuts, grains, and berries well, but they lost their shape and slumped into formless mud when water was poured into them. Then someone discovered (perhaps by accident) that if clay was placed in the glowing embers of a fire, it became as hard as rock and withstood water well. Molded figures (found in what is now the Czech Republic) that were made 24,000 years ago are the earliest fired ceramic objects discovered so far, and fired clay vessels from the Near East date from 8000 B.C. With the action of fire on clay, the art and science of ceramics began.

Ceramics offer stiffness, hardness, resistance to wear, and resistance to corrosion (particularly by oxygen and water), even at high temperature. They are less dense than most metals, which makes them desirable metal substitutes when weight is a factor. Most are good electrical insulators at ordinary temperatures, a property that is exploited in electronics and power transmission. Ceramics retain their strength well at high temperatures. Several important structural metals soften or melt at temperatures 1000°C below the melting points of their chemical compounds in ceramics. Aluminum, for example, melts at 660°C, whereas aluminum oxide (Al_2O_3), an important compound in many ceramics, does not melt until a temperature of 2051°C is reached.

Against these advantages must be listed some serious disadvantages. Ceramics are generally brittle and low in tensile strength. They tend to have high thermal expansion but low thermal conductivity, making them subject to **thermal shock,** in which sudden local temperature change causes cracking or shattering. Metals and plastics dent or deform under stress, but ceramics cannot absorb stress in this way: instead, they break. A major drawback of ceramics as structural materials is their tendency to fail unpredictably and catastrophically in use. Moreover, some ceramics lose mechanical strength as they age, an insidious and serious problem.

Composition and Structure of Ceramics

Ceramics use a variety of chemical compounds, and useful ceramic bodies are nearly always mixtures of several compounds. **Silicate ceramics,** which include the commonplace pots, dishes, and bricks, are made from aluminosilicate clay minerals. All contain the tetrahedral SiO_4 grouping discussed in Section 22.1. In **oxide ceramics,** silicon is a minor or nonexistent component. Instead, a number of metals combine with oxygen to give compounds such as alumina (Al_2O_3), magnesia

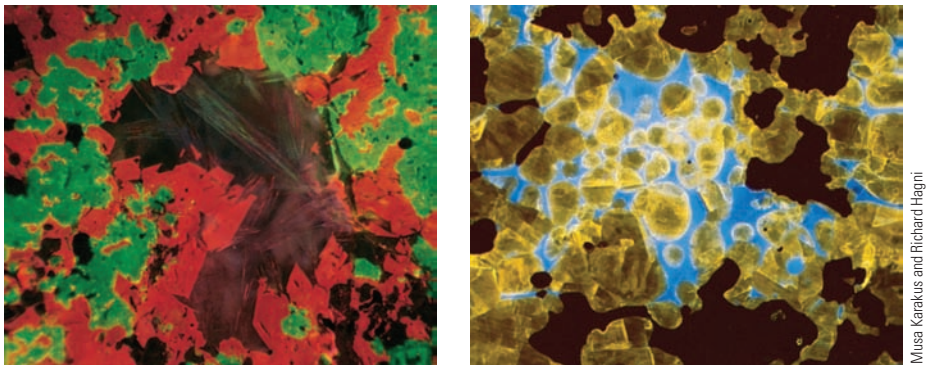

FIGURE 22.7 Microstructures of aluminosilicate ceramics, viewed by the different colors of light emitted after bombardment by electrons. (a) Forsterite (red), spinel (green), and periclase (dark brown) grains. (b) Periclase (blue) and oldhamite (yellow) grains.

(MgO), or yttria (Y_2O_3). **Nonoxide ceramics** contain compounds that are free of oxygen as principal components. Some important compounds in nonoxide ceramics are silicon nitride (Si_3N_4), silicon carbide (SiC), and boron carbide (approximate composition B_4C).

One important property of ceramics is their porosity. Porous ceramics have small openings into which fluids (typically air or water) can infiltrate. Fully dense ceramics have no channels of this sort. Two ceramic pieces can have the same chemical composition but quite different densities if the first is porous and the second is not.

A **ceramic phase** is any portion of the whole body that is physically homogeneous and bounded by a surface that separates it from other parts. Distinct phases are visible at a glance in coarse-grained ceramic pieces; in a fine-grained piece, phases can be seen with a microscope. When examined on a still finer scale, most ceramics, like metals, are microcrystalline, consisting of small crystalline grains cemented together (Fig. 22.7). The **microstructure** of such objects includes the sizes and shapes of the grains, the sizes and distribution of voids (openings between grains) and cracks, the identity and distribution of impurity grains, and the presence of stresses within the structure. Microstructural variations have enormous importance in ceramics because slight changes at this level strongly influence the properties of individual ceramic pieces. This is less true for plastic and metallic objects.

The microstructure of a ceramic body depends markedly on the details of its fabrication. The techniques of forming and firing a ceramic piece are as important as its chemical composition in determining ultimate behavior because they confer a unique microstructure. This fact calls attention to the biggest problem with ceramics as structural materials: inconsistent quality. Ceramic engineers can produce parts that are harder than steel (Fig. 22.8), but not reliably so because of the difficulties of monitoring and controlling microstructure. Gas turbine engines fabricated of silicon nitride, for example, run well at 1370°C, which is hot enough to soften or melt most metals. The higher operating temperature increases engine efficiency, and the ceramic turbines weigh less, which further boosts fuel economy. Despite these advantages, there is no commercial ceramic gas turbine. Acceptable ceramic turbines have to be built from selected, pretested components. The testing costs and rejection rates are so high that economical mass production has been impossible so far.

FIGURE 22.8 Silicon carbide ball bearings are harder, stiffer, and have smoother surfaces than steel bearings, resulting in improved performance due to reduced friction and less heat. Their high melting points make them the bearings of choice for demanding, high temperature applications.

Making Ceramics

The manufacture of most ceramics involves four steps: (1) the preparation of the raw material; (2) the forming of the desired shape, often achieved by mixing a powder with water or other binder and molding the resulting plastic mass; (3) the drying and firing of the piece, also called its **densification,** because pores (voids) in the dried ceramic fill in; and (4) the finishing of the piece by sawing, grooving, grinding, or polishing.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The raw materials for traditional ceramics are natural clays that come from the earth as powders or thick pastes and become plastic enough after adjustment of their water content to be formed freehand or on a potter's wheel. Special ceramics (both oxide and nonoxide) require chemically pure raw materials that are produced synthetically. Close control of the purity of the starting materials for these ceramics is essential to produce finished pieces with the desired properties. In addition to being formed by hand or in open molds, ceramic pieces are shaped by the squeezing (compacting) of the dry or semidry powders in a strong, closed mold of the desired shape, at either ordinary or elevated temperatures (hot pressing).

Firing a ceramic causes **sintering** to occur. In sintering, the fine particles of the ceramic start to merge together by diffusion at high temperatures. The density of the material increases as the voids between grains are partially filled. Sintering occurs below the melting point of the material and shrinks the ceramic body. In addition to the merging of the grains of the ceramic, firing causes partial melting, chemical reactions among different phases, reactions with gases in the atmosphere of the firing chamber, and recrystallization of compounds with an accompanying growth in crystal size. All of these changes influence the microstructure of a piece and must be understood and controlled. Firing accelerates physical and chemical changes, of course, but thermodynamic equilibrium in a fired ceramic piece is rarely reached. Kinetic factors—including the rate of heating, the length of time at which each temperature is held, and the rate of cooling—influence microstructure. As a result, the use of microwave radiation (as in microwave ovens) rather than kilns to fire ceramics is under development in ceramic factories, because it promises more exact control of the heating rate, and thereby more reliable quality.

22.3 SILICATE CERAMICS

The silicate ceramics include materials that vary widely in composition, structure, and use. They range from simple earthenware bricks and pottery to cement, fine porcelain, and glass. Their structural strength is based on the same linking of silicate ion tetrahedra that gives structure to silicate minerals in nature.

Pottery and Structural Clay Products

Aluminosilicate clays are products of the weathering of primary minerals. When water is added to such clays in moderate amount, a thick paste results that is easily molded into different shapes. Clays expand as water invades the space between adjacent aluminosilicate sheets of the mineral, but they release most of this water to a dry atmosphere and shrink. A small fraction of the water or hydroxide ions remains rather tightly bound by ion–dipole forces to cations between the aluminosilicate sheets and is lost only when the clay is heated to a high temperature. The firing of aluminosilicate clays simultaneously causes irreversible chemical changes to occur. The clay kaolinite ($Al_2Si_2O_5(OH)_4$) undergoes the following reaction:

$$\underset{\text{(kaolinite)}}{3\ Al_2Si_2O_5(OH)_4} \longrightarrow \underset{\text{(mullite)}}{Al_6Si_2O_{13}(s)} + \underset{\text{(silica)}}{4\ SiO_2(s)} + \underset{\text{(water)}}{6\ H_2O(g)}$$

The fired ceramic body is a mixture of two phases: mullite and silica. Mullite, a rare mineral in nature, takes the form of needlelike crystals that interpenetrate and confer strength on the ceramic. When the temperature is above 1470°C, the silica phase forms as minute grains of cristobalite, one of the several crystalline forms of SiO_2.

If chemically pure kaolinite is fired, the finished ceramic object is white. Such purified clay minerals are the raw material for fine china. As they occur in nature, clays contain impurities, such as transition-metal oxides, that affect the color of

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

both the unfired clay and the fired ceramic object if they are not removed. The colors of the metal oxides arise from their absorption of light at visible wavelengths, as explained by crystal field theory (see Section 8.4). Common colors for ceramics are yellow or greenish yellow, brown, and red. Bricks are red when the clay used to make them has high iron content.

Before a clay is fired in a kiln, it must first be freed of moisture by slowly heating to about 500°C. If a clay body dried at room temperature were to be placed directly into a hot kiln, it would literally explode from the sudden, uncontrolled expulsion of water. A fired ceramic shrinks somewhat as it cools, causing cracks to form. These imperfections limit the strength of the fired object and are undesirable. The occurrence of imperfections can be reduced by coating the surface of a partially fired clay object with a **glaze,** a thin layer that minimizes crack formation in the underlying ceramic by holding it in a state of tension as it cools. Glazes, as their name implies, are glasses that have no sharp melting temperature, but rather harden and develop resistance to shear stresses increasingly as the temperature of the high-fired clay object is gradually reduced. Glazes generally are aluminosilicates that have high aluminum content to raise their viscosity, and thereby reduce the tendency to run off the surface during firing. They also provide the means of coloring the surfaces of fired clays and imparting decorative designs to them. Transition-metal oxides (particularly those of titanium [Ti], vanadium [V], chromium [Cr], manganese [Mn], iron [Fe], cobalt [Co], nickel [Ni], and Cu) are responsible for the colors. The oxidation state of the transition metal in the glaze is critical in determining the color produced and is controlled by regulating the composition of the atmosphere in the kiln; atmospheres rich in oxygen give high oxidation states, and those poor or lacking in oxygen give low oxidation states.

Glass

Glassmaking probably originated in the Near East about 3500 years ago. It is one of the oldest domestic arts, but its beginnings, like those of metallurgy, are obscure. Both required high-temperature, charcoal-fueled ovens and vessels made of materials that did not easily melt to initiate and contain the necessary chemical reactions. In the early period of glassmaking, desired shapes were fabricated by sculpting them from solid chunks of glass. At a later date, molten glass was poured in successive layers over a core of sand. A great advance was the invention of glassblowing, which probably occurred in the first century B.C. A long iron tube was dipped into molten glass and a rough ball of viscous material was caused to accumulate on its end by rotating the tube. Blowing into the iron tube forced the soft glass to take the form of a hollow ball (Fig. 22.9) that could be further shaped into a vessel and severed from the blowing tube with a blade. Artisans in the Roman Empire developed glassblowing to a high degree, but with the decline of that civilization, the skill of glassmaking in Europe deteriorated until the Venetians redeveloped the lost techniques a thousand years later.

FIGURE 22.9 Handcrafted glassware is trimmed after being blown into the desired shape.

Glasses are amorphous solids of widely varying composition (see Section 21.4 for a discussion of the physical properties of glass). In this chapter, the term *glass* is used in the restricted and familiar sense to refer to materials formed from silica, usually in combination with metal oxides. The absence of long-range order in glasses has the consequence that they are **isotropic**—that is, their physical properties are the same in all directions. This has advantages in technology, including that glasses expand uniformly in all directions with an increase in temperature. The mechanical strength of glass is intrinsically high, exceeding the tensile strength of steel, provided the surface is free of scratches and other imperfections. Flaws in the surface provide sites where fractures can start when the glass is stressed. When a glass object of intricate shape and nonuniform thickness is suddenly cooled, internal stresses are locked in; these stresses may be relieved catastrophically when the object is heated or struck (Fig. 22.10). Slowly heating a strained object to a tem-

FIGURE 22.10 The strains associated with internal stresses in rapidly cooled glass can be made visible by viewing the glass in polarized light. They appear as colored regions.

perature somewhat below its softening point and holding it there for a while before allowing it to cool slowly is called **annealing;** it gives short-range diffusion of atoms a chance to occur and to eliminate internal stresses.

The softening and annealing temperatures of a glass and other properties, such as density, depend on its chemical composition (Table 22.2). Silica itself (SiO_2) forms a glass if it is heated above its melting point and then cooled rapidly to avoid crystallization. The resulting vitreous (glassy) silica has limited use because the high temperatures required to shape it make it quite expensive. Sodium silicate glasses are formed in the high-temperature reaction of silica sand with anhydrous sodium carbonate (soda ash, Na_2CO_3):

$$Na_2CO_3(s) + n\ SiO_2(s) \longrightarrow Na_2O{\cdot}(SiO_2)_n(s) + CO_2(g)$$

The melting point of the nonvolatile product is about 900°C, and the glassy state results if cooling through that temperature is rapid. The product, called "water glass," is water-soluble; thus, it is unsuitable for making vessels. Its aqueous solutions, however, are used in some detergents and as adhesives for sealing cardboard boxes.

An insoluble glass with useful structural properties results if lime (CaO) is added to the sodium carbonate–silica starting materials. **Soda-lime glass** is the resulting product, with the approximate composition $Na_2O{\cdot}CaO{\cdot}(SiO_2)_6$. Soda-lime glass is easy to melt and shape and is used in applications ranging from bottles to window glass. It accounts for more than 90% of all the glass manufactured today. The structure of this ionic glass is shown schematically in Figure 22.11. It is a three-dimensional network of the type discussed in Section 22.1, but with random coordination of the silicate tetrahedra. The network is a giant "polyanion," with Na^+

†The coefficient of linear thermal expansion is defined as the fractional increase in length of a body when its temperature is increased by 1°C.
‡The refractive index is a vital property of glass for optical applications. It is defined by $n = \sin\theta_i/\sin\theta_r$, where θ_i is the angle of incidence of a ray of light on the surface of the glass and θ_r is the angle of refraction of the ray of light in the glass.

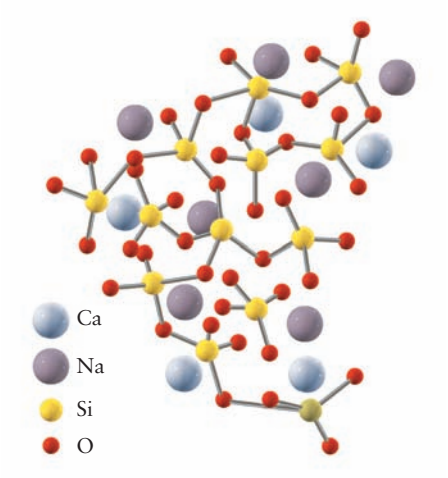

FIGURE 22.11 Structure of a soda-lime glass. Note the tetrahedral coordination of oxygen atoms around each silicon atom.

and Ca^{2+} ions distributed in the void spaces to compensate for the negative charge on the network.

Replacing lime and some of the silica in a glass by other oxides (Al_2O_3, B_2O_3, K_2O, or PbO) modifies its properties noticeably. For example, the thermal conductivity of ordinary (soda-lime) glass is quite low, and its coefficient of thermal expansion is high. This means that internal stresses are created when its surface is subjected locally to extreme heat or cold, and it may shatter. The coefficient of thermal expansion is appreciably lower in certain borosilicate glasses, in which many of the silicon sites are occupied by boron. Pyrex, the most familiar of these glasses, has a coefficient of linear expansion about one-third that of ordinary soda-lime glass and is the preferred material for laboratory glassware and household ovenware. Vycor has an even smaller coefficient of expansion (approximating that of fused silica) and is made by chemical treatment of a borosilicate glass to leach out its sodium. This leaves a porous structure that is densified by increasing the temperature and shrinking the glass to its final volume.

Cements

Hydraulic cement was first developed by the ancient Romans, who found that a mixture of lime (CaO) and dry volcanic ash reacts slowly with water, even at low temperatures, to form a durable solid. They used this knowledge to build the Pantheon in Rome, a circular building whose concrete dome, spanning 143 feet without internal support, still stands nearly 2000 years after its construction! The knowledge of cement making was lost for centuries after the fall of the Roman Empire. It was rediscovered in 1824 by an English bricklayer, Joseph Aspdin, who patented a process for calcining a mixture of limestone and clay. He called the product **Portland cement** because, when mixed with water, it hardened to a material that resembled a kind of limestone found on the Isle of Portland. Portland cement is now manufactured in every major country, and annual worldwide production is currently about 800 million metric tons, exceeding the production of all other materials. Portland cement opened up a new age in the methods of constructing highways and buildings: Rock could be crushed and then molded in cement, rather than shaped with cutting tools.

Portland cement is a finely ground, powdered mixture of compounds produced by the high-temperature reaction of lime, silica, alumina, and iron oxide. The lime (CaO) may come from limestone or chalk deposits, and the silica (SiO_2) and alumina (Al_2O_3) are often obtained in clays or slags. The blast furnaces of steel mills are a common source of slag, which is a byproduct of the smelting of iron ore. The composition of slag varies, but it can be represented as a calcium aluminum silicate of approximate formula $CaO{\cdot}Al_2O_3{\cdot}(SiO_2)_2$. Molten slag solidifies into "blast fur-

nace clinkers" on quenching in water. This material is crushed and ground to a fine powder, blended with lime in the correct proportion, and burned again in a horizontal rotary kiln at temperatures up to 1500°C to produce "cement clinker." A final stage of grinding and the addition of about 5% gypsum ($CaSO_4 \cdot 2\ H_2O$) to lengthen the setting time completes the process of manufacture. Table 22.3 presents the composition of a typical Portland cement and gives percentages of the separate oxides; these simple materials, which are the "elements" of cement making, combine in the cement in more complex compounds such as tricalcium silicate, $(CaO)_3 \cdot SiO_2$, and tricalcium aluminate, $(CaO)_3 \cdot Al_2O_3$.

Cement *sets* when the semiliquid slurry first formed by the addition of water to the powder becomes a solid of low strength. Subsequently, it gains strength in a slower *hardening* process. Setting and hardening involve a complex group of exothermic reactions in which several hydrated compounds form. Portland cement is a **hydraulic cement,** because it hardens not by loss of admixed water, but by chemical reactions that incorporate water into the final body. The main reaction during setting is the hydration of the tricalcium aluminate, which can be approximated by the following equation:

$$(CaO)_3 \cdot Al_2O_3(s) + 3\ (CaSO_4 \cdot 2H_2O)(s) + 26\ H_2O(\ell) \longrightarrow (CaO)_3 \cdot Al_2O_3 \cdot (CaSO_4)_3 \cdot 32H_2O(s)$$

The product forms after 5 or 6 hours as a microscopic forest of long crystalline needles that lock together to solidify the cement. Later, the calcium silicates react with water to harden the cement. For example:

$$6\ (CaO)_3 \cdot SiO_2(s) + 18\ H_2O(\ell) \longrightarrow (CaO)_5 \cdot (SiO_2)_6 \cdot 5H_2O(s) + 13\ Ca(OH)_2(s)$$

The hydrated calcium silicates develop as strong tendrils that coat and enclose unreacted grains of cement, each other, and other particles that may be present, binding them in a robust network. Most of the strength of cement comes from these entangled networks, which, in turn, depend ultimately for strength on chains of O—Si—O—Si silicate bonds. Hardening is slower than setting; it may take as long as 1 year for the final strength of a cement to be attained.

Portland cement is rarely used alone. Generally, it is combined with sand, water, and lime to make **mortar,** which is applied with a trowel to bond bricks or stone together in an assembled structure. When Portland cement is mixed with sand and aggregate (crushed stone or pebbles) in the proportions of 1 : 3.75 : 5 by volume, the mixture is called **concrete.** Concrete is outstanding in its resistance to compressive forces and is therefore the primary material in use for the foundations of buildings and the construction of dams, in which the compressive loads are enormous. The stiffness (resistance to bending) of concrete is high, but its fracture toughness (resistance to impact) is substantially lower and its tensile strength is relatively poor. For this reason, concrete is usually reinforced with steel rods when it is used in structural elements such as beams that are subject to transverse or tensile stresses.

As excess water evaporates from cement during hardening, pores form that typically comprise 25% to 30% of the volume of the solid. This porosity weakens concrete, and recent research has shown that the fracture strength is related inversely to the size of the largest pores in the cement. A new material, called "macro defect–free" (MDF) cement, has been developed in which the size of the pores is reduced from about a millimeter to a few micrometers by the addition of water-soluble polymers that make a doughlike "liquid" cement that is moldable with the use of far less water. Unset MDF cement is mechanically kneaded and extruded into the desired shape. The final result possesses substantially increased bending resistance and fracture toughness. MDF cement can even be molded into springs and shaped on a conventional lathe. When it is reinforced with organic fibers, its toughness is further increased. The development of MDF cement is a good illustration of the way in which chemistry and engineering collaborate to furnish new materials.

22.4 NONSILICATE CERAMICS

Many useful ceramics exist that are *not* based on the Si—O bond and the SiO_4 tetrahedron. They have important uses in electronics, optics, and the chemical industry. Some of these materials are oxides, but others contain neither silicon nor oxygen.

Oxide Ceramics

Oxide ceramics are materials that contain oxygen in combination with any of a number of metals. These materials are named by adding an *-ia* ending to the stem of the name of the metallic element. Thus, if the main chemical component of an oxide ceramic is Be_2O_3, it is a *beryllia* ceramic; if the main component is Y_2O_3, it is an *yttria* ceramic; and if it is MgO, it is a *magnesia* ceramic. As Table 22.4 shows, the melting points of these and other oxides are substantially higher than the melting points of the elements themselves. Such high temperatures are hard to achieve and maintain, and the molten oxides corrode most container materials. Oxide ceramic bodies are therefore not shaped by melting the appropriate oxide and pouring it into a mold. Instead, these ceramics are fabricated by sintering, like the silicate ceramics.

Alumina (Al_2O_3) is the most important nonsilicate ceramic material. It melts at a temperature of 2051°C and retains strength even at temperatures of 1500°C to 1700°C. Alumina has a large electrical resistivity and withstands both thermal shock and corrosion well. These properties make it a good material for spark plug insulators, and most spark plugs now use a ceramic that is 94% alumina.

FIGURE 22.12 The socket in this artificial hip is made of high-density alumina.

High-density alumina is fabricated in such a way that open pores between the grains are nearly completely eliminated; the grains are small, with an average diameter as low as 1.5 μm. Unlike most others, this ceramic has good mechanical strength against impact, which has led to its use in armor plating. The ceramic absorbs the energy of an impacting projectile by breaking; thus, penetration does not occur. High-density alumina is also used in high-speed cutting tools for machining metals. The temperature resistance of the ceramic allows much faster cutting speeds, and a ceramic cutting edge has no tendency to weld to the metallic work piece, as metallic tools do. These properties make alumina cutting tools superior to metallic tools, as long as they do not break too easily. High-density alumina is also used in artificial joints (Fig. 22.12).

If Al_2O_3 doped with a small percentage of MgO is fired in a vacuum or a hydrogen atmosphere (instead of air) at a temperature of 1800°C to 1900°C, even very small pores, which scatter light and make the material white, are removed. The resulting ceramic is translucent. This material is used to contain the sodium in high-intensity sodium discharge lamps. With envelopes of high-density alumina, these lamps can be operated at temperatures of 1500°C to give a whiter and more intense light. Old-style sodium-vapor lamps with glass envelopes were limited to a tem-

perature of 600°C because the sodium vapor reacted with the glass at higher temperatures. At low temperatures, the light from a sodium-vapor lamp has an undesirable yellow color.

Magnesia (MgO) is mainly used as a **refractory**—a ceramic material that withstands a temperature of more than 1500°C without melting (MgO melts at 2800°C). A major use of magnesia is as insulation in electrical heating devices, because it combines high thermal conductivity with excellent electrical resistance. Magnesia is prepared from magnesite ores, which consist of $MgCO_3$ and a variety of impurities. When purified magnesite is heated to 800°C to 900°C, carbon dioxide is driven off to form MgO(*s*) in fine grains:

$$MgCO_3(s) \longrightarrow MgO(s) + CO_2(g)$$

After cooling, fine-grained MgO reacts vigorously with water to form magnesium hydroxide:

$$MgO(s) + H_2O(\ell) \longrightarrow Mg(OH)_2(s)$$

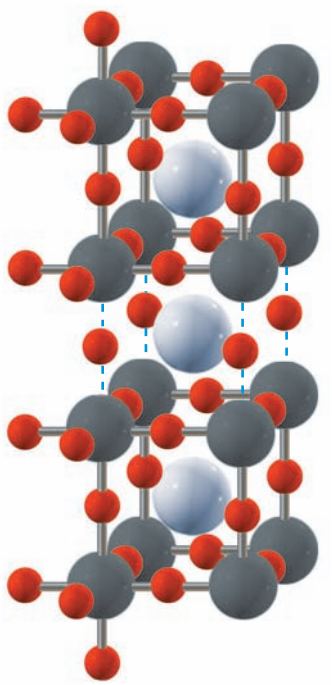
Heating fine-grained MgO(*s*) to 1700°C causes the MgO grains to sinter, giving a "dead-burned magnesia" that consists of large crystals and does not react with water. The $\Delta G°$ of the reaction between MgO and H_2O does not change when magnesia is dead burned. The altered microstructure (larger crystals vs. small) makes the reaction with water exceedingly slow, however.

Superconducting Ceramics

The oxide ceramics discussed so far in this chapter all consisted of single chemical compounds, except for minor additives. A natural idea for new ceramics is to make materials that contain two (or more) oxides in equal or nearly equal molar amounts. Thus, if $BaCO_3$ and TiO_2 are mixed and heated to high temperature, they react to give the ceramic barium titanate:

$$BaCO_3(s) + TiO_2(s) \rightarrow BaTiO_3(s) + CO_2(g)$$

Barium titanate, which has many novel properties, is a **mixed oxide ceramic.** It has the same structure as the mineral **perovskite,** $CaTiO_3$ (Fig. 22.13), except, of course, that Ba replaces Ca. Perovskites typically have two metal atoms for every three O atoms, giving them the general formula ABO_3, where A stands for a metal atom at the center of the unit cube and B stands for an atom of a different metal at the cube corners.



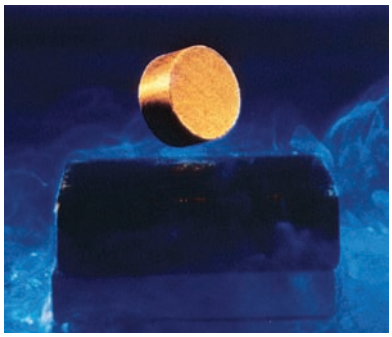


FIGURE 22.13 Structure of perovskite ($CaTiO_3$). A stack of three unit cells is shown, with some additional O atoms (red) from neighboring cells. Each Ti atom (gray) is surrounded by six O atoms; each Ca atom (white) has eight O atoms as nearest neighbors.

Research interest in perovskite ceramic compositions has grown explosively after the discovery that some of them become **superconducting** at relatively high temperatures. A superconducting material offers no resistance whatsoever to the flow of an electric current. The phenomenon was discovered by the Dutch physicist Heike Kamerlingh-Onnes in 1911, when he cooled mercury below its superconducting transition temperature of 4 K. Such low temperatures are difficult to achieve and maintain, but if practical superconductors could be made to work at higher temperatures (or even at room temperature!), then power transmission, electronics, transportation, medicine, and many other aspects of human life would be transformed. More than 60 years of research with metallic systems culminated in 1973 with the discovery of a niobium–tin alloy with a world-record superconducting transition temperature of 23.3 K. Progress toward higher temperature superconductors then stalled until 1986, when K. Alex Müller and J. Georg Bednorz, who had had the inspired notion to look for higher transition temperatures among perovskite ceramics, found a Ba—La—Cu—O perovskite phase having a transition temperature of 35 K. This result motivated other scientists, who soon discovered another rare-earth–containing perovskite ceramic that became a superconductor at 90 K. This result was particularly exciting because 90 K exceeds the boiling point of liquid nitrogen (77 K), a relatively cheap refrigerant (Fig. 22.14).

FIGURE 22.14 Levitation of a small magnet above a disk of superconducting material. A superconducting substance cannot be penetrated by an external magnetic field. At room temperature, the magnet rests on the ceramic disk. When the disk is cooled with liquid nitrogen, it becomes superconducting and excludes the magnet's field, forcing the magnet into the air.

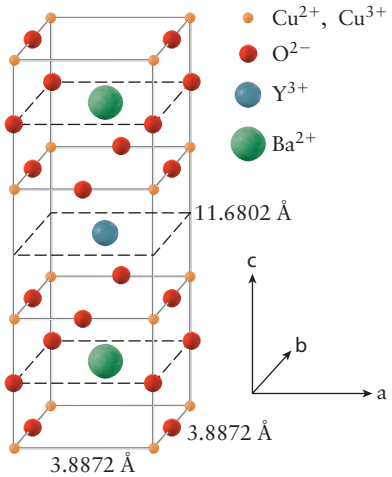

FIGURE 22.15 The structure of $YBa_2Cu_3O_{9-x}$ is a layered perovskite. Each Cu atom (orange) is bonded to O atoms (red). The layers differ because one-third of them contain Y atoms (blue-gray), whereas two-thirds contain Ba atoms (green). This structure is a variation of the perovskite structure in Figure 22.13. In a hypothetical "$BaCuO_3$" structure, every third Ba has been replaced by a Y, and the O atoms in the layer containing the Y have been removed.

This 1-2-3 compound (so called because its formula, $YBa_2Cu_3O_{(9-x)}$, has one Y, two Ba, and three Cu atoms per formula unit) is not an ideal perovskite because it has fewer than nine O atoms in combination with its six metal atoms. The deficiency makes x in the formula somewhat greater than 2, depending on the exact method of preparation. The structure of this nonstoichiometric solid is shown in Figure 22.15. More recently, the maximum superconducting transition temperature has increased to 125 K in another class of ceramics that does not contain rare-earth elements.

A crucial concern in the application of superconducting ceramics is to devise ways to fabricate the new materials in desired shapes such as wires. This will be quite a challenge because these superconductors are ceramics and have the brittleness and fragility typical of ceramic materials.

Nonoxide Ceramics

In nonoxide ceramics, nitrogen (N) or carbon (C) takes the place of oxygen in combination with silicon or boron. Specific substances are boron nitride (BN), boron carbide (B_4C), the silicon borides (SiB_4 and SiB_6), silicon nitride (Si_3N_4), and silicon carbide (SiC). All of these compounds possess strong, short covalent bonds. They are hard and strong, but brittle. Table 22.5 lists the enthalpies of the chemical bonds in these compounds.

Much research has aimed at making gas-turbine and other engines from ceramics. Of the oxide ceramics, only alumina and zirconia (ZrO_2) are strong enough, but both resist thermal shock too poorly for this application. Attention has therefore turned to the nonoxide **silicon nitride** (Si_3N_4). In this **network solid** (Fig. 22.16), every Si atom bonds to four N atoms that surround it at the corners of a tetrahedron; these tetrahedra link into a three-dimensional network by sharing corners. The Si—N bond is covalent and strong (the bond enthalpy is 439 kJ mol^{-1}). The similarity to the joining of SiO_4 units in silicate minerals (see Section 22.1) is clear.

At first, silicon nitride appears chemically unpromising as a high-temperature structural material. It is unstable in contact with water because the following reaction has a negative $\Delta G°$:

$$Si_3N_4(s) + 6\ H_2O(\ell) \longrightarrow 3\ SiO_2(s) + 4\ NH_3(g)$$

In fact, this reaction causes finely ground Si_3N_4 powder to give off an odor of ammonia in moist air at room temperature. Silicon nitride is also thermodynamically unstable in air, reacting spontaneously with oxygen:

$$Si_3N_4(s) + 3\ O_2(g) \longrightarrow 3\ SiO_3(s) + 2\ N_2(g)$$

The reaction has a $\Delta G°$ of -1927 kJ mol^{-1}. In practice, neither reaction occurs at a perceptible rate when Si_3N_4 is in bulk form. Initial contact of oxygen or water with $Si_3N_4(s)$ forms a surface film of $SiO_2(s)$ that protects the bulk of the $Si_3N_4(s)$

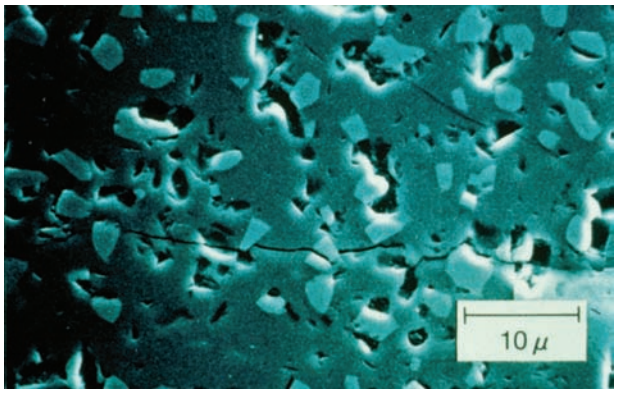
from further attack. When *strongly* heated in air (to about 1900°C), Si_3N_4 does decompose, violently, but until that temperature is reached, it resists attack.

Fully dense silicon nitride parts are stronger than metallic alloys at high temperatures. Ball bearings made of dense silicon nitride work well without lubrication at temperatures up to 700°C; for example, they last longer than steel ball bearings. Because the strength of silicon nitride increases with the density attained in the production process, the trick is to form a dense piece of silicon nitride in the desired shape. One method for making useful shapes of silicon nitride is "reaction bonding." Powdered silicon is compacted in molds, removed, and then fired under an atmosphere of nitrogen at 1250°C to 1450°C. The following reaction forms the ceramic:

$$3\ Si(s) + 2\ N_2(g) \longrightarrow Si_3N_4(s)$$

The parts neither swell nor shrink significantly during the chemical conversion from Si to Si_3N_4, making it possible to fabricate complex shapes reliably. Unfortunately, reaction-bonded Si_3N_4 is still somewhat porous and is not strong enough for many applications. In the "hot-pressed" forming process, Si_3N_4 powder is prepared in the form of exceedingly small particles by reaction of silicon tetrachloride with ammonia:



$$3\ SiCl_4(g) + 4\ NH_3(g) \longrightarrow Si_3N_4(s) + 12\ HCl(g)$$

The solid Si_3N_4 forms as a smoke. It is captured as a powder, mixed with a carefully controlled amount of MgO additive, placed in an enclosed mold, and sintered at 1850°C under a pressure of 230 atm. The resulting ceramic shrinks to nearly full density (no pores). Because the material does not flow well (to fill a complex mold completely), only simple shapes are possible. Hot-pressed silicon nitride is impressively tough and can be machined only with great difficulty and with diamond tools.

In the silicate minerals of Section 22.1, AlO_4^{5-} units routinely substitute for SiO_4^{4-} tetrahedra as long as positive ions of some type are present to balance the electric charge. This fact suggests that in silicon nitride some Si^{4+} ions, which lie at the centers of tetrahedra of N atoms, could be replaced by Al^{3+} if a compensating replacement of O^{2-} for N^{3-} were simultaneously made. Experiments show that ceramic alloying of this type works well, giving many new ceramics with great potential called **sialons** (named for the four elements Si—Al—O—N). These ceramics illustrate the way a structural theme in a naturally occurring material guided the search for new materials.

Boron has one fewer valence electron than carbon, and nitrogen has one more valence electron. **Boron nitride** (BN) is therefore isoelectronic with C_2, and it is not surprising that it has two structural modifications that resemble the structures of graphite and diamond. In hexagonal boron nitride, the B and N atoms take alternate places in an extended "chicken-wire" sheet in which the B—N distance is 1.45

Carborundum Company

FIGURE 22.17 Microstructure of a composite ceramic. The light-colored areas are TiB_2, the gray areas are SiC, and the dark areas are voids. The TiB_2 acts to toughen the SiC matrix. Note that the crack shown passing through from left to right is forced to deflect around the TiB_2 particles.

Å. The sheets stack in such a way that each B atom has a N atom directly above it and directly below it, and vice versa. The cubic form of boron nitride has the diamond structure, is comparable in hardness to diamond, and resists oxidation better. Boron nitride is often prepared by **chemical vapor deposition,** a method used in fabricating several other ceramics as well. In this method, a controlled chemical reaction of gases on a contoured, heated surface gives a solid product of the desired shape. If a cup made of BN is needed, a cup-shaped mold is heated to a temperature exceeding 1000°C and a mixture of $BCl_3(g)$ and $NH_3(g)$ is passed over its surface. The reaction

$$BCl_3(g) + NH_3(g) \longrightarrow BN(s) + 3\ HCl(g)$$

deposits a cup-shaped layer of BN(*s*). Boron nitride cups and tubes are used to contain and evaporate molten metals.

Silicon carbide (SiC) is diamond in which half of the C atoms are replaced by Si atoms. Also known by its trade name of Carborundum, silicon carbide was developed originally as an abrasive, but it is now used primarily as a refractory and as an additive in steel manufacture. It is formed and densified by methods similar to those used with silicon nitride. Silicon carbide is often produced in the form of small plates or whiskers to reinforce other ceramics. Fired silicon carbide whiskers are quite small (0.5 μm in diameter and 50 μm long) but are strong. They are mixed with a second ceramic material before that material is formed. Firing then gives a **composite ceramic.** Such composites are stronger and tougher than unreinforced bodies of the same primary material. Whiskers serve to reinforce the main material by stopping cracks; they either deflect advancing cracks or soak up their energy, and a widening crack must dislodge them to proceed (Fig. 22.17). Recently, SiC has been used in high-power, high-temperature semiconductor devices (Section 22.7).

22.5 ELECTRICAL CONDUCTION IN MATERIALS

Electronic properties describe the movement of charged particles in a material in response to an applied electric field. If the charges are free to move throughout the material, the process is *electrical conduction,* measured by the *electrical conductivity* of the material. Differences in the magnitude of the conductivity distinguish metals, semiconductors, and insulators. If the charges can move only limited distances and are then halted by opposing binding forces, separation of positive and negative charges leads to *electric polarization* of the material, measured by its *dielectric constant*. Conduction involves dissipation of energy as heat, whereas polarization involves storage of potential energy in the material.

An electric field applied to a material that has free charged particles causes these particles to flow through the material and into the external circuit. How do we

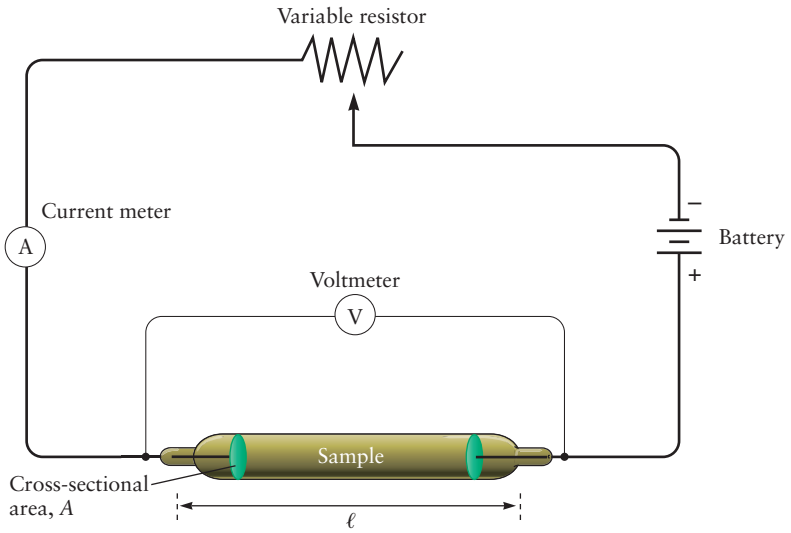

FIGURE 22.18 Test circuit for measuring conductivity.

define and measure the conductivity of a material? On what macroscopic properties does it depend? How does it relate to the detailed chemical structure of the material?

Measurement of Conductivity

The electrical conductivity of a material is measured by placing a cylindrical sample of cross-sectional area, A, and length, ℓ, in a simple electrical circuit as a resistor in series with a power supply and ammeter; a voltmeter measures the actual voltage across the sample (Fig. 22.18). If the voltage, V, is varied and the resulting current, I, is measured at each voltage, a plot of I versus V is a straight line (Fig. 22.19):

$$I = GV \qquad [22.1]$$

The resulting slope is called the **conductance** and is denoted by G. If V is measured in volts and I in amperes (A), then G has units of siemens (1 siemens = 1 A/V). If the value of G is constant, the material follows Ohm's law

$$V = IR$$

and G is the reciprocal of the **resistance** R, which is measured in ohms (Ω; 1 Ω = 1 V/A). So far, the measurement depends on the size and shape of the material sample, in addition to its composition. To remove these geometric effects, we note from experiment that R increases as ℓ increases, and it decreases as A increases. Therefore, we define the material property **resistivity,** denoted by ρ, as the proportionality constant that summarizes these two effects:

$$R = \frac{\ell}{A}\rho \qquad [22.2]$$

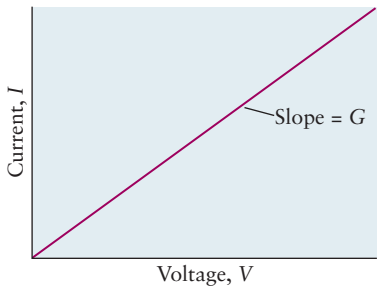

FIGURE 22.19 Plot of current against voltage is a straight line whose slope is the conductance *G*.

From this definition, ρ has dimensions of Ω m. Finally, we define the material property **conductivity,** σ, as the reciprocal of the resistivity:

$$\sigma = \frac{1}{\rho} = \frac{\ell}{RA} \qquad [22.3]$$

from which σ has units of $(\Omega\ \text{m})^{-1}$ or S m^{-1}. We now rewrite Ohm's law in a form independent of sample geometry. First, define the current density J (A m^{-2}) through the sample as I/A and define the electric field E (V m^{-1}) through the sample as V/ℓ.

Electrical Conductivity of Selected Metals at Room Temperature

Metal	Conductivity $[(\Omega\ m)^{-1}]$
Silver	6.8×10^7
Copper	6.0×10^7
Gold	4.3×10^7
Aluminum	3.8×10^7
Iron	1.0×10^7
Platinum	0.94×10^7
Stainless steel	0.2×10^7

Inserting these definitions and the definition of σ from Equation 22.3 into Equation 22.1 gives:

$$J = \sigma E \qquad [22.4]$$

According to Equation 22.4, the current density flowing through a material sample is proportional to the electric field applied to the sample, and the proportionality constant is the conductivity of the material of which the sample is made. This is the equation we use to relate the conductivity of a material to its microstructural properties. Table 22.6 lists conductivities for several common metals at room temperature.[2]

Microscopic Origins of the Conductivity

Insight into the conductivity is provided by measuring the electrical conductivity of aqueous ionic solutions (Fig. 22.20; this topic is referred to in Chapters 11 and 15). The conductivity of pure water, multiply distilled to remove all impurities, is about $0.043 \times 10^{-6}\ (\Omega\ cm)^{-1}$. Exposed to the air, pure water dissolves CO_2, which forms carbonic acid, H_2CO_3; dissociation produces H_3O^+ and HCO_3^-, which increase the conductivity to about $1 \times 10^{-6}\ (\Omega\ cm)^{-1}$. As ionic solutes are added to water, the conductivity increases rapidly; a 1.0-M solution in NaOH has conductivity of about $0.180\ (\Omega\ cm)^{-1}$ at 25°C. The conductivity depends strongly on both concentration and ionic species. The concentration dependence is summarized by the **molar conductivity,** defined by $\Lambda_m = \sigma/c$, where c is the concentration of the ion measured in moles per liter. To gain fundamental understanding of the conduction mechanism, we relate Λ_m to the details of the ionic motion in dilute solutions in response to the electric field. This leads to the concept of *mobility* of the ion, denoted by μ, which shows how its surroundings influence the response of an ion to an applied field.

As the electric field is turned on, each ion is accelerated by the field and experiences a force whose magnitude and direction are given by the vector relation

$$\vec{F} = ze\vec{E}$$

where z is the charge on the ion in units of the elementary charge, e, and the expression is valid for either cations or anions (the force points in opposite directions in the two cases). As the ion is accelerated by the field, however, its forward motion is

[2]Because the meter is inconveniently large for measuring the dimensions of most samples in material studies, you will frequently see ρ expressed in units of Ω cm and σ in units of $(\Omega\ cm)^{-1}$. Be alert to the actual units used. In base International System of Units (SI), resistivity has units expressed as kg m^3 s^{-3} A^{-2}.

retarded by friction from the surrounding solvent molecules. This retarding force $\vec{F}'$ opposes the direction of motion of the ion and is proportional to its velocity, $\vec{v}$:

$$\vec{F}' = -f\vec{v}$$

where f is the frictional drag coefficient. In due course, these forces balance and the ion achieves its steady drift velocity $\vec{v}_d$. This force balance condition provides the following relation:

$$\vec{v}_d = ze\frac{\vec{E}}{f}$$

This equation shows that the electric field increases the drift velocity, whereas the drag coefficient reduces it. We define the proportionality constant between the *drift speed* (the magnitude of the drift velocity) and the field to be the **mobility,** μ, of the ion (a positive number), giving the following relation:

$$|\vec{v}_d| = \mu|\vec{E}| \qquad [22.5]$$

Mobility has physical units of $m^2\ V^{-1}\ s^{-1}$. For ions in solution, the mobility is given by

$$\mu = \frac{|z|e}{f}$$

In more advanced work, it is possible to estimate the drag coefficient, f, and provide a theoretical prediction of the mobility. Experimentally, the mobility for ions is obtained from the molar conductivity through the following equation, which we do not justify:

$$\Lambda_m = |z|\mu F \qquad [22.6]$$

where F is the Faraday constant, 96,485.34 C mol^{-1} (the Faraday constant is introduced in Chapter 17).

Mobilities are shown in Table 22.7 for several ions in aqueous solution. One interesting feature is that the smaller cations have lower mobilities than the larger cations; for example, μ for Na^+ is smaller than that for K^+, and μ for Mg^{2+} is smaller than that for Ca^{2+}. One might expect that the smaller ions would have larger mobility, because their smaller size should encounter less frictional drag when moving through the solvent. However, the greater charge density on the smaller cations attracts a larger solvation shell than occurs on the larger cations (see Section 11.2 and Figure 11.4). The entity moving through the solution in response to the electric field is not the "bare" cation but the cation "dressed" with its solvation shell. The larger solvation shell on the smaller ions causes more frictional drag and lower mobility.

It can be shown that the conductivity of an ion is related to its mobility by the following equation:

$$\sigma_{ion} = |z|en_{ion}\mu_{ion} \qquad [22.7]$$

where n_{ion} is the number density of ions present, expressed in number per cubic meter. The conductivity depends on two fundamental microscopic variables: the number density of carriers and the carrier mobility. Both positive and negative ions can respond to the electric field in the solution, so the total conductivity must include a contribution from each:

$$\sigma_{tot} = |z_{cation}|en_{cation}\mu_{cation} + |z_{cation}|en_{anion}\mu_{anion} \qquad [22.8]$$

TABLE 22.7

Mobilities of Selected Ions in Aqueous Solution at 25°C

Ion	Mobility ($cm^2\ V^{-1}\ s^{-1}$)
Li^+	4.01×10^{-4}
Na^+	5.19×10^{-4}
K^+	7.62×10^{-4}
Mg^{2+}	5.50×10^{-4}
Ca^{2+}	6.17×10^{-4}
Ba^{2+}	6.60×10^{-4}
Cl^-	7.91×10^{-4}
Br^-	8.10×10^{-4}
NO_3^-	7.40×10^{-4}
ClO_4^-	6.98×10^{-4}
CH_3COO^-	4.24×10^{-4}

Equations 22.7 and 22.8 are valid for all electrical conduction processes: motion of positive and negative ions in solution and in ionic solids, and motion of electrons in solids. These equations are used in subsequent sections to discuss conduction in a variety of materials. These equations should remind you that the conductivity in any material depends on two separate microscopic parameters: the number of charge carriers present and their mobilities.

EXAMPLE 22.2

The molar conductivity of Na^+ ions in aqueous solution at 25°C has been determined to be $5.01 \times 10^{-2}\ (\Omega\ \text{cm})^{-1}\ \text{mol}^{-1}\ \text{L}$. Assume an electric field of $1.0 \times 10^2\ \text{V cm}^{-1}$ is applied to the solution. Calculate the mobility and the drift velocity of Na^+ ions.

Solution

From Equation 22.6, the mobility and molar conductivity are related by

$$\mu = \frac{\Lambda_m}{|z|F} = \frac{5.01 \times 10^{-2}\ \Omega^{-1}\ \text{cm}^{-1}\ \text{mol}^{-1}\ \text{L}}{(1)(96,485\ \text{C mol}^{-1})} = 5.19 \times 10^{-4}\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$$

We used Ohm's law $V = IR$ or $V = \text{C s}^{-1}\ \Omega$ to simplify the units, and we took $1\ \text{L} = 10^3\ \text{cm}^3$.

From Equation 22.5, the drift velocity is given by

$$v_d = \mu E = (5.19 \times 10^{-4}\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1})(1.0 \times 10^2\ \text{V cm}^{-1}) = 5.19 \times 10^{-2}\ \text{cm s}^{-1}$$

Illustration: Conductivity in Metals

Before the quantum theory of solids (see description in Chapter 21), microscopic descriptions of metals were based on the Drude model, named for the German physicist Paul Drude. The solid was viewed as a fixed array of positively charged metal ions, each localized to a site on the solid lattice. These fixed ions were surrounded by a sea of mobile electrons, one contributed by each of the atoms in the solid. The number density of the electrons, n_{el}, is then equal to the number density of atoms in the solid. As the electrons move through the ions in response to an applied electric field, they can be scattered away from their straight-line motions by collisions with the fixed ions; this influences the mobility of the electrons. As temperature increases, the electrons move more rapidly and the number of their collisions with the ions increases; therefore, the mobility of the electrons decreases as temperature increases. Equation 22.7 applied to the electrons in the Drude model gives

$$\sigma_{el} = e n_{el} \mu_{el} \qquad [22.9]$$

which predicts that the electrical conductivity of a metal will decrease as temperature increases, because the electron mobility decreases with temperature, whereas the electron number density is independent of temperature. This simple model prediction agrees with the experimental fact that the resistivity of metals increases as temperature increases.

22.6 BAND THEORY OF CONDUCTION

The characteristic property of metals is their good ability to conduct electricity and heat. Both phenomena are due to the ease with which valence electrons move; electrical conduction is a result of the flow of electrons from regions of high potential energy to those of low potential energy, and heat conduction is a result of the flow of electrons from high-temperature regions (where their kinetic energies are high)

to low-temperature regions (where their kinetic energies are low). Why are electrons so mobile in a metal but so tightly bound to atoms in an insulating solid, such as diamond or sodium chloride?

Figure 21.19 shows how the quantum energy levels of Na atoms in a crystal are spread out into a continuous band of states, which is half-occupied by electrons. Now, suppose a small electric potential difference is applied across a sodium crystal. The spin-paired electrons that lie deep in the band cannot be accelerated by a weak electric field because occupied levels exist just above them. They have no place to go (recall the Pauli principle, which states that an energy level contains at most two electrons). At the top of the "sea" of occupied levels, however, there is an uppermost electron-occupied or half-occupied level called the **Fermi level.** Electrons that lie near that level have the highest kinetic energy of all the valence electrons in the crystal and can be accelerated by the electric field to occupy the levels above. They are free to migrate in response to the electric field so that they conduct an electric current. These same electrons at the Fermi level are responsible for the high thermal conductivities of metals. They are also the electrons freed by the photoelectric effect when a photon gives them sufficient kinetic energy to escape from the metal (see Section 4.4).

A natural question arises: Why are the alkaline-earth elements metals, given the argument just presented? A metal such as magnesium contains two 3*s* electrons, and one might expect the band derived from the broadened 3*s* level to be completely filled. The answer to this question is that the energies of the 3*s* orbitals and 3*p* orbitals for magnesium are not greatly different. When the internuclear separation becomes small enough, the 3*p* band overlaps the 3*s* band, and many unoccupied sublevels are then available above the highest filled level.

Band Picture of Bonding in Silicon

An analogous procedure to that shown in Figure 21.19 can be used to construct a band picture for silicon. In this case, the $4N_A$ valence atomic orbitals (both 3*s* and 3*p*) from 1 mol (N_A atoms) silicon split into *two* bands in the silicon crystal, each containing $2N_A$ closely spaced levels (Fig. 22.21). The lower band is called the **valence band** and the upper one the **conduction band.** Between the top of the

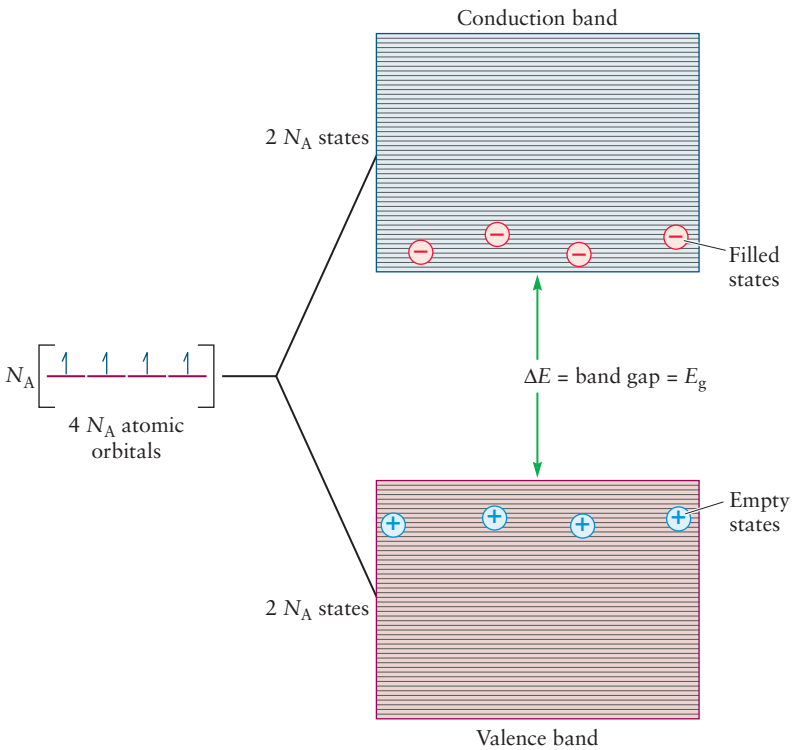

FIGURE 22.21 The valence orbitals of the silicon atom combine in crystalline silicon to give two bands of closely spaced levels. The valence band is almost completely filled, and the conduction band is almost empty.

valence band and the bottom of the conduction band is an energy region that is forbidden to electrons. The magnitude of the separation in energy between the valence band and the lowest level of the conduction band is called the **band gap,** E_g, which for pure silicon is 1.94×10^{-19} J. This is the amount of energy that an electron must gain to be excited from the top of the valence band to the bottom of the conduction band. For 1 mol of electrons to be excited in this way, the energy is larger by a factor of Avogadro's number N_A, giving 117 kJ mol^{-1}. (Another unit used for band gaps is the *electron volt,* defined in Section 3.3 as 1.60218×10^{-19} J. In this unit, the band gap in Si is 1.21 eV.)

Each Si atom in the crystal contributes four valence electrons to the bands of orbitals in Figure 22.21, for a total of $4N_A$ per mole. This is a sufficient number to place two electrons in each level of the valence band (with opposing spins) and leave the conduction band empty. There are no low-lying energy levels for those electrons at the top of the valence band to enter if given a small increment in their energy. The band gap means that an electron at the top of the filled valence band must acquire an energy of at least 1.94×10^{-19} J, equivalent to 117 kJ mol^{-1}, to jump to the lowest empty level of the conduction band. This is a large amount of energy. If it were to be supplied by a thermal source, the temperature of the source would have to be on the order of

$$T = \frac{\Delta E}{R} = \frac{117{,}000 \text{ J mol}^{-1}}{8.315 \text{ J K}^{-1} \text{ mol}^{-1}} = 14{,}000 \text{ K}$$

which is far above the temperature at which a crystalline sample could exist. At room temperature, only a few electrons per mole in the extreme tail of the Boltzmann distribution have enough energy to jump the gap; therefore, the conduction band in pure silicon is sparsely populated with electrons. The result is that silicon is not a good conductor of electricity; good electrical conductivity requires a net motion of many electrons under the impetus of a small electric potential difference. Silicon has an electrical conductivity that is 11 orders of magnitude smaller than that of copper at room temperature. It is called a **semiconductor,** because its electrical conductivity, although smaller than that of a metal, is far greater than that of an **insulator** such as diamond, which has a larger band gap. The conductivity of a semiconductor is increased by increasing the temperature, which excites more electrons into levels in the conduction band. Another way to increase the conductivity of a semiconductor is to irradiate it with a beam of electromagnetic radiation with a frequency high enough to excite electrons from the valence band to the conduction band. This process resembles the photoelectric effect described in Section 4.4, with the difference that now the electrons are not removed from the material but only moved into the conduction band, ready to conduct a current if a potential difference is imposed.

EXAMPLE 22.3

Calculate the longest wavelength of light that can excite electrons from the valence to the conduction band in silicon. In what region of the spectrum does this wavelength fall?

Solution

The energy carried by a photon is $h\nu = hc/\lambda$, where h is Planck's constant, ν the photon frequency, c the speed of light, and λ the photon wavelength. For a photon to just excite an electron across the band gap, this energy must be equal to that band gap energy, $E_g = 1.94 \times 10^{-19}$ J, where

$$\frac{hc}{\lambda} = E_g$$

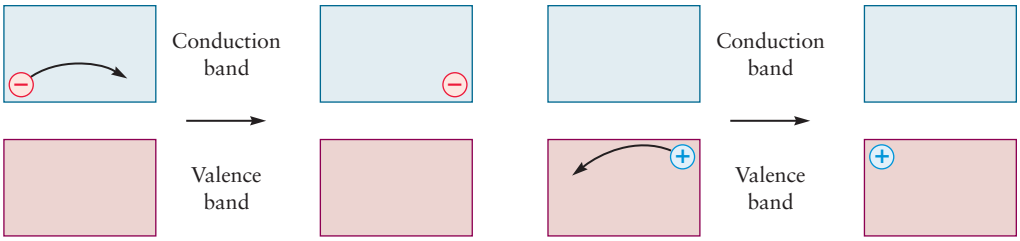
Solving for the wavelength gives

$$\lambda = \frac{hc}{E_g} = \frac{(6.626 \times 10^{-34}\ \text{J s}) * (2.998 \times 10^{8}\ \text{m s}^{-1})}{1.94 \times 10^{-19}\ \text{J}}$$

$$= 1.02 \times 10^{-6}\ \text{m} = 1020\ \text{nm}$$

This wavelength falls in the infrared region of the spectrum. Photons with shorter wavelengths (for example, visible light) carry more than enough energy to excite electrons to the conduction band in silicon.

Related Problems: 27, 28



22.7 SEMICONDUCTORS

Silicon in very high purity is said to display its **intrinsic properties.** When certain other elements are added to pure silicon in a process called **doping,** it acquires interesting electronic properties. For example, if atoms of a Group V element such as arsenic or antimony are diffused into silicon, they substitute for Si atoms in the network. Such atoms have five valence electrons, so each introduces one more electron into the silicon crystal than is needed for bonding. The extra electrons occupy energy levels just below the lowest level of the conduction band. Little energy is required to promote electrons from such a **donor impurity** level into the conduction band, and the electrical conductivity of the silicon crystal is increased without the necessity of increasing the temperature. Silicon doped with atoms of a Group V element is called an ***n*-type semiconductor** to indicate that the charge carrier is negative.

However, if a Group III element such as gallium is used as a dopant, there is one fewer electron in the valence band per dopant atom because Group III elements have only three valence electrons, not four. This situation corresponds to creating one **hole** in the valence band, with an effective charge of +1, for each Group III atom added. If a voltage difference is impressed across a crystal that is doped in this way, it causes the positively charged holes to move toward the negative source of potential. Equivalently, a valence band electron next to the (positive) hole will move in the opposite direction (that is, toward the positive source of potential). Whether we think of holes or electrons as the mobile charge carrier in the valence band, the result is the same; we are simply using different words to describe the same physical phenomenon (Fig. 22.22). Silicon that has been doped with a Group III element is called a ***p*-type semiconductor** to indicate that the carrier has an effective positive charge.

A different class of semiconductors is based not on silicon, but on equimolar compounds of Group III with Group V elements. Gallium arsenide, for example, is isoelectronic to the Group IV semiconductor germanium. When GaAs is doped with the Group VI element tellurium, an *n*-type semiconductor is produced; doping with zinc, which has one *fewer* valence electron than gallium, gives a *p*-type semiconductor. Other III–V combinations have different band gaps and are useful in particular applications. Indium antimonide (InSb), for example, has a small enough band gap that absorption of infrared radiation causes electrons to be excited from the valence to the conduction band, and an electric current then flows when a small potential difference is applied. This compound is therefore used as a detector of infrared radiation. Still other compounds formed between the zinc group (zinc, cadmium, and mercury) and Group VI elements such as sulfur also have the same average number of valence electrons per atom as silicon and make useful semiconductors.

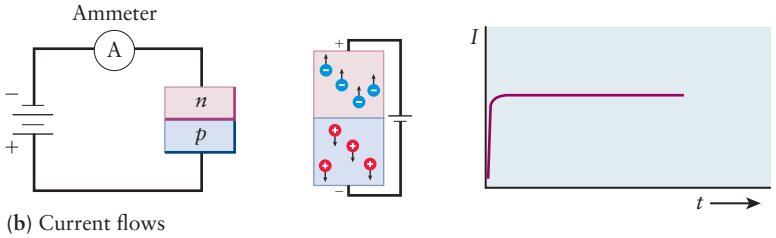
(a) Electron motion (b) "Hole" motion

FIGURE 22.22 (a) In an *n*-type semiconductor, a small number of electrons occupy levels in the conduction band. When an electric field is imposed, each electron moves (black arrows) into one of the numerous nearby vacant energy levels in the conduction band. (b) In a *p*-type semiconductor, a small number of levels in the valence band are unoccupied. Conduction occurs as electrons in the numerous occupied levels of the valence band jump into the sparsely distributed unoccupied levels. The arrow shows the motion of an electron to occupy a previously empty level. The process can also be described as the motion of positively charged holes in the opposite direction.



p–n Junctions and Device Performance

Of what value is it to have a semiconductor that can conduct an electric current by the flow of electrons if it is *n*-type or by the flow of holes if it is *p*-type? Many electronic functions can be fulfilled by semiconductors that possess these properties, but the simplest is **rectification**—the conversion of alternating current into direct current. Suppose thin crystals of *n*- and *p*-type silicon are placed in contact with one another and connected to a battery. In Figure 22.23a, the positive pole of the battery is connected to the *n*-type silicon, and the *p*-type silicon is connected to the negative pole. Only a small transient current can flow through the circuit in this

FIGURE 22.25 An integrated circuit, like the microprocessor in a laptop computer, can contain hundreds of millions of transistors in a chip whose area is about 1 cm^2. The integrated circuit shown in this figure is connected to a printed circuit board by rows of wires on all four sides.

case, because when the electrons in the conduction band of the *n*-type silicon have flowed out to the positive pole of the battery, there is none to take their place and current ceases to flow. However, if the negative pole of the battery is connected to the *n*-type silicon and the positive pole to the *p*-type silicon (see Fig. 22.23b), a steady current flows because electrons and holes move in opposite directions and recombine at the *n*–*p* junction. In effect, electrons flow toward the *n*–*p* junction in the *n*-type material, holes flow toward the *n*–*p* junction in the *p*-type material, and the junction is a "sink" where electrons fill the holes in the valence band and neutralize one another. If, instead of a galvanic cell, an alternating current source was connected to the *n*–*p* rectifier, current would flow in one direction only, creating pulsed direct current (see Fig. 22.23c).

Gallium arsenide and other semiconductors also provide materials for making solid-state lasers, which have applications ranging from reading compact discs to performing delicate eye surgery. When an electric current is passed through a material containing *n*–*p* junctions, electrons from the *n* regions and holes from the *p* regions flow toward the junctions, where they recombine and emit light. The light moves through the material, stimulating additional recombinations at other junctions and the emission of additional photons (Fig. 22.24). Critical to the operation of a laser is that these photons are coherent (in phase with one another), so the corresponding electric fields add constructively to create a plane wave. The light is reflected by a mirror at one end of the material and sets up a standing wave inside the semiconductor. At the other end, a partially reflecting mirror allows an intense beam of coherent light with a fixed wavelength to leave.

Semiconductors perform a wide range of electronic functions that formerly required the use of vacuum tubes. Vacuum tubes occupy much more space, generate large amounts of heat, and require considerably more energy to operate than **transistors,** their semiconductor counterparts. More important, semiconductors can be built into integrated circuits (Fig. 22.25) and made to store information and process it at great speeds.

Solar cells based on silicon or gallium arsenide provide a way to convert the radiant energy of the sun directly into electrical work by a technology that is virtually nonpolluting (Fig. 22.26). The high capital costs of solar cells make them uncompetitive with conventional fossil fuel sources of energy at this time, but as reserves of fossil fuels dwindle, solar energy will become an important option.

FIGURE 22.28 Crystalline cinnabar, HgS.

The band gap of an insulator or semiconductor has a significant effect on its color. Pure diamond has a large band gap, so even blue light does not have enough energy to excite electrons from the valence band to the conduction band. As a result, light passes through diamonds without being absorbed and the diamonds are colorless. Cadmium sulfide (CdS; Fig. 22.27) has a band gap of 4.2×10^{-19} J, which corresponds to a wavelength of 470 nm in the visible region of the spectrum. Cadmium sulfide, therefore, absorbs violet and blue light but strongly transmits yellow, giving it a deep yellow color. Cadmium sulfide is the pigment called cadmium yellow. Cinnabar (HgS, Fig. 22.28) has a smaller band gap of 3.2×10^{-19} J and absorbs all light except red. It has a deep red color and is the pigment vermilion. Semiconductors with band gaps of less than 2.8×10^{-19} J absorb all wavelengths of visible light and appear black. These include silicon (see Example 22.2), germanium, and gallium arsenide.

Doping silicon brings donor levels close enough to the conduction band or acceptor levels close enough to the valence band that thermal excitation can cause electrons to move into a conducting state. The corresponding doping of *insulators* or wide band-gap semiconductors can bring donor or acceptor states into positions where *visible light* can be absorbed or emitted. This changes the colors and optical properties of the materials. Nitrogen doped in diamond gives a donor impurity level in the band gap. Transitions to this level can absorb some blue light, giving the diamond an undesirable yellowish color. In contrast, boron doped into diamond gives an acceptor level that absorbs red light most strongly and gives the highly prized and rare "blue diamond."

Phosphors are wide band-gap materials with dopants selected to create new levels such that particular colors of light are emitted. Electrons in these materials are excited by light of other wavelengths or by electrons hitting their surfaces, and light is then emitted as they return to lower energy states. A fluorescent lamp, for example, is a mercury-vapor lamp in which the inside of the tube has been coated with phosphors. The phosphors absorb the violet and ultraviolet light emitted by mercury vapor and emit at lower energies and longer wavelengths, giving a nearly white light that is more desirable than the bluish light that comes from a mercury-vapor lamp without the phosphors.

Phosphors are also used in television screens. The picture is formed by scanning a beam of electrons (from an electron gun) over the screen. The electrons strike the phosphors coating the screen, exciting their electrons and causing them to emit light. In a black-and-white television tube, the phosphors are a mixture of silver doped into ZnS, which gives blue light, and silver doped into $Zn_xCd_{1-x}S$, which gives yellow light. The combination of the two provides a reasonable approximation of white. A color television uses three different electron guns, with three corresponding types of phosphor on the screen. Silver doped in ZnS gives blue, manganese doped in Zn_2SiO_4 is used for green, and europium doped in YVO_4 gives red light. Masks are used to ensure that each electron beam encounters only the phosphors corresponding to the desired color.

CHAPTER SUMMARY

The properties of solid materials are determined by their microscopic structure, which in turn depends on the nature of the chemical bonds created during synthesis and processing. Mechanical and structural properties originate in strong ionic and covalent bonding. Electrical conductivity measures the movement of charged particles throughout the material. Metals, semiconductors, and insulators are distinguished by differences in conductivity values, as explained by the differences in their band gaps. In effect, this difference measures the extent to which some valence electrons from the atoms comprising the solid are delocalized while the remainder are involved in formation of localized bonds. Optical properties measure the response of the solid to visible light. The magnitude of the band gap determines what wavelength of light is absorbed, and therefore the color of the material.

Section 22.1 – Minerals: Naturally Occurring Inorganic Materials

Show how the fundamental silicate tetrahedral unit (SiO_4^{4-}) *links to other silicate tetrahedra to form rings, chains, double chains, sheets, and space-filling crystalline networks (Problems 1–4).*

- Two or more tetrahedra may link together by sharing oxygen vertices. Several examples are shown in Figure 22.1 and Table 22.1. In these linked structures the Si:O ratio is no longer 1:4 because oxygen atoms are shared at each of the linked points.

Describe the chemical compositions and structures of aluminosilicates, clays, and zeolites (Problems 5–6).

- Aluminosilicates are produced when Al atoms replace some of the Si atoms in silicates. Because the Al has only three electrons, one additional electron is provided by an alkali metal. Both the Al and alkali ions occupy tetrahedral sites in the aluminosilicate structure.
- Zeolites are aluminosilicate materials with extended three-dimensional structures that enclose polyhedral cavities. The very large surface area of these cavities makes these very effective as ion exchange materials for water purification, absorbing small molecules, and as catalysts.
- Clays are produced from primary materials by the weathering action of water and heat. The structures and properties of clays can be understood from the structure of the primary materials from which they derive, such as talcs and micas.

Section 22.2 – Properties of Ceramics

Describe the structure of ceramic materials and the ways in which they are formed.

- Ceramics are synthetic materials fabricated from inorganic, nonmetallic materials. Ceramics are mixtures that include silicates, oxides of elements other than silicon, and non-oxide materials such as carbides and nitrides. The microstructure of ceramics includes grains, voids, and cracks of various sizes and orientations. The microstructure can be controlled by sintering and densification to reduce the size of pores and voids.
- The mechanical properties of solid materials are determined by their internal structure, which in turn depends on the nature of the chemical bonds created during synthesis and processing.

Section 22.3 – Silicate Ceramics

Outline the properties of pottery, glass, and cement and the chemical reactions that give them structural strength (Problems 7–14).

- Silicate ceramics are well suited for structural applications because of their strength, which originates in the partially ionic, strong silicon–oxygen bonds in the tetrahedral orthosilicate anion. This structural unit appears in naturally occurring minerals and clays, which are fashioned into ceramic pieces through sintering and densification processes.

Section 22.4 – Nonsilicate Ceramics

List several important oxide and mixed oxide ceramics and give some of their uses (Problems 15–16).

- Nonsilicate ceramics derive comparable properties from other inorganic structural units.
- Oxide ceramics are made from oxides of numerous metals including beryllium, aluminum, calcium, and yttrium; these metal-oxide bonds are essentially ionic.

Discuss the special properties of nonoxide ceramics and the kinetic and thermodynamic factors that make them useful (Problems 17–20).

- Nonoxide ceramics are based on the nitrogen and carbon compounds of silicon and boron. These compounds have short, strong, highly directional covalent bonds, so the materials have great structural strength but are brittle.

Section 22.5 – Electrical Conduction in Materials

Explain how the conductivity of a material is measured, and relate it to the number and mobility of charge carriers (Problems 21–26).

- The electrical properties measure the movement of charged particles in a material in response to an applied electric field. If the particles are free to move throughout the materials, electrical conduction is the result, and the magnitude is characterized as the electrical conductivity of the material.
- The resistance of a cylindrical sample of material is measured as in Ohm's law. Geometrical factors are included to define the resistivity ρ, and the conductivity σ is defined as the reciprocal of the resistivity.

$$\sigma = \frac{1}{\rho} = \frac{\ell}{RA}$$

- Ohm's law can be rewritten to state that the current density flowing through a sample is proportional to the applied electrical field, and the proportionality constant is the electrical conductivity. This expression is used to relate the conductivity of a material to its microstructural properties

$$J = \sigma E$$

Section 22.6 – Band Theory of Conduction

Use the band model to describe the conductivity of metals, semiconductors, and insulators (Problems 27–30).

- Electrical conductivity depends on the product of two separate microscopic parameters of a material: the number density of charge carriers present and the mobility of the carriers.
- The band theory of solids explains the three broad classes of electronic conductivity seen in nature in terms of the number density of charge carriers available in classes of solids.
- Metals have high conductivity values because the number density of free, mobile electrons is quite high—at least one per atom in the solid is in the conduction band. The "electron sea" is delocalized throughout the solid, and the free electrons respond easily to applied electric fields.
- Insulating materials, such as the ceramics, have very low electrical conductivity because they have essentially no free electrons to carry current. There are no electrons in the conduction band, and the band gap is too large for electrons to be promoted from the valence band to the conduction band.
- Semiconductors have conductivity values intermediate between metals and insulators because their bandgaps are small enough that electrons can be promoted from the valence band to the conduction band with modest thermal or optical excitation.

Section 22.7 – Semiconductors

Describe the mechanism of action of intrinsic, n-type, and p-type semiconductors (Problems 31–34).

- Doping a semiconductor by adding an electron donor impurity creates new states very near the bottom of the conduction band, so electrons can be promoted from the donor into the conduction band without increasing the temperature. These promoted electrons are now free to respond to an applied electric field. This doping process leads to an n-type semiconductor, in which the charge carrier is an electron.
- Doping a semiconductor by adding an electron acceptor impurity creates new states very near the top of the valence band. An electron can move to this impurity state from the valence band, leaving a positively charged hole in the valence band. The hole can move in response to an applied electric field. This doping process leads to a *p*-type semiconductor, in which the charge carrier is a hole.
- When a *p*-type semiconductor is placed in contact with an *n*-type semiconductor and the resulting *p–n* junction is placed in an electrical circuit, the junction can either pass or block DC current, or rectify AC current depending on details of the circuit. The device can emit light due to recombination of holes and electrons at the junction.

Section 22.8 – Pigments and Phosphors: Optical Displays

Relate the band gap of a semiconductor or phosphor to the frequencies of electromagnetic radiation absorbed or emitted when electrons make transitions between the valence and conduction bands (Problems 35–36).

- Optical properties describe the response of a material to light in the visible range of the electromagnetic spectrum.
- The band gap of an insulator or semiconductor determines the wavelength of light absorbed by the materials. Because the remaining portions of white light are transmitted through the materials, the color of the materials is complementary to the wavelength of the light absorbed.

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Many insulators are not colored because their band gaps are so large that no visible light is absorbed. Adding dopants can introduce donor or acceptor states that enable absorption of visible light, so the doped materials are colored.
- Phosphors are wide band gap materials doped to emit light at specific wavelengths upon excitation by electron impact or incident light at other wavelengths. Phosphors are used to generate visible light in fluorescent fixtures, and to display signals on video monitors.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.

Minerals: Naturally Occurring Inorganic Materials

1. Draw a Lewis electron-dot diagram for the disilicate ion ($Si_2O_7^{6-}$). What changes in this structure would be necessary to produce the structure of the pyrophosphate ion ($P_2O_7^{4-}$) and the pyrosulfate ion ($S_2O_7^{2-}$)? What is the analogous compound of chlorine?

2. Draw a Lewis electron-dot diagram for the cyclosilicate ion ($Si_6O_{18}^{12-}$), which forms part of the structures of beryl and emerald.

3. Using Table 22.1, predict the structure of each of the following silicate minerals (network, sheets, double chains, and so forth). Give the oxidation state of each atom.
(a) Andradite, $Ca_3Fe_2(SiO_4)_3$
(b) Vlasovite, $Na_2ZrSi_4O_{10}$
(c) Hardystonite, $Ca_2ZnSi_2O_7$
(d) Chrysotile, $Mg_3Si_2O_5(OH)_4$

4. Using Table 22.1, predict the structure of each of the following silicate minerals (network, sheets, double chains, and so forth). Give the oxidation state of each atom.
(a) Tremolite, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$
(b) Gillespite, $BaFeSi_4O_{10}$
(c) Uvarovite, $Ca_3Cr_2(SiO_4)_3$
(d) Barysilate, $MnPb_8(Si_2O_7)_3$

5. Using Table 22.1, predict the structure of each of the following aluminosilicate minerals (network, sheets, double chains, and so forth). In each case, the Al atoms grouped with the Si and O in the formula substitute for Si in tetrahedral sites. Give the oxidation state of each atom.
(a) Keatite, $Li(AlSi_2O_6)$
(b) Muscovite, $KAl_2(AlSi_3O_{10})(OH)_2$
(c) Cordierite, $Al_3Mg_2(AlSi_5O_{18})$

6. Using Table 22.1, predict the structure of each of the following aluminosilicate minerals (network, sheets, double chains, and so forth). In each case, the Al atoms grouped with the Si and O in the formula substitute for Si in tetrahedral sites. Give the oxidation state of each atom.
(a) Amesite, $Mg_2Al(AlSiO_5)(OH)_4$
(b) Phlogopite, $KMg_3(AlSi_3O_{10})(OH)_2$
(c) Thomsonite, $NaCa_2(Al_5Si_5O_{20}) \cdot 6\ H_2O$

Silicate Ceramics

7. A ceramic that has been much used by artisans and craftsmen for the carving of small figurines is based on the mineral steatite (commonly known as soapstone). Steatite is a hydrated magnesium silicate that has the composition $Mg_3Si_4O_{10}(OH)_2$. It is remarkably soft—a fingernail can scratch it. When heated in a furnace to about 1000°C, chemical reaction transforms it into a hard, two-phase composite of magnesium silicate ($MgSiO_3$) and quartz in much the same way that clay minerals are converted into mullite ($Al_6Si_2O_{13}$) and cristobalite (SiO_2) on firing. Write a balanced chemical equation for this reaction.

8. A clay mineral that is frequently used together with or in place of kaolinite is pyrophyllite ($Al_2Si_4O_{10}(OH)_2$). Write a balanced chemical equation for the production of mullite and cristobalite on the firing of pyrophyllite.

9. Calculate the volume of carbon dioxide produced at standard temperature and pressure when a sheet of ordinary glass of mass 2.50 kg is made from its starting materials—sodium carbonate, calcium carbonate, and silica. Take the composition of the glass to be $Na_2O{\cdot}CaO{\cdot}(SiO_2)_6$.

10. Calculate the volume of steam produced when a 4.0-kg brick made from pure kaolinite is completely dehydrated at 600°C and a pressure of 1.00 atm.

11. A sample of soda-lime glass for tableware is analyzed and found to contain the following percentages by mass of oxides: SiO_2, 72.4%; Na_2O, 18.1%; CaO, 8.1%; Al_2O_3, 1.0%; MgO, 0.2%; BaO, 0.2%. (The elements are not actually present as binary oxides, but this is the way compositions are usually given.) Calculate the chemical amounts of Si, Na, Ca, Al, Mg, and Ba atoms per mole of O atoms in this sample.

12. A sample of Portland cement is analyzed and found to contain the following percentages by mass of oxides: CaO, 64.3%; SiO_2, 21.2%; Al_2O_3, 5.9%; Fe_2O_3, 2.9%; MgO, 2.5%; SO_3, 1.8%; Na_2O, 1.4%. Calculate the chemical amounts of Ca, Si, Al, Fe, Mg, S, and Na atoms per mole of O atoms in this sample.

13. The most important contributor to the strength of hardened Portland cement is tricalcium silicate, $(CaO)_3{\cdot}SiO_2$, for which the measured standard enthalpy of formation is $-2929.2\ kJ\ mol^{-1}$. Calculate the standard enthalpy change for the production of 1.00 mol tricalcium silicate from quartz and lime.

14. One of the simplest of the heat-generating reactions that occur when water is added to cement is the production of calcium hydroxide (slaked lime) from lime. Write a balanced chemical equation for this reaction, and use data from Appendix D to calculate the amount of heat generated by the reaction of 1.00 kg lime with water at room conditions.

Nonsilicate Ceramics

15. Calculate the average oxidation number of the copper in $YBa_2Cu_3O_{9-x}$ if $x = 2$. Assume that the rare-earth element yttrium is in its usual +3 oxidation state.

16. The mixed oxide ceramic $Tl_2Ca_2Ba_2Cu_3O_{10+x}$ has zero electrical resistance at 125 K. Calculate the average oxidation number of the copper in this compound if $x = 0.50$ and thallium is in the +3 oxidation state.

17. Silicon carbide (SiC) is made by the high-temperature reaction of silica sand (quartz) with coke; the byproduct is carbon monoxide.
(a) Write a balanced chemical equation for this reaction.
(b) Calculate the standard enthalpy change per mole of SiC produced.
(c) Predict (qualitatively) the following physical properties of silicon carbide: conductivity, melting point, and hardness.

18. Boron nitride (BN) is made by the reaction of boron trichloride with ammonia.
(a) Write a balanced chemical equation for this reaction.
(b) Calculate the standard enthalpy change per mole of BN produced, given that the standard molar enthalpy of formation of BN(*s*) is (254.4 kJ mol^{-1}.
(c) Predict (qualitatively) the following physical properties of boron nitride: conductivity, melting point, and hardness.

19. The standard free energy of formation of cubic silicon carbide (SiC) is 62.8 kJ mol^{-1}. Determine the standard free energy change when 1.00 mol SiC reacts with oxygen to form SiO_2 (*s*, quartz) and $CO_2(g)$. Is silicon carbide thermodynamically stable in the air at room conditions?

20. The standard free energy of formation of boron carbide (B_4C) is (71 kJ mol^{-1}. Determine the standard free energy change when 1.00 mol B_4C reacts with oxygen to form $B_2O_3(s)$ and $CO_2(g)$. Is boron carbide thermodynamically stable in the air at room conditions?

Electrical Conduction in Materials

21. A cylindrical sample of solid germanium has length 55.0 mm and diameter 5.0 mm. In a test circuit, 0.150 A of current flowed through this sample when the voltage applied between its ends was 17.5 V. What is the electrical conductivity of this sample?

22. A gold wire 4.0 mm in diameter and 1.5 m in length is to be used in a test circuit. (a) Calculate the resistance of the wire. (b) Calculate the current density in the wire when the voltage applied between its ends is 0.070 V. (c) Calculate the electric field in the wire.

23. The mobilities for Na^+ and Cl^- in aqueous solution are given in Table 22.7. Calculate the conductivity of a 0.10-M solution of NaCl in water at 25°C.

24. Explain why the ionic mobility of CH_3COO^- is smaller than that for Cl^-.

25. The electrical conductivity for copper is given in Table 22.6. The electron mobility in copper at room temperature is 3.0×10^{-3} m^2 V^{-1} s^{-1}. Using the Drude model for metallic conductivity, calculate the number of free electrons per Cu atom. The density of copper is 8.9 g cm^{-3}.

26. A variety of useful metallic alloys can be prepared by dissolving Ni in Cu. The room temperature resistivity of pure copper is 1.6×10^{-8} Ω m. As nickel is dissolved in copper up to 50% mass, the resistivity increases in a nearly linear fashion to the value 47.0×10^{-8} Ω m. Explain this increase qualitatively.

Band Theory of Conduction

27. Electrons in a semiconductor can be excited from the valence band to the conduction band through the absorption of photons with energies exceeding the band gap. At room temperature, indium phosphide (InP) is a semiconductor that absorbs light only at wavelengths less than 920 nm. Calculate the band gap in InP.

28. Both GaAs and CdS are semiconductors that are being studied for possible use in solar cells to generate electric current from sunlight. Their band gaps are 2.29×10^{-19} J and 3.88×10^{-19} J, respectively, at room temperature. Calculate the longest wavelength of light that is capable of exciting electrons across the band gap in each of these substances. In which region of the electromagnetic spectrum do these wavelengths fall? Use this result to explain why CdS-based sensors are used in some cameras to estimate the proper exposure conditions.

29. The number of electrons excited to the conduction band per cubic centimeter in a semiconductor can be estimated from the following equation:

$$n_e = (4.8 \times 10^{15}\ \text{cm}^{-3}\ \text{K}^{-3/2})\, T^{3/2}\, e^{-E_g/(2RT)}$$

where T is the temperature in kelvins and E_g the band gap in joules *per mole*. The band gap of diamond at 300 K is 8.7×10^{-19} J. How many electrons are thermally excited to the conduction band at this temperature in a 1.00-cm^3 diamond crystal?

30. The band gap of pure crystalline germanium is 1.1×10^{-19} J at 300 K. How many electrons are excited from the valence band to the conduction band in a 1.00-cm^3 crystal of germanium at 300 K? Use the equation given in the preceding problem.

Semiconductors

31. Describe the nature of electrical conduction in (a) silicon doped with phosphorus and (b) indium antimonide doped with zinc.

32. Describe the nature of electrical conduction in (a) germanium doped with indium and (b) cadmium sulfide doped with arsenic.

33. In a light-emitting diode (LED), which is used in displays on electronic equipment, watches, and clocks, a voltage is imposed across an *n–p* semiconductor junction. The electrons on the *n* side combine with the holes on the *p* side and emit light at the frequency of the band gap. This process can also be described as the emission of light as electrons fall from levels in the conduction band to empty levels in the valence band. It is the reverse of the production of electric current by illumination of a semiconductor.

Many LEDs are made from semiconductors that have the general composition $GaAs_{1-x}P_x$. When x is varied between 0 and 1, the band gap changes and, with it, the color of light emitted by the diode. When $x = 0.4$, the band gap is 2.9×10^{-19} J. Determine the wavelength and color of the light emitted by this LED.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

34. When the LED described in Problem 33 has the composition $GaAs_{0.14}P_{0.86}$ (i.e., $x = 0.86$), the band gap has increased to 3.4×10^{-19} J. Determine the wavelength and color of the light emitted by this LED.

Pigments and Phosphors: Optical Displays

35. The pigment zinc white (ZnO) turns bright yellow when heated, but the white color returns when the sample is cooled. Does the band gap increase or decrease when the sample is heated?

36. Mercury(II) sulfide (HgS) exists in two different crystalline forms. In cinnabar, the band gap is 3.2×10^{-19} J; in metacinnabar, it is 2.6×10^{-19} J. In some old paintings with improperly formulated paints, the pigment vermilion (cinnabar) has transformed to metacinnabar on exposure to light. Describe the color change that results.

ADDITIONAL PROBLEMS

37. Predict the structure of each of the following silicate minerals (network, sheets, double chains, and so forth). Give the oxidation state of each atom.
    (a) Apophyllite, $KCa_4(Si_8O_{20})F \cdot 8\ H_2O$
    (b) Rhodonite, $CaMn_4(Si_5O_{15})$
    (c) Margarite, $CaAl_2(Al_2Si_2O_{10})(OH)_2$

38. Using Table 22.1, predict the kind of structure formed by manganpyrosmalite, a silicate mineral with chemical formula $Mn_{12}FeMg_3(Si_{12}O_{30})(OH)_{10}Cl_{10}$. Give the oxidation state of each atom in this formula unit.

39. A reference book lists the chemical formula of one form of vermiculite as

$$[(Mg_{2.36}Fe_{0.48}Al_{0.16})(Si_{2.72}Al_{1.28})O_{10}(OH)_2][Mg_{0.32}(H_2O)_{4.32}]$$

    Determine the oxidation state of the iron in this mineral.

40. The most common feldspars are those that contain potassium, sodium, and calcium cations. They are called, respectively, orthoclase ($KAlSi_3O_8$), albite ($NaAlSi_3O_8$), and anorthite ($CaAl_2Si_2O_8$). The solid solubility of orthoclase in albite is limited, and its solubility in anorthite is almost negligible. Albite and anorthite, however, are completely miscible at high temperatures and show complete solid solution. Offer an explanation for these observations, based on the tabulated radii of the K^+, Na^+, and Ca^{2+} ions from Appendix F.

41. The clay mineral kaolinite ($Al_2Si_2O_5(OH)_4$) is formed by the weathering action of water containing dissolved carbon dioxide on the feldspar mineral anorthite ($CaAl_2Si_2O_8$). Write a balanced chemical equation for the reaction that occurs. The CO_2 forms H_2CO_3 as it dissolves. As the pH is lowered, will the weathering occur to a greater or a lesser extent?

42. Certain kinds of zeolite have the general formula $M_2O \cdot Al_2O_3 \cdot ySiO_2 \cdot wH_2O$, where M is an alkali metal such as sodium or potassium, y is 2 or more, and w is any integer. Compute the mass percentage of aluminum in a zeolite that has M = K, $y = 4$, and $w = 6$.

43. (a) Use data from Tables 15.2 and 16.2 to calculate the solubility of $CaCO_3$ in water at pH 7.
    (b) Will the solubility increase or decrease if the pH is lowered and the water becomes more acidic?
    (c) Calculate the maximum amount of limestone (primarily calcium carbonate) that could dissolve per year in a river at pH 7 with an average flow rate of 1.0×10^6 m^3/h.

44. Silica (SiO_2) exists in several forms, including quartz (molar volume 22.69 $cm^3\ mol^{-1}$) and cristobalite (molar volume 25.74 $cm^3\ mol^{-1}$).
    (a) Use data from Appendix D to calculate $\Delta H°$, $\Delta S°$, and ΔG at 25°C.
    (b) Which form is thermodynamically stable at 25°C?
    (c) Which form is stable at very high temperatures, provided that melting does not occur first?

45. Talc, $Mg_3Si_4O_{10}(OH)_2$, reacts with forsterite (Mg_2SiO_4) to form enstatite ($MgSiO_3$) and water vapor.
    (a) Write a balanced chemical equation for this reaction.
    (b) If the water pressure is equal to the total pressure, will formation of products be favored or disfavored with increasing total pressure?
    (c) The entropy change for this reaction is positive. Will the slope of the coexistence curve (pressure plotted against temperature) be positive or negative?

46. In what ways does soda-lime glass resemble and in what ways does it differ from a pot made from the firing of kaolinite? Include the following aspects in your discussion: composition, structure, physical properties, and method of preparation.

47. Iron oxides are red when the average oxidation state of iron is high and black when it is low. To impart each of these colors to a pot made from clay that contains iron oxides, would you use an air-rich or a smoky atmosphere in the kiln? Explain.

48. Refractories can be classified as acidic or basic, depending on the properties of the oxides in question. A basic refractory must not be used in contact with acid, and an acidic refractory must not be used in contact with a base. Classify magnesia and silica as acidic or basic refractories.

49. Dolomite bricks are used in the linings of furnaces in the cement and steel industries. Pure dolomite contains 45.7% $MgCO_3$ and 54.3% $CaCO_3$ by mass. Determine the empirical formula of dolomite.

50. Beryllia (BeO) ceramics have some use but show only poor resistance to strong acids and bases. Write likely chemical equations for the reaction of BeO with a strong acid and with a strong base.

51. Silicon nitride resists all acids except hydrofluoric, with which it reacts to give silicon tetrafluoride and ammonia. Write a balanced chemical equation for this reaction.

52. Compare oxide ceramics such as alumina (Al_2O_3) and magnesia (MgO), which have significant ionic character, with covalently bonded nonoxide ceramics such as silicon car-

bide (SiC) and boron carbide (B_4C; see Problems 19 and 20) with respect to thermodynamic stability at ordinary conditions.

53. Compare the hybridization of Si atoms in Si(*s*) with that of C atoms in graphite (see Fig. 21.26). If silicon were to adopt the graphite structure, would its electrical conductivity be high or low?

54. Describe how the band gap varies from a metal to a semiconductor to an insulator.

55. Suppose some people are sitting in a row at a movie theater, with a single empty seat on the left end of the row. Every 5 minutes, a person moves into a seat on his or her left if it is empty. In what direction and with what speed does the empty seat "move" along the row? Comment on the connection with hole motion in *p*-type semiconductors.

56. A sample of silicon doped with antimony is an *n*-type semiconductor. Suppose a small amount of gallium is added to such a semiconductor. Describe how the conduction properties of the solid will vary with the amount of gallium added.

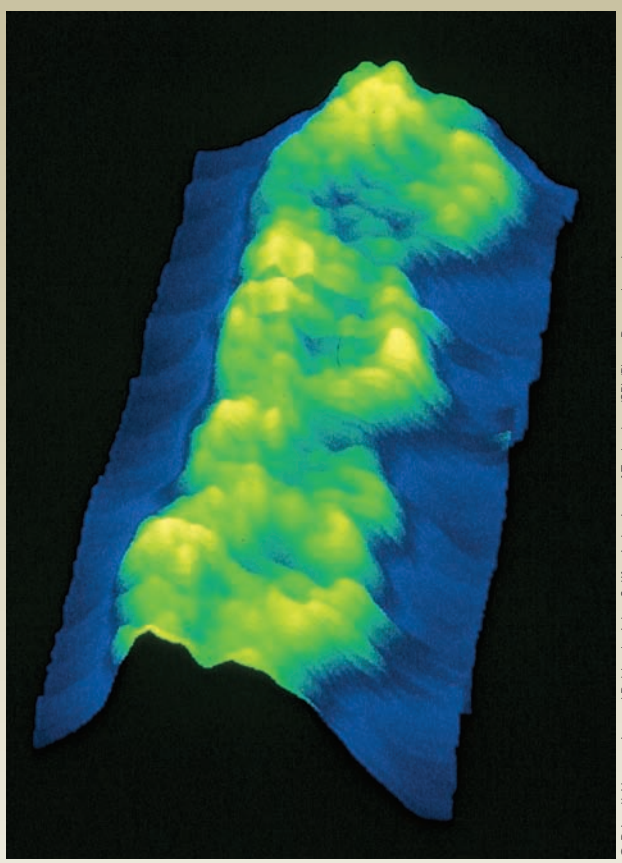
23 CHAPTER



POLYMERIC MATERIALS AND SOFT CONDENSED MATTER

23.1 Polymerization Reactions for Synthetic Polymers

23.2 Applications for Synthetic Polymers

23.3 Liquid Crystals

23.4 Natural Polymers

© Driscoll, Youngquist, and Baldeschwieler, California Institute of Technology/SPL/Photo Researchers, Inc.

A false-color scanning tunneling micrograph (STM) of a DNA double-helix molecule adsorbed on a graphite substrate.

The organic compounds discussed in Chapter 7 were relatively small molecules, ranging from four or five atoms (such as methane or formaldehyde) to long-chain hydrocarbons up to 30 carbon atoms with relative molecular masses of several hundred. In addition to these smaller molecules, carbon atoms string together in stable chains of essentially unlimited length. Such chains provide the backbones of truly huge molecules that may contain hundreds of thousands or even millions of atoms. Such compounds, called **polymers,** are formed by linking numerous separate small **monomer units** in strands and webs.

Although many polymers are based on the ability of carbon to form stable long-chain molecules with various functional groups attached, carbon is not unique in this ability. Recall from Chapter 22 the chains, sheets, and networks found in natu-

ral silicates, in which the elements silicon and oxygen join together to form extended structures. This chapter focuses on organic polymers, whose chemical and physical properties depend on the bonding and functional group chemistry discussed in Section 7.6. We examine both synthetic polymers, which are built largely from the hydrocarbon raw materials discussed in Section 7.1, and naturally occurring biopolymers such as starch, proteins, and nucleic acids, which are built from products of biological synthesis.

23.1 POLYMERIZATION REACTIONS FOR SYNTHETIC POLYMERS

To construct a polymer, very many monomers must add to a growing polymer molecule, and the reaction must not falter after the first few molecules have reacted. This is achieved by having the polymer molecule retain highly reactive functional groups at all times during its synthesis. The two major types of polymer growth are addition polymerization and condensation polymerization.

In **addition polymerization,** monomers react to form a polymer chain without net loss of atoms. The most common type of addition polymerization involves the free-radical chain reaction of molecules that have C=C bonds. As in the chain reactions considered in Section 18.4, the overall process consists of three steps: initiation, propagation (repeated many times to build up a long chain), and termination. As an example, consider the polymerization of vinyl chloride (chloroethene, $CH_2{=}CHCl$) to polyvinyl chloride (Fig. 23.1). This process can be initiated by a small concentration of molecules that have bonds weak enough to be broken by the action of light or heat, giving radicals. An example of such an **initiator** is a peroxide, which can be represented as R—O—O—R′, where R and R′ represent alkyl groups. The weak O—O bonds break

$$R{-}\ddot{O}{-}\ddot{O}{-}R' \longrightarrow R{-}\ddot{O}\cdot + \cdot\ddot{O}{-}R' \quad \text{(initiation)}$$

to give radicals, whose oxygen valence shells are incomplete. The radicals remedy this by reacting readily with vinyl chloride, accepting electrons from the C=C bonds to reestablish a closed-shell electron configuration on the oxygen atoms:

$$R{-}\ddot{O}\cdot + CH_2{=}CHCl \longrightarrow R{-}\ddot{O}{-}CH_2{-}\underset{\displaystyle Cl}{\overset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}\cdot \quad \text{(propagation)}$$

One of the two π electrons in the vinyl chloride double bond has been used to form a single bond with the R—O · radical. The other remains on the second carbon atom, leaving it as a seven–valence-electron atom that will react with another vinyl chloride molecule:

$$R{-}O{-}CH_2{-}\underset{\displaystyle Cl}{\overset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}\cdot + CH_2{=}\underset{\displaystyle Cl}{\overset{\displaystyle H}{\overset{|}{\underset{|}{C}}}} \longrightarrow R{-}O{-}CH_2{-}\underset{\displaystyle Cl}{\overset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}{-}CH_2{-}\underset{\displaystyle Cl}{\overset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}\cdot \quad \text{(propagation)}$$

At each stage, the end group of the lengthening chain is one electron short of a valence octet and remains quite reactive. The reaction can continue, building up long-chain molecules of high molecular mass. The vinyl chloride monomers always

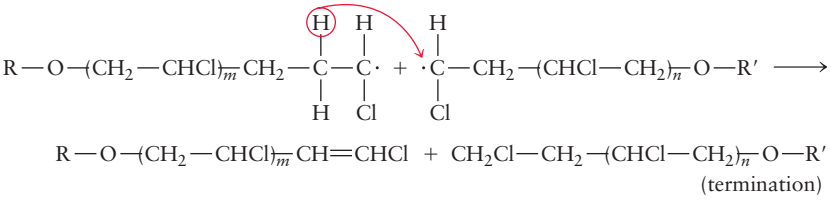

FIGURE 23.1 A pipefitting of polyvinyl chloride.

attach to the growing chain with their CH_2 group because the odd electron is more stable on a CHCl end group. This gives the polymer a regular alternation of $-CH_2-$ and $-CHCl-$ groups. Its chemical formula is $(-CH_2CHCl-)_n$.

Termination occurs when the radical end groups on two different chains encounter each other and the two chains couple to give a longer chain:

Alternatively, a hydrogen atom may transfer from one end group to the other:

The latter termination step leaves a double bond on one chain end and a $-CH_2Cl$ group on the other. When the polymer molecules are long, the exact natures of the end groups have little effect on the physical and chemical properties of the material. A different type of hydrogen transfer step often has a much greater effect on the properties of the resulting polymer. Suppose that a hydrogen atom transfers not from the monomer unit on the *end* of a second chain but from a monomer unit in the middle of that chain (Fig. 23.2). Then the first chain stops growing, but the radical site moves to the middle of the second chain, and growth resumes from that point, forming a *branched* polymeric chain with very different properties.

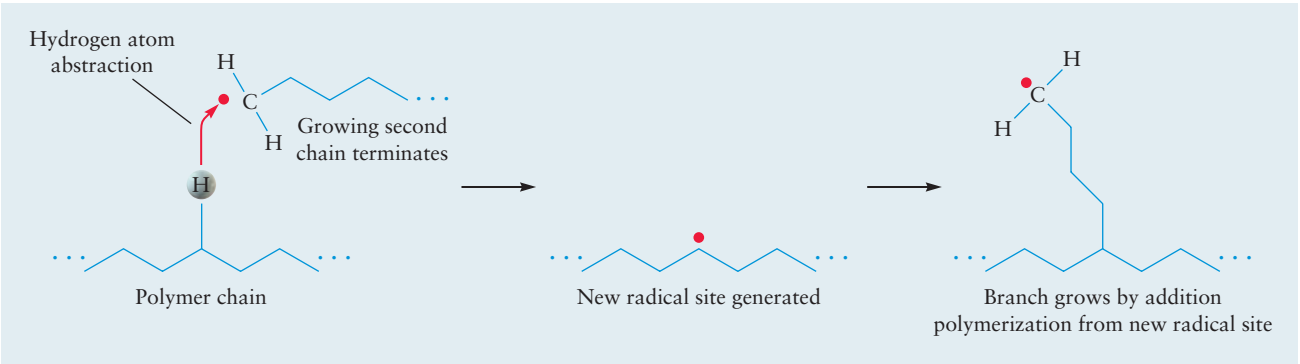

FIGURE 23.2 Chain branching can occur when a hydrogen atom is transferred (abstracted) from the middle of one chain to the free radical end of a second chain, thus terminating the growth of the second chain. The newly generated free radical in the middle of the polymer chain provides a site for the growth of a branched chain via continued monomer addition polymerization.

Addition polymerization can be initiated by ions as well as by free radicals. An example is the polymerization of acrylonitrile:

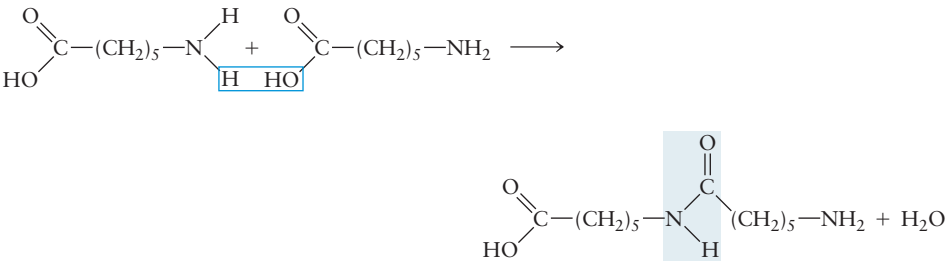
$$n\ CH_2{=}CH(C{\equiv}N) \longrightarrow -[CH_2CH(C{\equiv}N)]_n-$$

A suitable initiator for this process is butyl lithium, $(CH_3CH_2CH_2CH_2)^-Li^+$. The butyl anion (abbreviated Bu^-) reacts with the end carbon atom in a molecule of acrylonitrile to give a new anion:

$$Bu^{\ominus}Li^{\oplus} + CH_2{=}CH(C{\equiv}N) \longrightarrow Bu{-}CH_2{-}CH(C{\equiv}N)^{\ominus}Li^{\oplus} \quad \text{(initiation)}$$

The new anion then reacts with an additional molecule of acrylonitrile:

$$Bu{-}CH_2{-}CH(C{\equiv}N)^{\ominus}Li^{\oplus} + CH_2{=}CH(C{\equiv}N) \longrightarrow Bu{-}CH_2{-}CH(C{\equiv}N){-}CH_2{-}CH(C{\equiv}N)^{\ominus}Li^{\oplus} \quad \text{(propagation)}$$



The process continues, building up a long-chain polymer.

Ionic polymerization differs from free-radical polymerization because the negatively charged end groups repel one another, ruling out termination by the coupling of two chains. The ionic group at the end of the growing polymer is stable at each stage. Once the supply of monomer has been used up, the polymer can exist indefinitely with its ionic end group, in contrast with the free-radical case, in which some reaction must take place to terminate the process. Ion-initiated polymers are called "living" polymers because, when additional monomer is added (even months later), they resume growth and increase in molecular mass. Termination can be achieved by adding water to replace the Li^+ with a hydrogen ion:

$$-(CH_2{-}CH(C{\equiv}N))_n{-}CH_2{-}CH(C{\equiv}N)^{\ominus}Li^{\oplus} + H_2O \longrightarrow -(CH_2{-}CH(C{\equiv}N))_n{-}CH_2{-}CH_2(C{\equiv}N) + Li^{\oplus} + OH^{\ominus} \quad \text{(termination)}$$

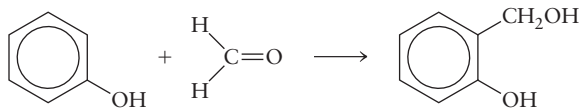
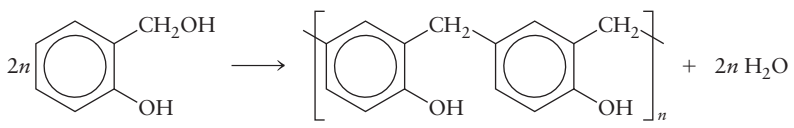
A second important mechanism of polymerization is **condensation polymerization,** in which a small molecule (frequently water) is split off as each monomer unit is attached to the growing polymer.[1] An example is the polymerization of 6-aminohexanoic acid. The first two molecules react upon heating according to



An amide linkage and water form from the reaction of an amine with a carboxylic acid. The new molecule still has an amine group on one end and a carboxylic acid group on the other; it can therefore react with two more molecules of 6-aminohexanoic acid. The process repeats to build up a long-chain molecule. For each monomer unit added, one molecule of water is split off. The final polymer in this case is called nylon 6 and is used in fiber-belted radial tires and in carpets.

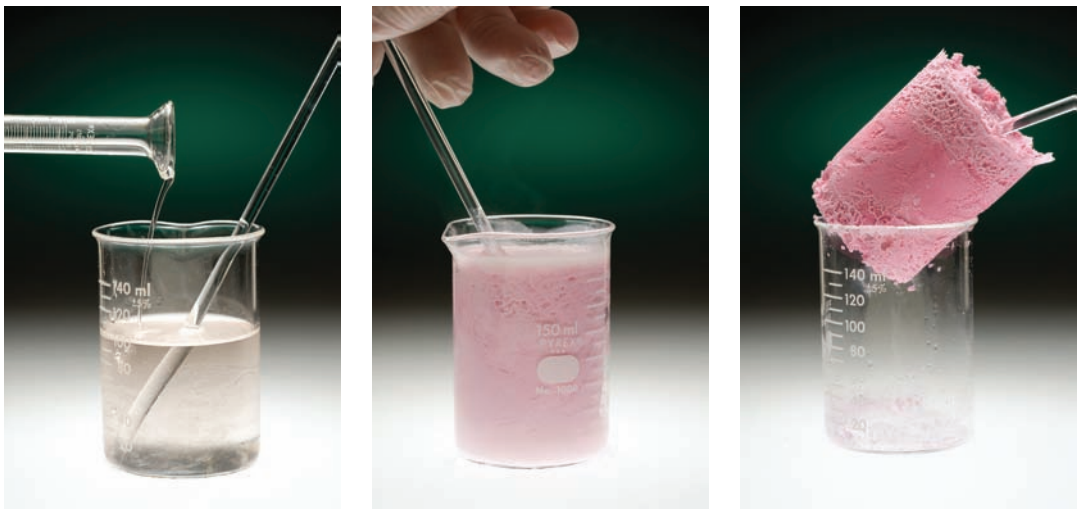
Both addition and condensation polymerization can be carried out with mixtures of two or more types of monomers present in the reaction mixture. The result is a **random copolymer** that incorporates both types of monomers in an irregular sequence along the chain. For example, a 1:6 molar ratio of styrene to butadiene monomers is used to make styrene–butadiene rubber (SBR) for automobile tires, and a 2:1 ratio gives a copolymer that is an ingredient in latex paints.



Cross-Linking: Nonlinear Synthetic Polymers

If every monomer forming a polymer has only two reactive sites, then only chains and rings can be made. The 6-aminohexanoic acid used in making nylon 6 has one amine group and one carboxylic acid group per molecule. When both functional groups react, one link is forged in the polymer chain, but that link cannot react further. If some or all of the monomers in a polymer have three or more reactive sites, however, then cross-linking to form sheets or networks is possible.

One important example of cross-linking involves phenol–formaldehyde copolymers (Fig. 23.3). When these two compounds are mixed (with the phenol in excess in the presence of an acid catalyst), straight-chain polymers form. The first step is the addition of formaldehyde to phenol to give methylolphenol:



Molecules of methylolphenol then undergo condensation reactions (releasing water) to form a linear polymer called novalac:

[1]Condensation reactions have appeared several times outside the context of polymer synthesis. For example, two molecules of H_2SO_4 condense to form disulfuric acid ($H_2S_2O_7$), and a carboxylic acid condenses with an alcohol to form an ester (see Section 7.6).

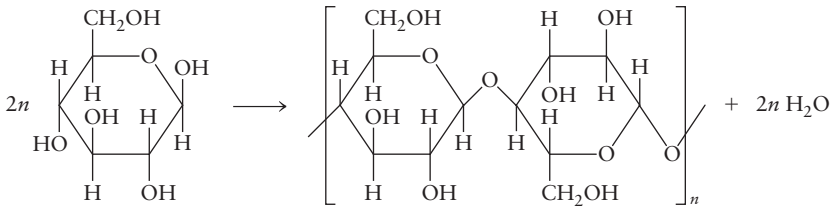
FIGURE 23.3 When a mixture of phenol (C_6H_5OH) and formaldehyde (CH_2O) dissolved in acetic acid is treated with concentrated hydrochloric acid, a phenol–formaldehyde polymer grows.

If, on the other hand, the reaction is carried out with an excess of formaldehyde, dimethylolphenols and trimethylolphenols form:

Each of these monomers has more than two reactive sites and can react with up to three others to form a cross-linked polymer that is much stronger and more impact-resistant than the linear polymer. The very first synthetic plastic, Bakelite, was made in 1907 from cross-linked phenol and formaldehyde. Modern phenol–formaldehyde polymers are used as adhesives for plywood; more than a billion kilograms are produced per year in the United States.

Cross-linking is often desirable because it leads to a stronger material. Sometimes cross-linking agents are added deliberately to form additional bonds between polymer chains. Polybutadiene contains double bonds that can be linked upon addition of appropriate oxidizing agents. One especially important kind of cross-linking occurs through sulfur chains in rubber, as we will see.



23.2 APPLICATIONS FOR SYNTHETIC POLYMERS

The three largest uses for polymers are in fibers, plastics, and elastomers (rubbers). We can distinguish between these three types of materials on the basis of their physical properties, especially their resistance to stretching. A typical fiber strongly resists stretching and can be elongated by less than 10% before breaking. Plastics are intermediate in their resistance to stretching and elongate 20% to 100% before breaking. Finally, elastomers stretch readily, with elongations of 100% to 1000% (that is, some types of rubber can be stretched by a factor of 10 without breaking). A fourth important class is the more recently developed electrically conducting polymers, which combine the optical and electronic properties of inorganic semiconductors with the processibility of conventional polymers. This section examines the major kinds of synthetic polymers and their uses.

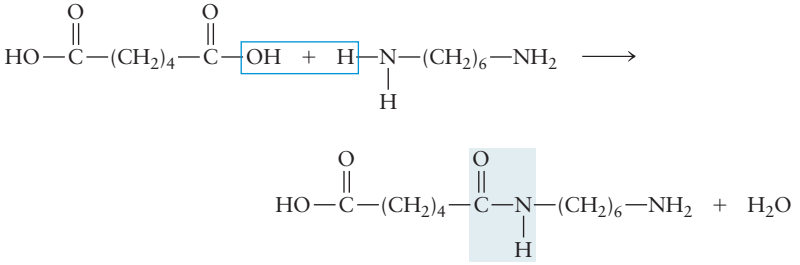
Fibers

Many important fibers, including cotton and wool, are naturally occurring polymers. The first commercially successful synthetic polymers were made not by polymerization reactions but through the chemical regeneration of the natural polymer cellulose, a condensation polymer of the sugar glucose that is made by plants:

In the viscose rayon process, still used today, cellulose is digested in a concentrated solution of NaOH to convert the $-OH$ groups to $-O^- Na^+$ ionic groups. Reaction with CS_2 leads to the formation of about one "xanthate" group for every two glucose monomer units:

Xanthate



Such substitutions reduce the hydrogen-bond forces holding polymer chains together. In the ripening step, some of these xanthate groups are removed with regeneration of CS_2, and others migrate to the $-CH_2OH$ groups from the ring $-OH$ groups. Afterward, sulfuric acid is added to neutralize the NaOH and to remove the remaining xanthate groups. At the same time, the viscose rayon is spun out to form fibers (Fig. 23.4) while new hydrogen bonds form.

Rayon is a "semisynthetic" fiber because it is prepared from a natural polymeric starting material. The first truly synthetic polymeric fiber was nylon, developed in the 1930s by the American chemist Wallace Carothers at DuPont Company. He knew of the condensation of an amine with a carboxylic acid to form an amide linkage (see Section 7.6) and noted that, if each molecule had *two* amine or carboxylic acid functional groups, long-chain polymers could form. The specific starting materials upon which Carothers settled, after numerous attempts, were adipic acid and hexamethylenediamine:

Adipic acid Hexamethylenediamine

The two react with loss of water, according to the equation

The resulting molecule has a carboxylic acid group on one end (which can react with another molecule of hexamethylenediamine) and an amine group on the other

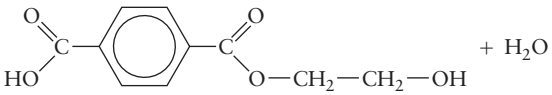
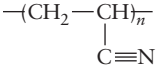
end (which can react with another molecule of adipic acid). The process can continue indefinitely, leading to a polymer with the formula



called nylon 66 (Fig. 23.5). The nylon is extruded as a thread or spun as a fiber from the melt. The combination of well-aligned polymer molecules and N—H···O hydrogen bonds between chains makes nylon one of the strongest materials known. The designation "66" indicates that this nylon has six carbon atoms on the starting carboxylic acid and six on the diamine. Other nylons can be made with different numbers of carbon atoms.

Just as a carboxylic acid reacts with an amine to give an amide, it also reacts with an alcohol to give an ester. This suggests the possible reaction of a dicarboxylic acid and a glycol (dialcohol) to form a polymer. The polymer produced most extensively in this way is polyethylene terephthalate, which is built up from terephthalic acid (a benzene ring with —COOH groups on both ends) and ethylene glycol. The first two molecules react according to

Terephthalic acid Ethylene glycol



Further reaction then builds up the polymer, which is called polyester and sold under trade names such as Dacron. The planar benzene rings in this polymer make it stiffer than nylon, which has no aromatic groups in its backbone, and help make polyester fabrics crush-resistant. The same polymer formed in a thin sheet rather than a fiber becomes Mylar, a very strong film used for audio and video tapes.

Table 23.1 summarizes the structures, properties, and uses of some important fibers.

TABLE 23.1

Fibers

Name	Structural Units	Properties	Sample Uses
Rayon	Regenerated cellulose	Absorbent, soft, easy to dye, poor wash and wear	Dresses, suits, coats, curtains, blankets
Acetate	Acetylated cellulose	Fast drying, supple, shrink-resistant	Dresses, shirts, draperies, upholstery
Nylon	Polyamide	Strong, lustrous, easy to wash, smooth, resilient	Carpeting, upholstery, tents, sails, hosiery, stretch fabrics, rope
Dacron	Polyester	Strong, easy to dye, shrink-resistant	Permanent-press fabrics, rope, sails, thread
Acrylic (Orlon)		Warm, lightweight, resilient, quick-drying	Carpeting, sweaters, baby clothes, socks

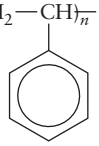
Plastics

Plastics are loosely defined as polymeric materials that can be molded or extruded into desired shapes and that harden upon cooling or solvent evaporation. Rather than being spun into threads in which their molecules are aligned, as in fibers, plastics are cast into three-dimensional forms or spread into films for packaging applications. Although celluloid articles were fabricated by plastic processing by the late 1800s, the first important synthetic plastic was Bakelite, the phenol–formaldehyde resin whose cross-linking was discussed earlier in this section. Table 23.2 lists some of the most important plastics and their properties.

Ethylene ($CH_2{=}CH_2$) is the simplest monomer that will polymerize. Through free-radical–initiated addition polymerization at high pressures (1000 atm to 3000 atm) and temperatures (300°C to 500°C), it forms polyethylene:

$$n\ CH_2{=}CH_2 \longrightarrow \text{-}(CH_2CH_2)_n\text{-}$$



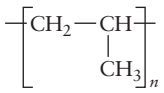
The polyethylene formed in this way is not the perfect linear chain implied by this simple equation. Free radicals frequently abstract hydrogen from the middles of chains in this synthesis, so the polyethylene is heavily branched with hydrocarbon side chains of varying length. It is called **low-density polyethylene** (LDPE) because the difficulty of packing the irregular side chains gives it a lower density (<0.94 g cm^{-3}) than that of perfectly linear polyethylene. This irregularity also makes it relatively soft, so its primary uses are in coatings, plastic packaging, trash bags, and squeeze bottles in which softness is an advantage, not a drawback.

A major breakthrough occurred in 1954, when the German chemist Karl Ziegler showed that ethylene could also be polymerized with a catalyst consisting of $TiCl_4$ and an organoaluminum compound [for example, $Al(C_2H_5)_3$]. The addition of ethylene takes place at each stage within the coordination sphere of the titanium atom, so monomers can add only at the end of the growing chain. The result is linear polyethylene, also called **high-density polyethylene** (HDPE) because of its density (0.96 g cm^{-3}). Because its linear chains are regular, HDPE contains large crystalline regions, which make it much harder than LDPE and thus suitable for molding into plastic bowls, lids, and toys.

A third kind of polyethylene introduced in the late 1970s is called **linear low-density polyethylene** (LLDPE). It is made by the same metal-catalyzed reactions as HDPE, but it is a deliberate copolymer with other 1-alkenes such as 1-butene. It

TABLE 23.2

Plastics



Polyethylene	$\text{-}(CH_2{-}CH_2)_n\text{-}$	High density: hard, strong, stiff	Molded containers, lids, toys, pipe
		Low density: soft, flexible, clear	Packaging, trash bags, squeeze bottles
Polypropylene	$\text{-}(CH_2{-}CH(CH_3))_n\text{-}$	Stiffer, harder than high-density polyethylene, higher melting point	Containers, lids, carpeting, luggage, rope
Polyvinyl chloride	$\text{-}(CH_2{-}CH(Cl))_n\text{-}$	Nonflammable, resistant to chemicals	Water pipes, roofing, credit cards, records
Polystyrene		Brittle, flammable, not resistant to chemicals, easy to process and dye	Furniture, toys, refrigerator linings, insulation
Phenolics	Phenol–formaldehyde copolymer	Resistant to heat, water, chemicals	Plywood adhesive, Fiberglass binder, circuit boards

has some side groups (which reduce the crystallinity and density), but they have a controlled short length instead of the irregular, long side branches in LDPE. LLDPE is stronger and more rigid than LDPE; it is also less expensive because lower pressures and temperatures are used in its manufacture.

If one of the hydrogen atoms of the ethylene monomer unit is replaced with a different type of atom or functional group, the plastics that form upon polymerization have different properties. Substitution of a methyl group (that is, the use of propylene as monomer) leads to polypropylene:

This reaction cannot be carried out successfully by free-radical polymerization. It was first achieved in 1953–1954 by Ziegler and the Italian chemist Giulio Natta, who used the Ziegler catalyst later employed in making HDPE. In polypropylene, the methyl groups attached to the carbon backbone can be arranged in different conformations (Fig. 23.6). In the **isotactic form,** all the methyl groups are arranged on the same side, whereas in the **syndiotactic form** they alternate in a regular fashion. The **atactic form** shows a random positioning of methyl groups. Natta showed that the Ziegler catalyst led to isotactic polypropylene, and he developed another catalyst, using VCl_4, that gave the syndiotactic form. Polypropylene plastic is stiffer and harder than HDPE and has a higher melting point, so it is particularly useful in applications requiring high temperatures (such as the sterilization of medical instruments).

In polystyrene, a benzene ring replaces one hydrogen atom of each ethylene monomer unit. Because such a ring is bulky, atactic polystyrene does not crystallize to any significant extent. The most familiar application of this polymer is in the polystyrene foam used in disposable containers for food and drinks and as insulation. A volatile liquid or a compound that dissociates to gaseous products on heating is added to the molten polystyrene. It forms bubbles that remain as the polymer is cooled and molded. The gas-filled pockets in the final product make it a good thermal insulator.

Synthetic polymers with other elements beyond carbon and hydrogen offer many additional possibilities for making plastics. Polyvinylchloride was already discussed in Section 23.1. Another well-known plastic is the solid perfluorocarbon

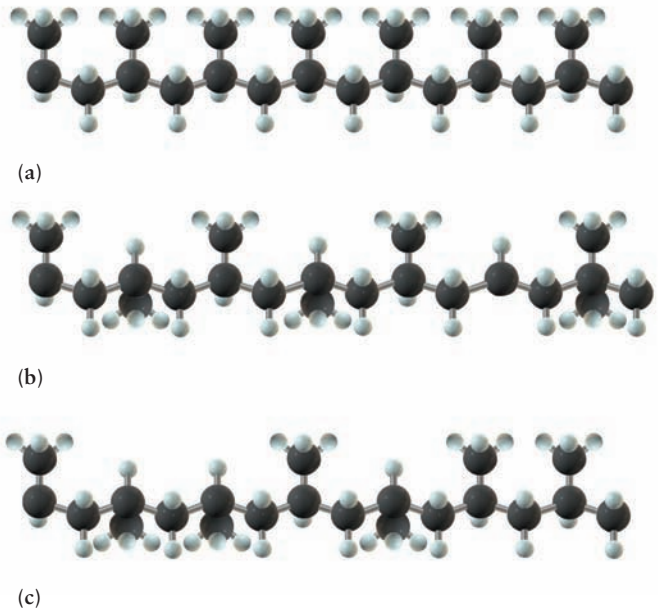

FIGURE 23.6 The structures of (a) isotactic, (b) syndiotactic, and (c) atactic polypropylene.

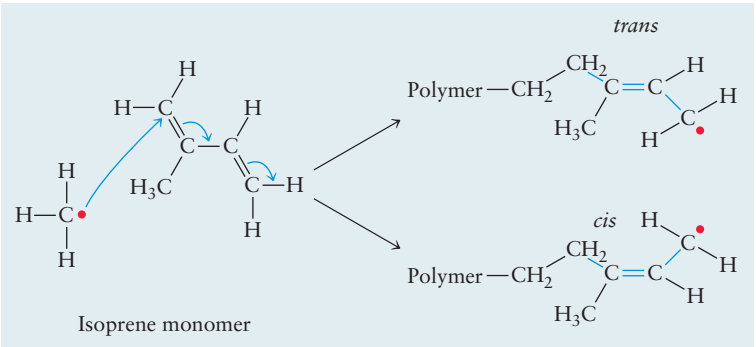
FIGURE 23.7 A model of the molecular structure of Teflon shows that the fluorine atoms shield the carbon chain very effectively. Note that the chain must twist to accommodate the bulk of the fluorine atoms, completing a full spiral every 26 C atoms along the chain.

called polytetrafluoroethylene (Teflon), formulated as $(-CF_2-CF_{2-})_n$, where n is a large number. Chemically, this compound is nearly completely inert, resisting attack from boiling sulfuric acid, molten potassium hydroxide, gaseous fluorine, and other aggressive chemicals. Physically, it has excellent heat stability (a working temperature up to 260°C), is a very good electrical insulator, and has a low coefficient of friction that makes it useful for bearing surfaces in machines as well as coating frying pans ("non-stick" Teflon). In Teflon the carbon atoms lie in a long chain that is encased by tightly bound fluorine atoms (Fig. 23.7). Even reactants with a strong innate ability to disrupt C—C bonds (such as fluorine itself) fail to attack Teflon at observable rates because there is no way to get past the surrounding fluorine atoms and their tightly held electrons.



Rubber

An **elastomer** is a polymer that can be deformed to a great extent and still recover its original form when the deforming stress is removed. The term *rubber* was introduced by Joseph Priestley, who observed that such materials can be used to rub out pencil marks. Natural rubber is a polymer of isoprene (2-methylbutadiene). The isoprene molecule contains two double bonds of which polymerization removes only one; natural rubber is therefore unsaturated, containing one double bond per isoprene unit. In polymeric isoprene, the geometry at each double bond can be either *cis* or *trans* (Fig. 23.8). Natural rubber is all-*cis* polyisoprene. The all-*trans* form also occurs in nature in the sap of certain trees and is called gutta-percha. This material is used to cover golf balls because it is particularly tough. Isoprene can be polymerized by free-radical addition polymerization, but the resulting polymer contains a mixture of *cis* and *trans* double bonds and is useless as an elastomer.

Even pure natural rubber has limited utility because it melts, is soft, and does not fully spring back to its original form after being stretched. In 1839 the American inventor Charles Goodyear discovered that if sulfur is added to rubber and the mixture is heated, the rubber hardens, becomes more resilient, and does not melt. This process is referred to as **vulcanization** and involves the formation of sulfur bridges between the methyl side groups on different chains. Small amounts of sulfur (<5%) yield an elastic material in which sulfur links between chains remain after stretching and enable the rubber to regain its original form when the external force is removed. Large amounts of sulfur give the very hard, nonelastic material ebonite.

Research on synthetic substitutes for natural rubber began in the United States and Europe before World War II. Attention focused on copolymers of butadiene with styrene (now called SBR rubber) and with acrylonitrile (NBR rubber). The Japanese occupation of the rubber-producing countries of Southeast Asia sharply curtailed the supply of natural rubber to the Allied nations, and rapid steps were taken to increase production of synthetic rubber. The initial production goal was 40,000 tons per year of SBR. By 1945, U.S. production had reached an incredible total of more than 600,000 tons per year. During those few years, many advances

FIGURE 23.8 In the polymerization of isoprene, a *cis* or *trans* configuration can form at each double bond in the polymer. The blue arrows show the redistribution of the electrons upon bond formation.

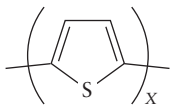
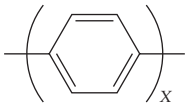
were made in production techniques, quantitative analysis, and basic understanding of rubber elasticity. Styrene–butadiene rubber production continued after the war, and in 1950 SBR exceeded natural rubber in overall production volume for the first time. More recently, several factors have favored natural rubber: the increasing cost of the hydrocarbon feed stock for synthetic rubber, gains in productivity of natural rubber, and the growing preference for belted radial tires, which use more natural rubber.

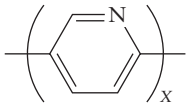


The development of the Ziegler–Natta catalysts has affected rubber production as well. First, it facilitated the synthesis of all-*cis* polyisoprene and the demonstration that its properties were nearly identical to those of natural rubber. (A small amount of "synthetic natural rubber" is produced today.) Second, a new kind of synthetic rubber was developed: all-*cis* polybutadiene. It now ranks second in production after styrene–butadiene rubber.

Electrically Conducting Polymers



Electrically conducting polymers, sometimes called *synthetic metals*, have a backbone that is a π-conjugated system, with alternating double and single bonds. This system is formed by overlap of carbon $2p_z$-orbitals, as in Figure 7.11. The polymers are named after the monomer units on which their structures are based. The simplest conducting polymer is polyacetylene, which is a continuation of the 1,3-butadiene structure in Figure 7.17 to much longer chain lengths. Other conducting polymers include ring structures in the conjugated backbone. The monomeric units are shown below for *trans*-polyacetylene, polythiophene, poly(*para*-phenylene), and poly(*para*-pyridine).



trans-Polyacetylene

Polythiophene

Poly(*para*-phenylene)

Poly(*para*-pyridine)

As the chain length increases, the energy levels shown in Figure 7.17 for 1,3-butadiene increase in number and coalesce into bands. Thus, the conjugated electronic structure for the individual linear polymer molecule is described by bands, which previously we have seen only for extended three-dimensional solids (see Figs. 21.20 and 22.21). The ground state for the polymer chain is that of an insulator, with an energy gap between occupied and empty levels.

The pure polymers are made conductive by doping; the conductivity increases as the doping level increases. Room temperature conductivity for polyacetylene doped with iodine has reached values of 5×10^4 S cm^{-1}, which is about one-tenth the value for copper. (See Section 23.1 for the definition and dimensions of conductivity.) Doping of conductive polymers does not involve substitutional replacement of lattice atoms as in the inorganic semiconductors (see Section 22.7). Rather, doping proceeds by partial oxidation or reduction of the polymer. Electron-donating dopants like Na, K, and Li produce *n*-type material (partly reduced), whereas electron acceptors like I_2, PF_6, and BF_4 produce *p*-type material (partly oxidized). The dopant ions appear interstitially between the polymer chains and promote conductivity by exchanging charges with the conjugated polymer backbones. A wide variety of interesting structural arrangements of polymer chains and dopants can be produced. The details of the conduction process depend strongly on structure and on the degree of ordering of the polymer chains. Research in this area is a fascinat-

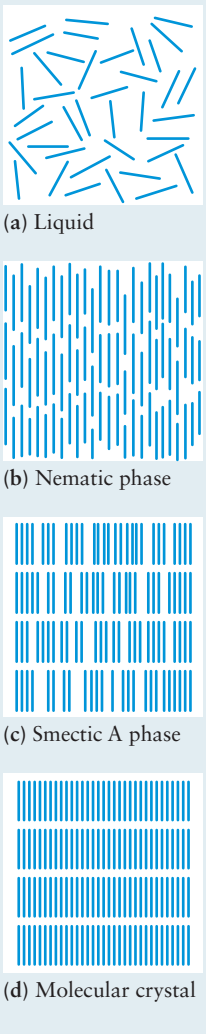
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ing interplay between concepts of solid state physics and synthetic organic chemistry.

Applications of conductive polymers rely on their combination of electrical and optical properties (comparable to metallic conductors and inorganic semiconductors) with the mechanical flexibility and the chemical processibility of organic polymers. Applications have already appeared in packaging materials for items that are sensitive to electrostatic discharges, in flexible materials for shielding against electromagnetic interference (previously achieved only with rigid metal enclosures), and in rechargeable batteries. Applications are envisioned for electrochemical drug delivery in medicine. Very recent applications include light-emitting diodes, transistors, and memory cells. This field holds rich opportunity for cross-disciplinary developments in chemistry, physics, materials science and engineering, and electrical engineering.

23.3 LIQUID CRYSTALS

Liquid crystals constitute an interesting state of matter with properties intermediate between those of true liquids and those of crystals. Unlike glasses, liquid-crystal states are thermodynamically stable. Many organic materials do not show a single solid-to-liquid transition but rather a cascade of transitions involving new intermediate phases. In recent years, liquid crystals have been used in a variety of practical applications, ranging from temperature sensors to displays on calculators and other electronic devices.



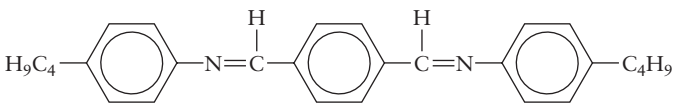


FIGURE 23.9 Different states of structural order for rod-shaped molecules. The figure is only schematic; in a real sample, the lining up of the molecules would not be so nearly perfect.

The Structure of Liquid Crystals

Substances that form liquid crystals are usually characterized by molecules with elongated, rod-like shapes. An example is terephthal-bis-(4-*n*-butylaniline), called TBBA, whose molecular structure can be represented as

with hydrocarbon groups at the ends separated by a relatively rigid backbone of benzene rings and N=C bonds. Such rod-like molecules tend to line up even in the liquid phase, as Figure 23.9a shows. Ordering in this phase persists only over small distances, however, and on average a given molecule is equally likely to take any orientation.

The simplest type of liquid-crystal phase is the **nematic phase** (see Fig. 23.9b); TBBA undergoes a transition from liquid to nematic at 237°C. In a nematic liquid crystal, the molecules display a preferred orientation in a particular direction, but their centers are distributed at random, as they would be in an ordinary liquid. Although liquid-crystal phases are characterized by a net orientation of molecules over large distances, not all the molecules point in exactly the same direction. There are fluctuations in the orientation of each molecule, and only *on average* do the molecules have a greater probability of pointing in a particular direction.

Some liquid crystals form one or more **smectic phases.** These display a variety of microscopic structures that are indicated by the letters A, B, C, and so forth. Figure 23.9c shows one of them, the smectic A structure; the molecules continue to display net orientational ordering, but now, unlike in the nematic phase, the centers of the molecules also tend to lie in layers. Within each layer, however, these centers are distributed at random as in an ordinary liquid. TBBA enters the smectic A phase at 200°C, before undergoing transitions to two other more ordered smectic phases at lower temperatures.

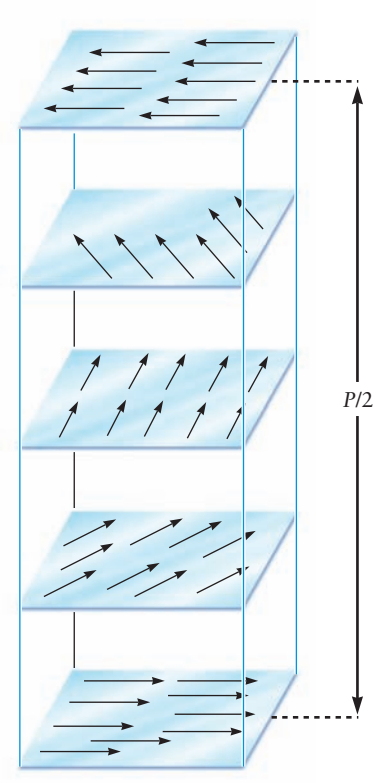

FIGURE 23.10 Several cuts through a cholesteric liquid crystal, showing how the molecular orientation changes with position. The pitch *P* is the distance over which the orientation repeats itself; here, one half of this distance is shown.

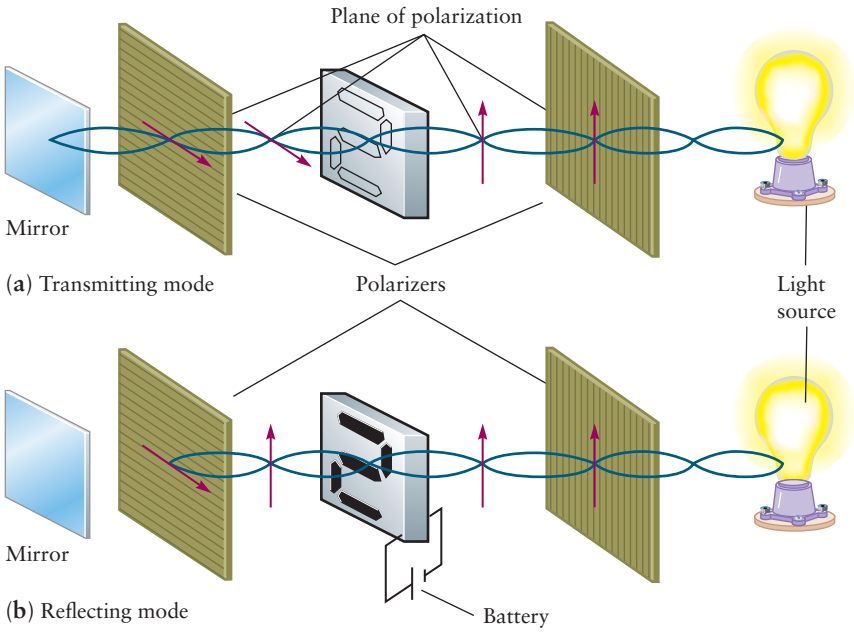
At low enough temperatures (below 113°C for TBBA), a liquid crystal freezes into a crystalline solid (see Fig. 23.9d) in which the molecules' orientations are ordered and their centers lie on a regular three-dimensional lattice. The progression of structures in Figure 23.9 illustrates the meaning of the term *liquid crystal*. Liquid crystals are solid-like in showing orientational ordering but liquid-like in the random distribution of the centers of their molecules.



A third type of liquid crystal is called **cholesteric.** The name stems from the fact that many of these liquid crystals involve derivatives of the cholesterol molecule. The structure of a cholesteric liquid crystal is shown schematically in Figure 23.10. In each plane the molecules show a nematic type of ordering, but the orientation of the molecules changes by a regular amount from plane to plane, leading to a helical structure. The distance between planes with the same orientations is referred to as the **pitch** *P*, which can be quite large (on the order of hundreds of nanometers or longer). A cholesteric liquid crystal will strongly diffract light with wavelengths λ comparable to the pitch. As the temperature changes, the pitch changes as well; the color of the diffracted light can therefore be used as a simple temperature sensor.

The particular orientation taken by a liquid crystal is very sensitive to both the nature of the surfaces with which it is in contact and small electric or magnetic fields. This sensitivity is the basis for the use of nematic liquid crystals in electronic display devices such as digital watches and calculators (Fig. 23.11), as well as in large-screen liquid-crystal displays.

Micelles and Membranes

The liquid crystals we have discussed so far have all been single-component systems, but an interesting second type can be formed from two-component mixtures. One component of the mixture is frequently water, and a typical second component is sodium stearate, which has the chemical formula $CH_3(CH_2)_{16}COO^-Na^+$. Preparation of this soap from animal fat was described in Section 7.6. It is a salt analogous to sodium acetate, and its special properties arise from the different natures of the two ends of the molecules. The long hydrocarbon tail is **hydrophobic** ("water fearing") because hydrocarbons do not dissolve in water and avoid contact with it. The ionic carboxylate group ($-COO^-$), on the other hand, is **hydrophilic** and dissolves readily in water both because of its ionic nature and because it can participate in hydrogen bonds. Such molecules are called **amphiphiles.**

FIGURE 23.11 The mode of operation of a liquid-crystal display device. (a) The light has a polarization that permits it to pass through the second polarizing filter and strike the mirror, giving a bright display. (b) Imposition of a potential difference across some portion of the display causes the liquid-crystal molecules to rotate, creating a different polarization of light. Because the "rotated" light is blocked by the second filter, it does not reach the mirror, and that part of the display appears black.

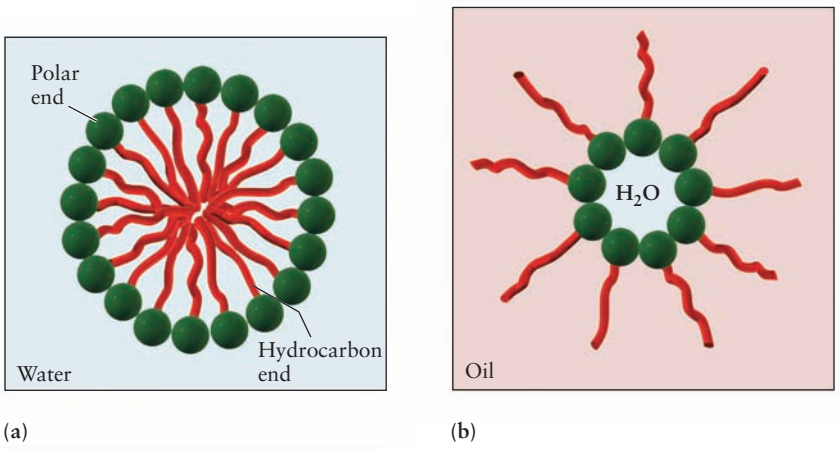

FIGURE 23.12 The structure of a micelle (a) and a reverse micelle (b).

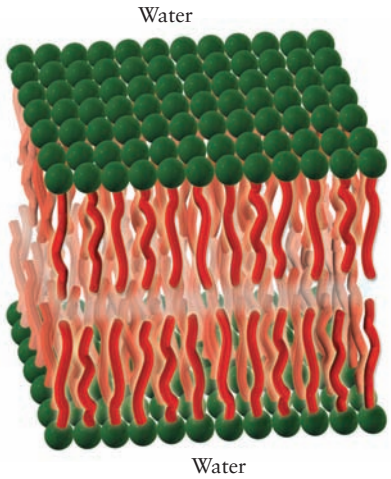

FIGURE 23.13 A bilayer membrane.

If a very small amount of an amphiphile is dissolved in water, it will separate into solvated individual molecules; as soon as a critical concentration is exceeded, however, the molecules organize into **micelles** containing 40 to 100 molecules (Fig. 23.12a). These are small, nearly spherical clusters of molecules whose hydrocarbon tails are in the nonpolar interior and whose ionic groups are exposed to the water. This organization requires a decrease in entropy but leads to a significant lowering of the energy because the hydrophobic chains are removed from direct contact with water. If, on the other hand, a hydrocarbon solvent is used, **reverse micelles** can form, in which the hydrocarbon tails of the long-chain ions make contact with the solvent and small amounts of water are collected in the polar interior of the micelle (see Fig. 23.12b).

Micelle formation is critical to the action of soaps and detergents. Grease and fat are oily substances that are more soluble in hydrocarbons than in pure water. The function of a soap such as sodium stearate in the cleaning of fabrics is to detach the grease and associated materials (dirt) from the surfaces to which it has adhered and to form a suspension of oil drops surrounded by amphiphile molecules, which can then be rinsed off. The main disadvantage of natural soaps is that their salts with ions such as Ca^{2+} and Mg^{2+} (present in dirt or hard water) are not soluble and precipitate, leaving a scum or residue in the objects being washed. To prevent this, a number of analogs to natural soaps have been developed whose calcium and magnesium salts are more soluble in water. Such amphiphilic synthetic agents are called **detergents**.

Micelles are not the only structures that can form when molecules with hydrophilic and hydrophobic sections are dissolved in water. At higher concentrations, flat **bilayer membranes** form (Fig. 23.13) and can stack into layered, or **lamellar,** phases that resemble smectic liquid crystals in their macroscopic properties. A bilayer membrane consists of two planar layers of molecules, with the hydrophilic portions in contact with water and with the hydrophobic portions of one layer in contact with the corresponding hydrophobic portions of a second layer. Such membranes can be made artificially with detergent solutions and serve as models for biological membranes that enclose living cells. Biological membranes contain embedded proteins that control the passage of ions and molecules through the cell wall. In this way they affect the response of the cell to nerve signals and hormones.

23.4 NATURAL POLYMERS

All the products of human ingenuity in the design of polymers pale beside the products of nature. Plants and animals employ a tremendous variety of long-chain molecules with different functions: some for structural strength, others to act as catalysts, and still others to provide instructions for the synthesis of vital components of the cell. In this section we discuss these three important classes of natural polymers: polysaccharides, proteins, and nucleic acids.

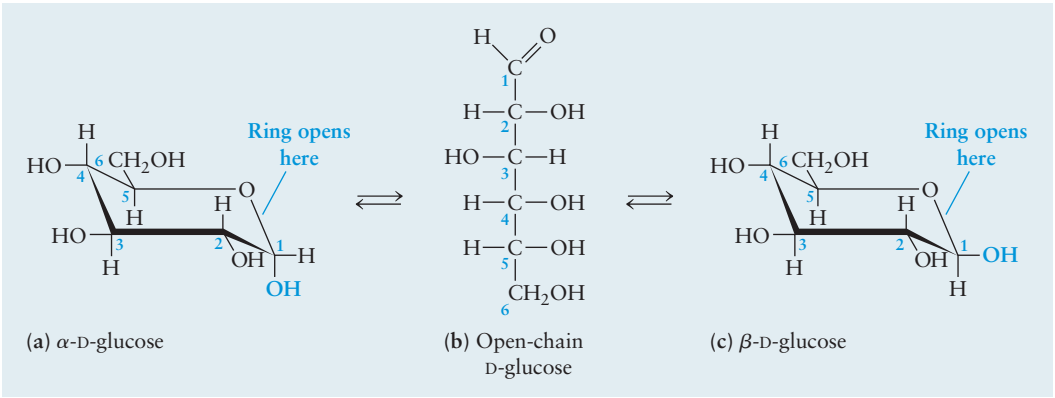

FIGURE 23.14 D-Glucose exists in two ring forms in solution (a and c), which interconvert via an open-chain form (b). The two rings differ in the placement of the —OH and —H groups on carbon atom 1.

Carbohydrates and Polysaccharides

Carbohydrates form a class of compounds of carbon with hydrogen and oxygen. The name comes from the chemical formulas of these compounds, which can be written $C_n(H_2O)_m$, suggesting a "hydrate" of carbon. Simple **sugars,** or **monosaccharides,** are carbohydrates with the chemical formula $C_nH_{2n}O_n$. Sugars with three, four, five, and six carbon atoms are called trioses, tetroses, pentoses, and hexoses, respectively.

Glucose is a hexose sugar that exists in several forms in solution (Fig. 23.14). There is a rapid equilibrium between a straight-chain form (a six-carbon molecule with five —OH groups and one aldehyde —CHO group) and a cyclic form, in which the ring is composed of five carbon atoms and one oxygen, with four —OH side groups and one $-CH_2OH$ side group. In the straight-chain form, four of the carbon atoms (those numbered 2 through 5) are chiral centers, with four different groups bonded to them. As discussed in Section 7.2 (see Fig. 7.9), each such carbon atom can exist in two configurations, each labeled L- for *levo* or D- for *dextro* (Latin for *left* and *right,* respectively). These configurations give rise to $2^4 = 16$ distinct hexose sugars. The glucose formed in plant photosynthesis always has the chirality shown in Figure 23.14b. Of the 15 other straight-chain hexose sugars, the only ones found in nature are D-galactose (in the milk sugar lactose) and D-mannose (a plant sugar).

Figure 23.14 shows that glucose actually has two different ring forms, depending on whether the —OH group created from the aldehyde by the closing of the ring lies above or below the plane of the ring. Another way to see this is to note that closing the ring creates a fifth chiral carbon atom. The two ring forms of D-glucose are called α-D-glucose (Fig. 23.14a) and β-D-glucose (see Fig. 23.14c). In aqueous solution, these two forms interconvert rapidly via the open-chain glucose form and cannot be separated. They can be isolated separately in crystalline form, however. D-fructose, a common sugar found in fruit and honey, has the same molecular formula as D-glucose but is a member of a class of hexose sugars that are ketones rather than aldehydes. In their straight-chain forms, these sugars have the C=O bond at carbon atom 2 rather than carbon atom 1 (Fig. 23.15).

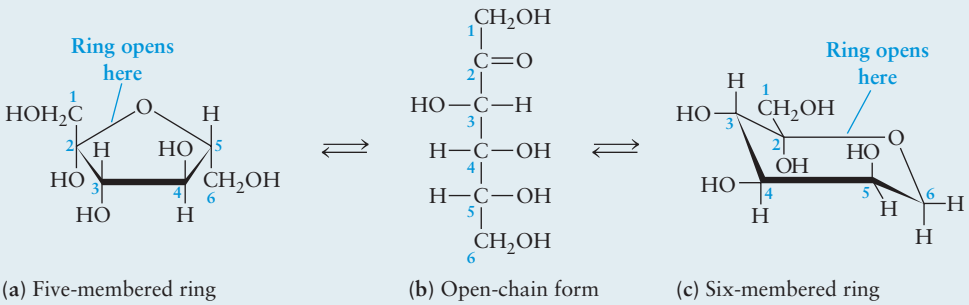

FIGURE 23.15 In aqueous solutions of the sugar D-fructose, an equilibrium exists among a five-atom ring, an open chain, and a six-atom ring. In addition to the β isomers shown here, both ring forms have α isomers, in which the $-CH_2OH$ and —OH on carbon 2 are exchanged.

Many plant cells do not stop the synthesis process with simple sugars such as glucose, but rather continue by linking sugars together to form more complex carbohydrates. **Disaccharides** are composed of two simple sugars linked together by a condensation reaction with the elimination of water. Examples shown in Figure 23.16 are the milk sugar lactose and the plant sugar sucrose (ordinary table sugar, extracted from sugarcane and sugar beets). Further linkages of sugar units lead to polymers called **polysaccharides.** The position of the oxygen atom linking the monomer units has a fundamental effect on the properties and functions of the polymers that result. Starch (Fig. 23.17a) is a polymer of α-D-glucose and is

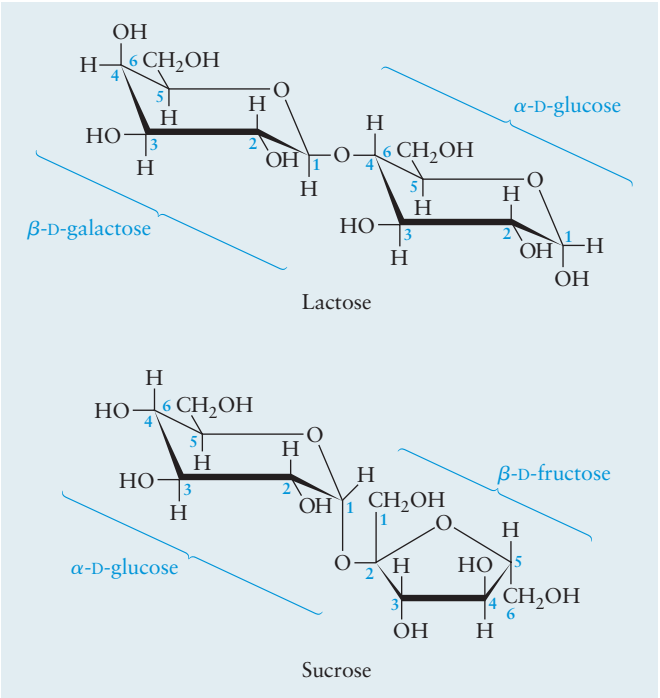

FIGURE 23.16 Two disaccharides. Their derivations from monosaccharide building blocks are shown.

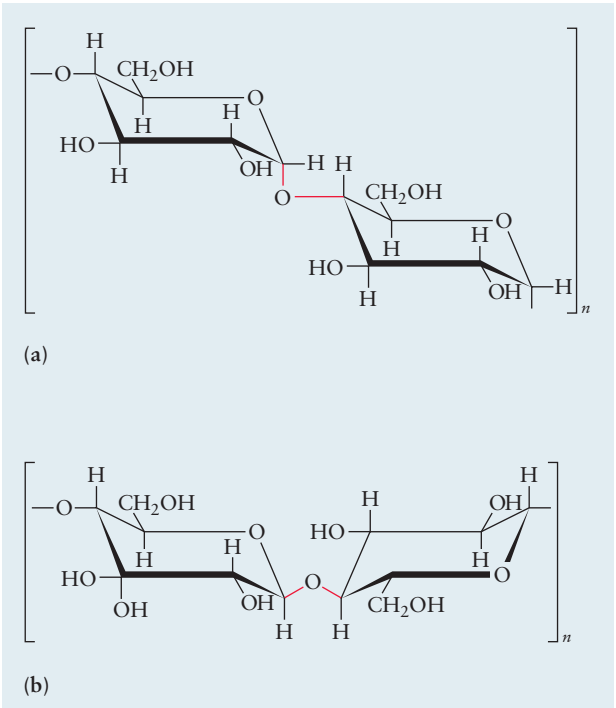

FIGURE 23.17 Both starch (a) and cellulose (b) are polymers of glucose. In starch, all the cyclic glucose units are α-D-glucose. In cellulose, all the monomer units are β-D-glucose.

metabolized by humans and animals. Cellulose (see Fig. 23.17b), a polymer of β-D-glucose, cannot be digested except by certain bacteria that live in the digestive tracts of goats, cows, and other ruminants and in some insects, such as termites. It forms the structural fiber of trees and plants and is present in linen, cotton, and paper. It is the most abundant organic compound on earth.

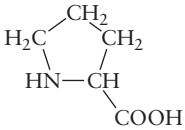
Amino Acids and Proteins

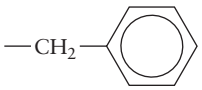
The monomeric building blocks of the biopolymers, called proteins, are the α-amino acids. The simplest amino acid is glycine, which has the molecular structure shown in Figure 23.18. An amino acid, as indicated by the name, must contain an amine group ($—NH_2$) and a carboxylic acid group (—COOH). In α-amino acids, the two groups are bonded to the same carbon atom. In acidic aqueous solution, the amine group is protonated to form $—NH_3^+$; in basic solution, the carboxylic acid group loses a proton to form $—COO^-$. At intermediate pH, both reactions occur. The net result is that the simple amino acid form shown in Figure 23.18 is almost never present in aqueous solution.

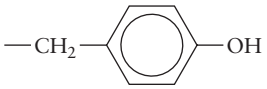
Two glycine molecules can condense with loss of water to form an amide:

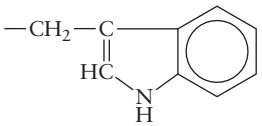
The amide functional group connecting two amino acids is referred to as a **peptide linkage,** and the resulting molecule is a *dipeptide*—in this case, diglycine. Because the two ends of the molecule still have carboxylic acid and amine groups, further condensation reactions to form a **polypeptide,** a polymer comprised of many amino acid groups, are possible. If glycine were the only amino acid available, the result would be polyglycine, a rather uninteresting protein. There is a close similarity between this naturally occurring condensation polymer and the synthetic polyamide nylon. Polyglycine could be called "nylon 2," a simple polyamide in which each repeating unit contains two carbon atoms.

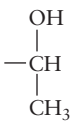
Nature does not stop with glycine as a monomer unit. Instead, any of 20 different α-amino acids are found in most natural polypeptides. In each of these, one of the hydrogen atoms on the central carbon atom of glycine is replaced by another side group. Alanine is the next simplest α-amino acid after glycine; it has a $—CH_3$ group in place of an —H atom. This substitution has a profound consequence. In alanine, four different groups are attached to a central carbon: —COOH, $—NH_2$, $—CH_3$, and —H. There are two ways in which four different groups can be arranged in a tetrahedral structure about a central atom (see Fig. 7.9). The two optical isomers of alanine are designated by the prefixes L- and D- for *levo* and *dextro* (Latin for "left" and "right," respectively).

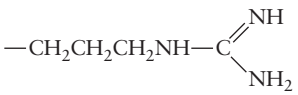


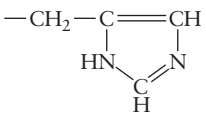


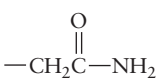


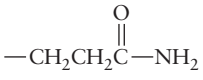












If a mixture of L- and D-alanine were caused to polymerize, nearly all the polymer molecules would have different structures because their sequences of D-alanine and L-alanine monomer units would differ. To create polymers with definite structures for particular roles, there is only one recourse: to build all polypeptides from one of the optical isomers so that the properties will be reproducible from molecule to molecule. Nearly all naturally occurring α-amino acids are of the L form, and most earthly organisms have no use for D-α-amino acids in making polypeptides. Terrestrial life could presumably have begun equally well using mainly D-amino acids (all biomolecules would be mirror images of their present forms). The mechanism by which the established preference was initially selected is not known.

The —H group of glycine and $—CH_3$ group of alanine give just the first two amino acid building blocks. Table 23.3 shows all 20 important α-amino acids,

TABLE 23.3

α-Amino Acid Side Groups

Hydrogen "Side Group"		
Glycine	Gly	—H
Alkyl Side Groups		
Alanine	Ala	$-CH_3$
Valine	Val	$-CH(CH_3)-CH_3$
Leucine	Leu	$-CH_2-CH(CH_3)-CH_3$
Isoleucine	Ile	$-CH(CH_3)-CH_2-CH_3$
Proline	Pro (structure of entire amino acid)	
Aromatic Side Groups		
Phenylalanine	Phe	
Tyrosine	Tyr	
Tryptophan	Trp	
Alcohol-Containing Side Groups		
Serine	Ser	$-CH_2OH$
Threonine	Thr	
Basic Side Groups		
Lysine	Lys	$-CH_2CH_2CH_2CH_2NH_2$
Arginine	Arg	
Histidine	His	
Acidic Side Groups		
Aspartic acid	Asp	$-CH_2COOH$
Glutamic acid	Glu	$-CH_2CH_2COOH$
Amide-Containing Side Groups		
Asparagine	Asn	
Glutamine	Gln	
Sulfur-Containing Side Groups		
Cysteine	Cys	$-CH_2-SH$
Methionine	Met	$-CH_2CH_2-S-CH_3$

arranged by side group. Note the variety in their chemical and physical properties. Some side groups contain basic groups; others are acidic. Some are compact; others are bulky. Some can take part in hydrogen bonds; others can complex readily with metal ions to form coordination complexes.

This variety in properties of the α-amino acids leads to even more variety in the polymers derived from them, called **proteins.** The term *protein* is usually applied to polymers with more than about 50 amino acid groups; large proteins may contain many thousand such groups. Given the fact that any one of 20 α-amino acids may appear at each point in the chain, the number of possible sequences of amino acids in even small proteins is staggering. Moreover, the amino acid sequence describes only one aspect of the molecular structure of a protein. It contains no information about the three-dimensional conformation adopted by the protein. The carbonyl group and the amine group in each amino acid along the protein chain are potential sites for hydrogen bonds, which may also involve functional groups on the amino acid side chains. Also, the cysteine side groups ($-CH_2-SH$) can react with one another, with loss of hydrogen, to form $-CH_2-S-S-CH_2-$ disulfide bridges between different cysteine groups in a single chain or between neighboring chains (the same kind of cross-linking by sulfur occurs in the vulcanization of rubber). As a result of these strong intrachain interactions, the molecules of a given protein have a rather well-defined conformation even in solution, as compared with the much more varied range of conformations available to a simple alkane chain (see Fig. 7.3). The three-dimensional structures of many proteins have been determined by X-ray diffraction.

There are two primary categories of proteins: fibrous and globular. **Fibrous proteins** are usually structural materials and consist of polymer chains linked in sheets or twisted in long fibers. Silk is a fibrous protein in which the monomer units are primarily glycine and alanine, with smaller amounts of serine and tyrosine. The protein chains are cross-linked by hydrogen bonds to form sheet-like structures (Fig. 23.19) that are arranged so that the nonhydrogen side groups all lie on one side of the sheet; the sheets then stack in layers. The relatively weak forces between sheets give silk its characteristic smooth feel. The amino acids in wool and hair have side chains that are larger, bulkier, and less regularly distributed than those in silk; therefore, sheet structures do not form. Instead, the protein molecules twist into a right-handed coil called an α-**helix** (Fig. 23.20). In this structure, each carbonyl group is hydrogen-bonded to the amine group of the fourth amino acid farther along the chain; the bulky side groups jut out from the helix and do not interfere with one another.

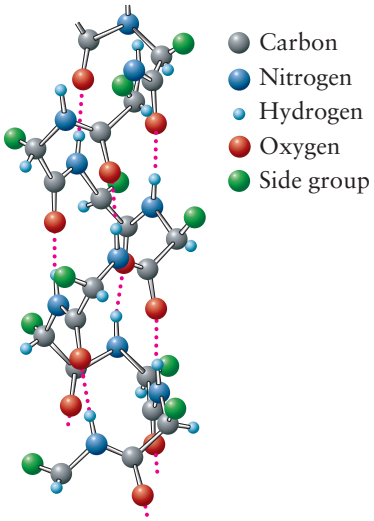

FIGURE 23.20 α-helix protein secondary structure, with interchain hydrogen bonds shown.

The second type of protein is the **globular protein.** Globular proteins include the carriers of oxygen in the blood (hemoglobin) and in cells (myoglobin). They have irregular folded structures (Fig. 23.21) and typically consist of 100 to 1000 amino acid groups in one or more chains. Globular proteins frequently have parts of their structures in α-helices and sheets, with other portions in more disordered forms. Hydrocarbon side groups tend to cluster in regions that exclude water, whereas

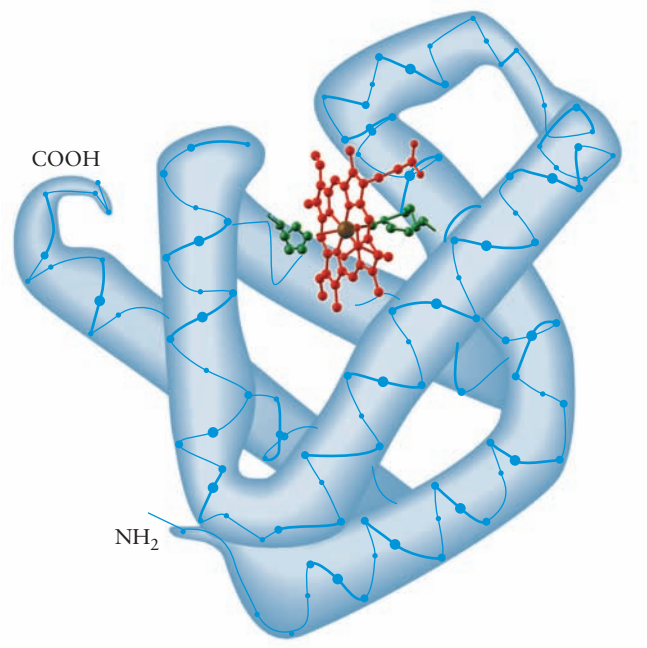

FIGURE 23.21 A computer-generated model of the structure of myoglobin. The central heme group (red) is shown in greater detail in Chapter 8—*Connection to Biology:* Heme Proteins; two histidine groups (green) extend toward the central iron atom. Much of the protein (blue tube) is coiled in α-helices.

charged and polar side groups tend to remain in close contact with water. The sequences of amino acid units for many such proteins have been worked out by cleaving them into smaller pieces and analyzing the structure of the fragments. It took Frederick Sanger 10 years to complete the first such determination of sequence for the 51 amino acids in bovine insulin, an accomplishment that earned him the Nobel Prize in chemistry in 1958. Now, automated procedures enable scientists to rapidly determine amino acid sequences in much longer protein molecules.

Enzymes constitute a very important class of globular proteins. They catalyze particular reactions in the cell, such as the synthesis and breakdown of proteins, the transport of substances across cell walls, and the recognition and resistance of foreign bodies. Enzymes act by lowering the activation barrier for a reaction, and they must be selective so as to act only on a restricted group of substrates.

Let's examine the enzyme carboxypeptidase A, whose structure has been determined by X-ray diffraction. It removes amino acids one at a time from the carboxylic acid end of a polypeptide. Figure 23.22 shows the structure of the active site (with a peptide chain in place, ready to be cleaved). A special feature of this enzyme

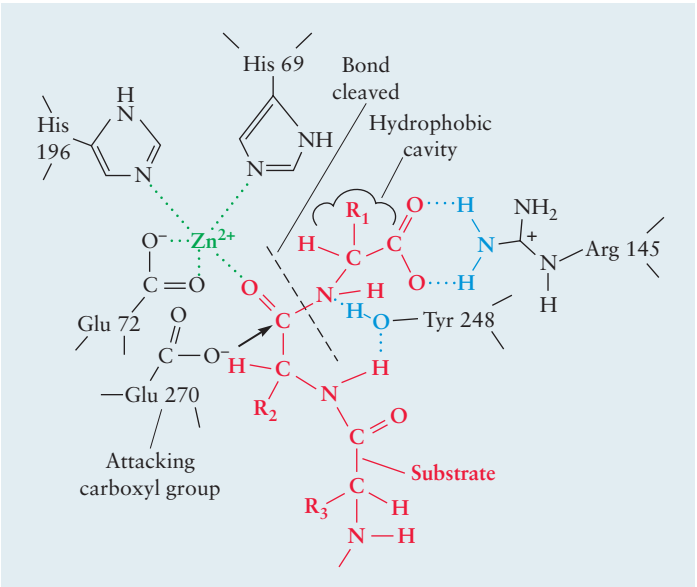

FIGURE 23.22 The active site of carboxypeptidase A. Shown in red is a substrate polypeptide that is being cleaved by the enzyme. Green is used to show the role of Zn^{2+} as a complexing ion, and blue is used to show the hydrogen bonds that maintain the geometry.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is the role played by the zinc ion, which is coordinated to two histidine residues in the enzyme and to a carboxylate group on a nearby glutamic acid residue. The zinc ion helps remove electrons from the carbonyl group of the peptide linkage, making it more positive and thereby more susceptible to attack by water or by the carboxylate group of a second glutamic acid residue. The side chain on the outer amino acid of the peptide being cleaved is positioned in a hydrophobic cavity, which favors large aromatic or branched side chains (such as that in tyrosine) over smaller hydrophilic side chains (such as that in aspartic acid). Carboxypeptidase A is thus selective about the sites at which it cleaves peptide chains.

The molecular "engineering" that lies behind nature's design of carboxypeptidase A and other enzymes is truly remarkable. The amino acid residues that form the active site and determine its catalytic properties are *not* adjacent to one another in the protein chain. As indicated by the numbers after the residues in Figure 23.22, the two glutamic acid residues are the 72nd and 270th amino acids along the chain. The enzyme adopts a conformation in which the key residues, distant from one another in terms of chain position, are nonetheless quite close in three-dimensional space, allowing the enzyme to carry out its specialized function.

Nucleotides and Nucleic Acids

We have seen that proteins are copolymers made up typically of 20 types of monomer units. Simply mixing the amino acids and letting them dehydrate to form polymer chains at random would never lead to the particular structures needed by living cells. How does the cell preserve information about the amino acid sequences that make up its proteins, and how does it transmit this information to daughter cells through the reproductive process? These questions lie in the field of molecular genetics, an area in which chemistry plays the central role.

The primary genetic material is deoxyribonucleic acid (DNA). This biopolymer is made up of four types of monomer units called **nucleotides**. Each nucleotide is composed of three parts:

1. One molecule of a pyrimidine or purine base. The four bases are thymine, cytosine, adenine, and guanine (Fig. 23.23a).
2. One molecule of the sugar D-deoxyribose ($C_5H_{10}O_4$). D-Ribose is a pentose sugar with a five-membered ring.
3. One molecule of phosphoric acid (H_3PO_4).

The cyclic sugar molecule links the base to the phosphate group, undergoing two condensation reactions, with loss of water, to form the nucleotide (see Fig. 23.23b). The first key to discovering the structure of DNA was the following observation: Although the proportions of the four bases in DNA from different organisms are quite variable, the chemical amount of cytosine (C) is always approximately equal to that of guanine (G) and the chemical amount of adenine (A) is always approximately equal to that of thymine (T). This suggested some type of base pairing in DNA that could lead to association of C with G and of A with T. The second crucial observation was an X-ray diffraction study by Rosalind Franklin and Maurice Wilkins that suggested the presence of helical structures of more than one chain in DNA.

James Watson and Francis Crick put together these two pieces of information in their famous 1953 proposal of a double-helix structure for DNA. They concluded that DNA consists of two interacting helical strands of nucleic acid polymer (Fig. 23.24), with each cytosine on one strand linked through hydrogen bonds to a guanine on the other and each adenine to a thymine. This accounted for the observed molar ratios of the bases, and it also provided a model for the replication of the molecule, which is crucial for passing on information during the reproductive process. One DNA strand serves as a template upon which a second DNA

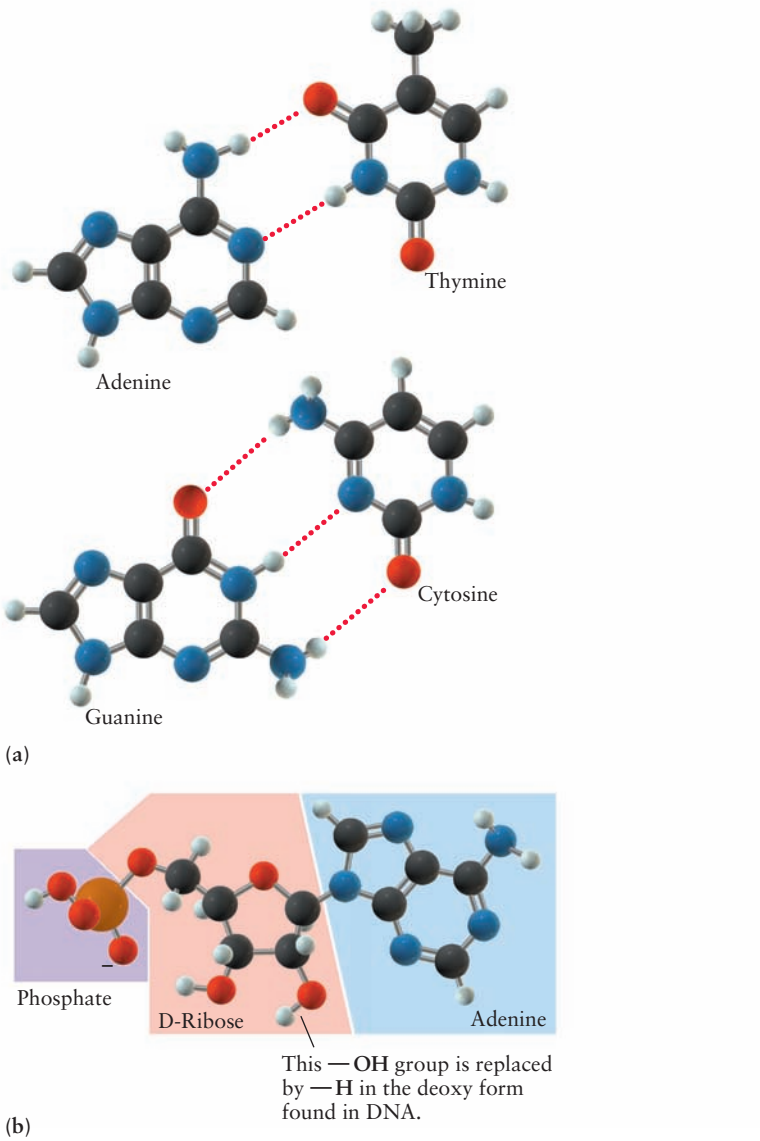

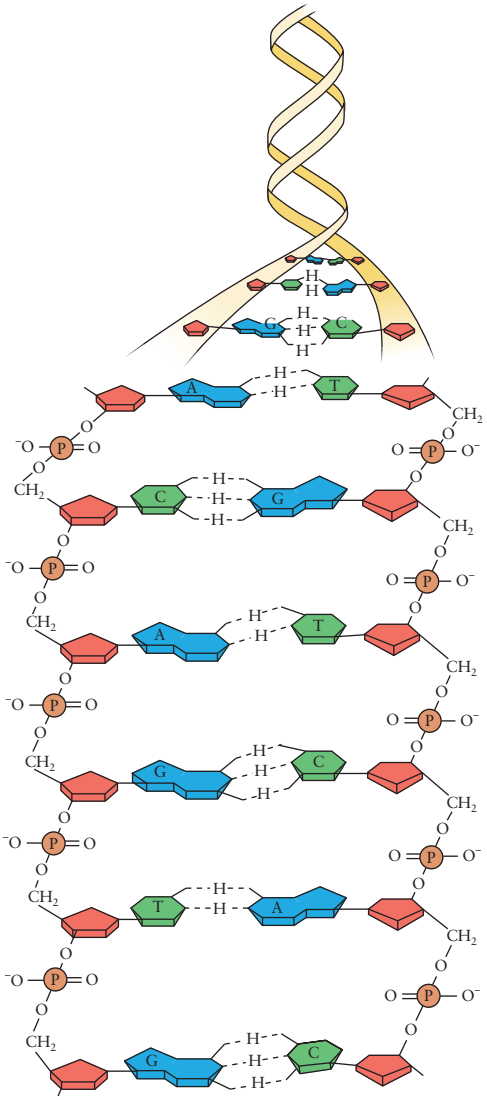

FIGURE 23.23 (a) The structures of the purine and pyrimidine bases. Hydrogen-bonding between pairs of bases is indicated by red dots. (b) The structure of the nucleotide adenosine monophosphate (AMP).

strand is synthesized. A DNA molecule reproduces by starting to unwind at one end. As it does so, new nucleotides are guided into position opposite the proper bases on each of the two strands. If the nucleotide does not fit the template, it cannot link to the polymeric strand under construction. The result of the polymer synthesis is two double-helix molecules, each containing one strand from the original and one new strand that is identical to the original in every respect.

Information is encoded in DNA in the sequence of the base pairs. Subsequent research has broken this genetic code and established the connection between the base sequence in a segment of DNA and the amino acid sequence of the protein synthesized according to the directions in that segment. The code in a nucleic acid is read as consecutive, nonoverlapping triplets of bases, with each triplet standing for a particular amino acid. Thus, a nucleic acid strand consisting of pure cytosine gives a polypeptide of pure proline, meaning that the triplet CCC codes for proline. The nucleic acid strand AGAGAGAG . . . is read as the alternating triplets AGA and GAG and gives a polypeptide consisting of alternating arginine (coded by AGA) and glutamic acid (coded by GAG) monomer units. There are 64 (4^3) possible triplets, so typically more than one code exists for a particular amino acid. Some triplets serve as signals to terminate a polypeptide chain. Remarkably, the

B-DNA

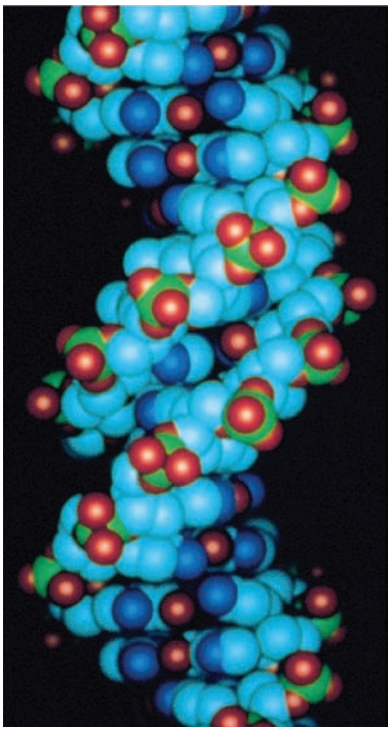

FIGURE 23.24 The double-helix structure of DNA.

genetic code appears to be universal, independent of the species of plant or animal, a finding that suggests a common origin for all terrestrial life.

A single change in a base pair in DNA causes a change in one amino acid of the protein that is coded for by that DNA. Such a change may seem small, but it may have dramatic (even fatal) effects for the organism in question. For example, the triplets GAA and GAG both code for glutamic acid (an acidic residue), whereas the triplets GTA and GTG code for valine (a nonpolar residue). A single change in the central A to T in the DNA thus changes an amino acid in a protein produced by the organism. This might seem like a small effect, but it can change the structure and mode of action of the protein. This particular change is responsible for the presence of hemoglobin S (instead of hemoglobin A) in the blood of people who have sickle cell anemia. In two of the four hemoglobin S chains a glutamic acid amino acid is changed to a valine, and the result is a decrease in the solubility of S relative to A by a factor of 25. This leads to polymerization of the hemoglobin to form insoluble structures that bend red blood cells into sickle shapes, a change that can lead to early death. One of the challenges of modern genetic engineering is to use chemistry to modify coding molecules in living species to eliminate fatal or disease-causing mutants.

CHAPTER SUMMARY

Mankind has long used naturally occurring polymers, obtained from plants and animals, as useful materials. These are familiar in cotton, wool, and silk fabrics, and in structural applications of wood and rubber. Inspired by these natural products, chemists have invented synthetic routes to these and similar materials, often with modified or improved properties. Curiosity about life processes in living systems has inspired research on natural polymers, such as polysaccharides, proteins, enzymes, and DNA, to discern the relation between their structure and function. The structures of these solid synthetic and natural polymeric materials range from purely amorphous to highly crystalline. The route to controlling their molecular and crystalline structures lies through understanding their local bonding.

CONCEPTS AND SKILLS

OWL
Interactive versions of these problems are assignable in OWL.

Section 23.1 – Polymerization Reactions for Synthetic Polymers

Contrast the methods of addition and condensation polymerization (Problems 1–6).

- Polymer formation requires that many monomers must be attached to a growing polymer molecule. This requires that highly reactive functional groups must be available at each growth step. This is achieved by two main mechanisms.
  - Addition polymerization requires monomers to join the polymer without net loss of atoms. This usually involves free radical reaction of molecules that have C=C double bonds, and proceeds through three steps: initiation, propagation, and termination.
  - Condensation polymerization requires that a small molecule such as water is split off as each monomer is added to the polymer.
- Both addition and condensation polymerization can occur with mixtures of monomers to produce a random copolymer of the two monomers.
- If monomers have three or more reactive sites, cross-linking reactions to form sheets or networks is possible. Cross-linking is often brought about deliberately to obtain stronger materials.

Section 23.2 – Applications for Synthetic Polymers

Give several examples of fibers, plastics, and rubbers and describe how they are made and used (Problems 7–10).

- Synthetic polymers are selected for four major classes of applications based on their physical properties.
  - Fibers for use in fabrics are spun into threads in which their molecules are aligned. They must resist stretching, and usually break after only 10% elongation. The first purely synthetic fiber was nylon, developed by condensation polymerization.
  - Plastics are molded or extruded into desired shapes that harden upon cooling or solvent evaporation. They typically elongate 20% to 100% before breaking. Many of these are formed by addition polymerization of ethylene or its derivatives. Examples include polyethylene, polystyrene, and Teflon. By using proper catalysts and manipulating the size of side group substituents, it is possible to overcome the tendency of addition polymerization to form highly branched chains. These tools make it possible to control the degree of crystallinity in polymer materials.
  - Rubbers, or elastomers, stretch readily to elongate by a factor of 10 before breaking. Natural rubber, obtained from the sap of certain trees, can be hardened and toughened by addition of sulfur in the vulcanization process.

Synthetic rubber is produced by addition copolymerization of butadiene and styrene.

- Electrically conducting polymers combine the optical and electronic properties of inorganic semiconductors with the processing ease of conventional polymers. Their structures are continuations of the 1,3-butadiene structure to greater lengths, and the electronic structure for the individual molecule is described by bands. These polymers are made electrically conducting by doping.

Section 23.3 – Liquid Crystals

Explain what a liquid crystal is, and state how nematic and smectic phases differ from ordinary liquids and crystalline solids (Problems 11–12).

- Liquid crystals have properties intermediate between those of true liquids and crystals. Unlike glasses, they are thermodynamically stable.
- Based on microscopic structural details, liquid crystals form three separate ordered phases: nematic, smectic, and cholesteric.
- Orientation of liquid crystals depends sensitively on small electric and magnetic fields. This is the basis of liquid crystal displays for digital information.

Describe the formation of ordered structures such as micelles and membranes in surfactant solutions (Problems 13–14).

- Amphiphiles are molecules with a water soluble ionic structure on one end (hydrophilic) and a long hydrocarbon tail on the other end (hydrophobic). When amphiphiles are dissolved in water above a critical concentration, they form ordered clusters called micelles in which the organic tails of the molecules are enclosed in a shell of hydrophilic structures that shield the organic phase from interaction with the water. This structure is stable because it eliminates the repulsive interaction between the organic tails and water. Amphiphiles can form reverse micelles in organic solvents by shielding the hydrophilic structures in a shell of hydrocarbon tails that are dissolved in the organic solvent. At still higher concentrations, amphiphiles can be organized into two-dimensional sheets rather than spherical clusters. The hydrophobic sides of two sheets interact to form a stable bilayer membrane in which the two facing hydrophobic sheets are sandwiched between two hydrophilic layers.

Section 23.4 – Natural Polymers

Describe the formation of polysaccharides from sugars, proteins from amino acids, and DNA from nucleotides, and the roles of these biopolymers in living cells (Problems 15–22).

- Naturally occurring polymers are synthesized by plants and animals to support a variety of life processes.
- Polysaccharides are grown by linkage of simple sugar units (carbohydrates). One example is starch, which is readily metabolized by humans and animals. Another is cellulose, which forms the structural fibers of plants and trees and appears in linen and cotton fabrics and in paper.
- The biological polymers called proteins are built up from the amino acid units, ranging in number from 50 to several thousand per polymer. Since 20 amino acids are available, a very large number of sequences can be realized. Fibrous proteins consist of polymers linked in sheets or twisted in long fibers; they are structural materials. Globular proteins include hemoglobin and enzymes; they generally control chemical reactions in living systems.
- The primary genetic material DNA is a biopolymer made up of four types of monomer units called nucleotides. DNA serves as a template during reproduction to enable a cell to preserve information about the amino acid sequences that make up its proteins, and transfer this information to daughter cells through the genetic code.

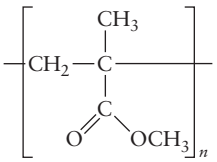
PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G. Problems that are more challenging are indicated with asterisks.



Polymerization Reactions for Synthetic Polymers

1. Write a balanced chemical equation to represent the addition polymerization of 1,1-dichloroethylene. The product of this reaction is Saran, used as a plastic wrap.

2. Write a balanced chemical equation to represent the addition polymerization of tetrafluoroethylene. The product of this reaction is Teflon.

3. A polymer produced by addition polymerization consists of $(-CH_2-O-)$ groups joined in a long chain. What was the starting monomer?

4. The polymer polymethyl methacrylate is used to make Plexiglas. It has the formula

Draw the structural formula of the starting monomer.

5. The monomer glycine (NH_2-CH_2-COOH) can undergo condensation polymerization to form polyglycine, in which the structural units are joined by amide linkages.

(a) What molecule is split off in the formation of polyglycine?

(b) Draw the structure of the repeat unit in polyglycine.

6. The polymer forms $-(NH-CH(CH_3)-C)_n-$ (with O double-bonded to the carbonyl C) upon condensation polymerization with loss of water. Draw the structure of the starting monomer.

Applications for Synthetic Polymers

7. Determine the mass of adipic acid and the mass of hexamethylenediamine needed to make 1.00×10^3 kg of nylon 66 fiber.

8. Determine the mass of terephthalic acid and the mass of ethylene glycol needed to make 10.0 kg of polyester fiber.

9. In a recent year, 4.37 billion kilograms of low-density polyethylene was produced in the United States. What volume of gaseous ethylene at 0°C and 1.00 atm would give this amount?

10. In a recent year, 2.84 billion kilograms of polystyrene was produced in the United States. Polystyrene is the addition polymer formed from the styrene monomer, $C_6H_5CH=CH_2$. How many styrene monomer units were incorporated in that 2.84 billion kilograms of polymer?

Liquid Crystals

11. Compare the natures and extents of order in the smectic liquid-crystal and isotropic liquid phases of a substance. Which has the higher entropy? Which has the higher enthalpy?

12. Nematic liquid crystals form when a liquid of long rod-like molecules is cooled. What *additional* types of intermolecular interactions would you expect to favor the formation of a *smectic* phase?

13. Consider a ternary (three-component) system of amphiphile, hydrocarbon, and water. What structure do you expect to form if small amounts of the first two components are mixed with a large amount of water?

14. In addition to spherical micelles and lamellar phases, a binary amphiphile-water mixture can also form extended cylindrical rolls, with the hydrophilic groups pointing out and the hydrophobic chains on the interior. Over what composition range are such cylinders most likely to be found, relative to spherical micelles and planar layers?

Natural Polymers

15. By referring to Figure 23.16a, draw the structure of the ring form of β-D-galactose. How many asymmetric carbon atoms (chiral centers) are there in the molecule?

16. By referring to Figure 23.23b, draw the structure of the ring form of D-ribose. How many asymmetric carbon atoms (chiral centers) are there in the molecule?

17. How many tripeptides can be synthesized using just three different species of α-amino acids?

18. How many different polypeptides, each containing ten amino acids, can be made from the amino acids listed in Table 23.3? How many different polypeptides, each containing 100 amino acids, can be made?

19. Draw the structure of the pentapeptide alanine—leucine—phenylalanine—glycine—isoleucine. Assume that the free $-NH_2$ group is at the alanine end of the peptide chain. Would this compound be more likely to dissolve in water or in octane? Explain.

20. Draw the structure of the pentapeptide aspartic acid—serine—lysine—glutamic acid—tyrosine. Assume that the free $-NH_2$ group is at the aspartic acid end of the peptide chain. Would this compound be more likely to dissolve in water or in octane? Explain.

21. Suppose a long-chain polypeptide is constructed entirely from phenylalanine monomer units. What is its empirical formula? How many amino acids does it contain if its molar mass is 17,500 g mol^{-1}?

22. A typical bacterial DNA has a molar mass of 4×10^9 g mol^{-1}. Approximately how many nucleotides does it contain?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ADDITIONAL PROBLEMS

23. In the addition polymerization of acrylonitrile, a very small amount of butyl lithium causes a reaction that can consume hundreds of pounds of the monomer; however, the butyl lithium is called an initiator, not a catalyst. Explain why.

24. Based on the facts that the free-radical polymerization of ethylene is spontaneous and that polymer molecules are less disorganized than the starting monomers, decide whether the polymerization reaction is exothermic or endothermic. Explain.

25. According to a trade journal, approximately 950 million lb of ethylene dichloride was exported from the United States in a recent year. The article states that "between 500 million and 550 million pounds of PVC could have been made from that ethylene dichloride." Compute the range of percentage yields of PVC from ethylene dichloride that is implied by these figures.

26. The complete hydrogenation of natural rubber (the addition of H_2 to all double bonds) gives a product that is indistinguishable from the product of the complete hydrogenation of gutta-percha. Explain how this strengthens the conclusion that these two substances are isomers of each other.

27. A reducing solution breaks S—S bonds in proteins, whereas an oxidizing solution allows them to re-form. Discuss how such solutions might be used to carry out the curling of hair.

28. L-Sucrose tastes sweet, but it is not metabolized. It has been suggested as a potential nonnutritive sweetener. Draw the molecular structure of L-sucrose, using Figure 23.16b as a starting point.

29. Polypeptides are synthesized from a 50:50 mixture of L-alanine and D-alanine. How many different isomeric molecules containing 22 monomer units are possible?

30. An osmotic pressure measurement taken on a solution containing hemoglobin shows that the molar mass of that protein is approximately 65,000 g mol^{-1}. A chemical analysis shows it to contain 0.344% of iron by mass. How many iron atoms does each hemoglobin molecule contain?

* 31. At very low pH, alanine is a diprotic acid that can be represented as $H_3N^+—CH(CH_3)—COOH$. The pK_a of the carboxyl group is 2.3, and the pK_a of the $—NH_3^+$ group is 9.7.
   (a) At pH 7, what fraction of the amino acid molecules dissolved in an aqueous solution will have the form $H_3N^+—CH(CH_3)—COO^-$?
   (b) What fraction of the molecules at this pH will have the form $H_2N—CH(CH_3)—COOH$?

32. The sequence of bases in one strand of DNA reads ACTTGACCG. Write the sequence of bases in the complementary strand.

33. Nucleic acids are diesters of phosphoric acid. Esters are not usually acidic. Why are nucleic acids acidic, or is this name inappropriate?

34. The codons in the genetic code are sequences of three bases. Explain why sequences of only two bases could not be used to code for the 20 different amino acids commonly found in proteins.

35. The average distance between base pairs measured parallel to the axis of a double-helical DNA molecule is 3.4 angstroms. The average molecular weight of a pair of nucleotides is about 650 g mol^{-1}. What is the approximate length in millimeters of a single DNA molecule of molecular weight 2.8×10^9 g mol^{-1} (a value typical for the DNA of some bacteria)? About how many base pairs does this DNA contain?

APPENDIX A

SCIENTIFIC NOTATION AND EXPERIMENTAL ERROR

A.1 SCIENTIFIC NOTATION

Very large and very small numbers are common in chemistry. Repeatedly writing such numbers in the ordinary way (for example, the important number 602,214,200,000,000,000,000,000) would be tedious and would engender errors. **Scientific notation** offers a better way. A number in scientific notation is expressed as a number from 1 to 10 multiplied by 10 raised to some power. Any number can be represented in this way, as the following examples show.

$$643.8 = 6.438 \times 10^{2}$$
$$-19,000,000 = -1.9 \times 10^{7}$$
$$0.0236 = 2.36 \times 10^{-2}$$
$$602,214,200,000,000,000,000,000 = 6.022142 \times 10^{23}$$

A simple rule of thumb is that the power to which 10 is raised is n if the decimal point is moved n places to the left and is $-n$ if the decimal is moved n places to the right.

When two or more numbers written in scientific notation are to be added or subtracted, they should first be expressed as multiples of the *same* power of 10:

$$\begin{array}{rl} 6.431 \times 10^{4} & \longrightarrow \quad 6.431 \times 10^{4} \\ +2.1 \times 10^{2} & \longrightarrow \quad +0.021 \times 10^{4} \\ \underline{+3.67 \times 10^{3}} & \longrightarrow \quad \underline{+0.367 \times 10^{4}} \\ ? & \qquad\quad 6.819 \times 10^{4} \end{array}$$

When two numbers in scientific notation are multiplied, the coefficients are multiplied and then the powers of 10 are multiplied (by adding the exponents):

$$\begin{aligned} 1.38 \times 10^{-16} \times 8.80 \times 10^{3} &= \left(1.38 \times 8.80\right) \times 10^{(-16+3)} \\ &= 12.1 \times 10^{-13} = 1.21 \times 10^{-12} \end{aligned}$$

We divide one number by a second by dividing the coefficients and then multiplying by 10 raised to the first exponent minus the second (exponents are subtracted):

$$\begin{aligned} \frac{6.63 \times 10^{-27}}{2.34 \times 10^{-16}} &= \frac{6.63}{2.34} \times \frac{10^{-27}}{10^{-16}} \\ &= 2.83 \times 10^{[-27-(-16)]} = 2.83 \times 10^{-11} \end{aligned}$$

Any calculator or computer equipped to perform scientific and engineering calculations can accept and display numbers in scientific notation. It cannot determine whether the input has an error, however, or whether the answer makes sense. That is your responsibility! Develop the habit of mentally estimating the order of magnitude of the answer as a rough check on your calculator's result.

A.2 EXPERIMENTAL ERROR

Chemistry is an experimental science in which every quantitative measurement is subject to some degree of error. We can seek to reduce error by carrying out additional measurements or by changing our experimental apparatus, but we can never eliminate error altogether. It is important, therefore, to be able to assess the results of an experiment quantitatively to establish the limits of the experiment's validity. Errors are of two types: random (lack of precision) and systematic (lack of accuracy).

Precision and Random Errors

Precision refers to the degree of agreement in a collection of experimental results and is estimated by repeating the measurement under conditions as nearly identical as possible. If the conditions are truly identical, then differences among the trials are due to random error. As a specific example, consider some actual results of an early, important experiment by American physicist Robert Millikan in 1909, to measure the charge e on the electron. The experiment (discussed in greater detail in Chapter 1) involved a study of the motion of charged oil drops suspended in air in an electric field. Millikan made hundreds of measurements on many different oil drops, but we shall consider only a set of results for e found for one particular drop (Table A.1). The values he found ranged from 4.894 to 4.941 $\times 10^{-10}$ esu. What do we choose to report as the best estimate for e? The proper procedure is to first examine the data to see whether any of the results are especially far from the rest (a value above 5×10^{-10} esu would fall into this category). Such values are likely to result from some mistake in carrying out or reporting that particular measurement and therefore are excluded from further consideration (although there have been cases in science where just such exceptional results have led to significant breakthroughs). In Millikan's data, no such points should be excluded. To obtain our best estimate for e, we calculate the **mean,** or **average value,** by adding up the values found and dividing by the number of measurements. We can write the average value of any property after a series of N measurements $x_1, x_2, \ldots, x_N$ as

$$\bar{x} = \frac{1}{N}(x_1 + x_2 + \cdots + x_N) = \frac{1}{N}\sum_{i=1}^{N} x_i$$

where a capital Greek sigma (Σ) is introduced to indicate a summation of x_i over values of i from 1 to N. In the present case, this gives an average for e of 4.917 $\times$ 10^{-10} esu.

This average by itself does not convey any estimate of uncertainty. If all of the measurements had given results between 4.91 $\times 10^{-10}$ and 4.92 $\times 10^{-10}$ esu, the uncertainty would be less than if the results had ranged from 4 $\times 10^{-10}$ to 6 $\times$ 10^{-10} esu. Furthermore, an average of 100 measurements should have less uncertainty than an average of 5. How are these ideas made quantitative? A statistical

TABLE A.1

Measurement Number	1	2	3	4	5	6	7	8	9	10	11	12	13
e (10^{-10} esu)	4.915	4.920	4.937	4.923	4.931	4.936	4.941	4.902	4.927	4.900	4.904	4.897	4.894

From R. A. Millikan, *Phys. Rev.* 32:349, 1911. [1 esu = 3.3356 $\times 10^{-10}$ C]

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

measure of the spread of data, called the **standard deviation** σ, is useful in this regard. It is given by the formula

$$\sigma = \sqrt{\frac{(x_1 - \bar{x})^2 + (x_2 - \bar{x})^2 + \cdots + (x_N - \bar{x})^2}{N - 1}}$$

$$= \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(x_i - \bar{x})^2}$$

The standard deviation is found by adding up the squares of the deviations of the individual data points from the average value $\bar{x}$, dividing by $N - 1$, and taking the square root. Table A.2 shows how σ is used quantitatively. A **confidence limit** is defined as

$$\text{confidence limit} = \pm\frac{t\sigma}{\sqrt{N}}$$

The table gives the factor t for various numbers of measurements, N, and for various levels of confidence.

For Millikan's data, $N = 13$ and $\sigma = 0.017 \times 10^{-10}$. For 95% confidence with 13 measurements, the table shows $t = 2.18$ and the confidence limit is

$$\text{confidence limit} = \pm\frac{(2.18)(0.017 \times 10^{-10})}{\sqrt{13}} = \pm 0.010 \times 10^{-10} \text{ esu}$$

Thus, a 95% probability exists that the *true* average (obtained by repeating the experiment under the same conditions an infinite number of times) will lie within $\pm 0.010 \times 10^{-10}$ esu of the average 4.917×10^{-10} esu. Within this 95% confidence level, our best estimate for e is written as

$$(4.917 \pm 0.010) \times 10^{-10} \text{ esu}$$

For other confidence levels and other numbers of measurements, the factor t and therefore the confidence limit change.

TABLE A.2

N	Factor t for Confidence Interval of			
(Number of Observations)	80%	90%	95%	99%
2	3.08	6.31	12.7	63.7
3	1.89	2.92	4.30	9.92
4	1.64	2.35	3.18	5.84
5	1.53	2.13	2.78	4.60
6	1.48	2.02	2.57	4.03
7	1.44	1.94	2.45	3.71
8	1.42	1.90	2.36	3.50
9	1.40	1.86	2.31	3.36
10	1.38	1.83	2.26	3.25
11	1.37	1.81	2.23	3.17
12	1.36	1.80	2.20	3.11
13	1.36	1.78	2.18	3.06
14	1.35	1.77	2.16	3.01
15	1.34	1.76	2.14	2.98
∞	1.29	1.64	1.96	2.58

Accuracy and Systematic Errors

The charge e on the electron has been measured by several different techniques since Millikan's day. The current best estimate for e is

$$e = (4.80320775 \pm 0.0000015) \times 10^{-10} \text{ esu}$$
$$= (1.60217646 \pm 0.00000049) \times 10^{-19} \text{ C}$$

This value lies outside the range of uncertainty we estimated from Millikan's original data. In fact, it lies well below the smallest of the 13 measurements of e. Why?

To understand this discrepancy, we need to remember that there is a second source of error in any experiment: *systematic* error that causes a shift in the measured values from the true value and reduces the **accuracy** of the result. By making more measurements, we can reduce the uncertainty due to *random* errors and improve the *precision* of our result; however, if systematic errors are present, the average value will continue to deviate from the true value. Such systematic errors may result from a miscalibration of the experimental apparatus or from a fundamental inadequacy in the technique for measuring a property. In the case of Millikan's experiment, the then-accepted value for the viscosity of air (used in calculating the charge e) was subsequently found to be wrong. This caused his results to be systematically too high.

Error thus arises from two sources. Lack of precision (random errors) can be estimated by a statistical analysis of a series of measurements. Lack of accuracy (systematic errors) is much more problematic. If a systematic error is known to be present, we should do our best to correct for it before reporting the result. (For example, if our apparatus has not been calibrated correctly, it should be recalibrated.) The problem is that systematic errors of which we have no knowledge may be present. In this case the experiment should be repeated with different apparatus to eliminate the systematic error caused by a particular piece of equipment; better still, a different and independent way to measure the property might be devised. Only after enough independent experimental data are available can we be convinced of the accuracy of a result—that is, how closely it approximates the true result.

A.3 SIGNIFICANT FIGURES

The number of **significant figures** is the number of digits used to express a measured or calculated quantity, excluding zeros that may precede the first nonzero digit. Suppose the mass of a sample of sodium chloride is measured to be 8.241 g and the uncertainty is estimated to be ± 0.001 g. The mass is said to be given to four significant figures because we are confident of the first three digits (8, 2, 4) and the uncertainty appears in the fourth (1), which nevertheless is still significant. Writing additional digits beyond the 1 would not be justified, however, unless the accuracy of the weighing could be improved. When we record a volume as 22.4 L, we imply that the uncertainty in the measurement is in the last digit written ($V = 22.4 \pm 0.3$ L, for example). A volume written as 22.43 L, on the other hand, implies that the uncertainty is far less and appears only in the fourth significant figure.

In the same way, writing 20.000 m is quite different from writing 20.0 m. The second measurement (with three significant figures) could easily be made with a common meterstick. The first (with five significant figures) would require a more precise method. We should avoid reporting results such as "700 m," however, because the two trailing zeros may or may not be significant. The uncertainty in the measurement could be of order ± 1 m or ± 10 m or perhaps ± 100 m; it is impossible to tell which without further information. To avoid this ambiguity, we can

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

write such measurements using the scientific notation described in Section A.1. The measurement "700 m" translates into any of the following:

7.00×10^2 m	Three significant figures
7.0×10^2 m	Two significant figures
7×10^2 m	One significant figure

Frequently, it is necessary to combine several different experimental measurements to obtain a final result. Some operations involve addition or subtraction, and others entail multiplication or division. These operations affect the number of significant figures that should be retained in the calculated result. Suppose, for example, that a weighed sample of 8.241 g of sodium chloride is dissolved in 160.1 g of water. What will be the mass of the solution that results? It is tempting to simply write 160.1 + 8.241 = 168.341 g, but this is *not* correct. In saying that the mass of water is 160.1 g, we imply that there is some uncertainty about the number of tenths of a gram measured. This uncertainty must also apply to the sum of the masses, so the last two digits in the sum are not significant and should be **rounded off,** leaving 168.3 as the final result.

Following addition or subtraction, round off the result to the leftmost decimal place that contained an uncertain digit in the original numbers.

Rounding off is a straightforward operation. It consists of first discarding the digits that are not significant and then adjusting the last remaining digit. If the first discarded digit is less than 5, the remaining digits are left as they are (for example, 168.341 is rounded down to 168.3 because the first discarded digit, 4, is less than 5). If the first discarded digit is greater than 5, or if it is equal to 5 and is followed by one or more nonzero digits, then the last digit is increased by 1 (for example, 168.364 and 168.3503 both become 168.4 when rounded off to four digits). Finally, if the first digit discarded is 5 and all subsequent digits are zeros, the last digit remaining is rounded to the nearest even digit (for example, both 168.35 and 168.45 would be rounded to 168.4). This last rule is chosen so that, on the average, as many numbers are rounded up as down. Other conventions are sometimes used.

In multiplication or division it is not the number of decimal places that matters (as in addition or subtraction) but the number of significant figures in the least precisely known quantity. Suppose, for example, the measured volume of a sample is 4.34 cm^3 and its mass is 8.241 g. The density, found by dividing the mass by the volume on a calculator, for example, is

$$\frac{8.241\ \text{g}}{4.34\ \text{cm}^3} = 1.89884\ldots\ \text{g cm}^{-3}$$

How many significant figures should we report? Because the volume is the less precisely known quantity (three significant figures as opposed to four for the mass), it controls the precision that may properly be reported in the answer. Only three significant figures are justified, so the result is rounded to 1.90 g cm^{-3}.

The number of significant figures in the result of a multiplication or division is the smallest of the numbers of significant figures used as input.

It is best to carry out the arithmetical operations and *then* round the final answer to the correct number of significant figures, rather than round off the input data first. The difference is usually small, but this recommendation is nevertheless worth following. For example, the correct way to add the three distances 15 m, 6.6 m, and 12.6 m is

$$\begin{array}{r} 15\ \text{m} \\ +\ 6.6\ \text{m} \\ +12.6\ \text{m} \\ \hline 34.2\ \text{m} \longrightarrow 34\ \text{m} \end{array}$$

rather than

$$\begin{array}{r} 15\ \text{m} \longrightarrow 15\ \text{m} \\ 6.6\ \text{m} \longrightarrow\ 7\ \text{m} \\ 12.6\ \text{m} \longrightarrow 13\ \text{m} \\ \hline 35\ \text{m} \end{array}$$

For the same reason, we frequently carry extra digits through the intermediate steps of a worked example and round off only for the final answer. If a calculation is done entirely on a scientific calculator or a computer, several extra digits are usually carried along automatically. Before the final answer is reported, however, it is important to round off to the proper number of significant figures.

Sometimes pure constants appear in expressions. In this case the accuracy of the result is determined by the accuracy of the other factors. The uncertainty in the volume of a sphere, $\frac{4}{3}\pi r^3$, depends only on the uncertainty in the radius r; 4 and 3 are pure constants (4.000 . . . and 3.000 . . . , respectively), and π can be given to as many significant figures (3.14159265 . . .) as are warranted by the radius.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G.

Scientific Notation

1. Express the following in scientific notation.
(a) 0.0000582
(b) 402
(c) 7.93
(d) −6593.00
(e) 0.002530
(f) 1.47

2. Express the following in scientific notation.
(a) 4579
(b) −0.05020
(c) 2134.560
(d) 3.825
(e) 0.0000450
(f) 9.814

3. Convert the following from scientific notation to decimal form.
(a) 5.37×10^{-4}
(b) 9.390×10^{6}
(c) -2.47×10^{-3}
(d) 6.020×10^{-3}
(e) 2×10^{4}

4. Convert the following from scientific notation to decimal form.
(a) 3.333×10^{-3}
(b) -1.20×10^{7}
(c) 2.79×10^{-5}
(d) 3×10^{1}
(e) 6.700×10^{-2}

5. A certain chemical plant produces 7.46×10^{8} kg of polyethylene in one year. Express this amount in decimal form.

6. A microorganism contains 0.0000046 g of vanadium. Express this amount in scientific notation.

Experimental Error

7. A group of students took turns using a laboratory balance to weigh the water contained in a beaker. The results they reported were 111.42 g, 111.67 g, 111.21 g, 135.64 g, 111.02 g, 111.29 g, and 111.42 g.
(a) Should any of the data be excluded before the average is calculated?
(b) From the remaining measurements, calculate the average value of the mass of the water in the beaker.
(c) Calculate the standard deviation σ and, from it, the 95% confidence limit.

8. By measuring the sides of a small box, a group of students made the following estimates for its volume: 544 cm^3, 590 cm^3, 523 cm^3, 560 cm^3, 519 cm^3, 570 cm^3, and 578 cm^3.
(a) Should any of the data be excluded before the average is calculated?
(b) Calculate the average value of the volume of the box from the remaining measurements.
(c) Calculate the standard deviation σ and, from it, the 90% confidence limit.

9. Of the measurements in problems 7 and 8, which is more precise?

10. A more accurate determination of the mass in problem 7 (using a better balance) gives the value 104.67 g, and an accurate determination of the volume in problem 8 gives the value 553 cm^3. Which of the two measurements in problems 7 and 8 is more accurate, in the sense of having the smaller systematic error relative to the actual value?

Significant Figures

11. State the number of significant figures in each of the following measurements.
(a) 13.604 L
(b) −0.00345°C
(c) 340 lb
(d) 3.40×10^{2} miles
(e) 6.248×10^{-27} J

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

12. State the number of significant figures in each of the following measurements.
    (a) -0.0025 in
    (b) 7000 g
    (c) 143.7902 s
    (d) 2.670×10^{7} Pa
    (e) 2.05×10^{-19} J

13. Round off each of the measurements in problem 11 to two significant figures.

14. Round off each of the measurements in problem 12 to two significant figures.

15. Round off the measured number 2,997,215.548 to nine significant digits.

16. Round off the measured number in problem 15 to eight, seven, six, five, four, three, two, and one significant digits.

17. Express the results of the following additions and subtractions to the proper number of significant figures. All of the numbers are measured quantities.
    (a) $67.314 + 8.63 - 243.198 =$
    (b) $4.31 + 64 + 7.19 =$
    (c) $3.1256 \times 10^{15} - 4.631 \times 10^{13} =$
    (d) $2.41 \times 10^{-26} - 7.83 \times 10^{-25} =$

18. Express the results of the following additions and subtractions to the proper number of significant figures. All of the numbers are measured quantities.
    (a) $245.876 + 4.65 + 0.3678 =$
    (b) $798.36 - 1005.7 + 129.652 =$
    (c) $7.98 \times 10^{17} + 6.472 \times 10^{19} =$
    (d) $(4.32 \times 10^{-15}) + (6.257 \times 10^{-14}) - (2.136 \times 10^{-13}) =$

19. Express the results of the following multiplications and divisions to the proper number of significant figures. All of the numbers are measured quantities.
    (a) $\dfrac{-72.415}{8.62} =$
    (b) $52.814 \times 0.00279 =$
    (c) $(7.023 \times 10^{14}) \times (4.62 \times 10^{-27}) =$
    (d) $\dfrac{4.3 \times 10^{-12}}{9.632 \times 10^{-26}} =$

20. Express the results of the following multiplications and divisions to the proper number of significant figures. All of the numbers are measured quantities.
    (a) $129.587 \times 32.33 =$
    (b) $\dfrac{4.7791}{3.21 \times 5.793} =$
    (c) $\dfrac{10566.9}{3.584 \times 10^{29}} =$
    (d) $(5.247 \times 10^{13}) \times (1.3 \times 10^{-17}) =$

21. Compute the area of a triangle (according to the formula $A = \frac{1}{2}ba$) if its base and altitude are measured to equal 42.07 cm and 16.0 cm, respectively. Justify the number of significant figures in the answer.

22. An inch is defined as exactly 2.54 cm. The length of a table is measured as 505.16 cm. Compute the length of the table in inches. Justify the number of significant figures in the answer.

APPENDIX B

SI UNITS, UNIT CONVERSIONS, AND PHYSICS FOR GENERAL CHEMISTRY

This appendix reviews essential concepts of physics, as well as systems of units of measure, essential for work in general chemistry.

B.1 SI UNITS AND UNIT CONVERSIONS

Scientific work requires measurement of quantities or properties observed in the laboratory. Results are expressed not as pure numbers but rather as **dimensions** that reflect the nature of the property under study. For example, mass, time, length, area, volume, energy, and temperature are fundamentally distinct quantities, each of which is characterized by its unique dimension. The magnitude of each dimensioned quantity can be expressed in various **units** (for example, feet or centimeters for length). Several systems of units are available for use, and facility at conversion among them is essential for scientific work. Over the course of history, different countries evolved different sets of units to express length, mass, and many other physical dimensions. Gradually, these diverse sets of units are being replaced by international standards that facilitate comparison of measurements made in different localities and that help avoid complications and confusion. The unified system of units recommended by international agreement is called SI, which stands for "Système International d'Unités," or the International System of Units. In this section we outline the use of SI units and discuss interconversions with other systems of units.

The SI uses seven **base units,** which are listed in Table B.1. All other units can be written as combinations of the base units. In writing the units for a measurement, we abbreviate them (see Table B.1), and we use exponential notation to denote the power to which a unit is raised; a minus sign appears in the exponent when the unit is in the denominator. For example, velocity is a quantity with dimensions of length divided by time, so in SI it is expressed in meters per second, or m s^{-1}. Some derived units that are used frequently have special names. Energy, for example, is the prod-

TABLE B.1

Base Units in the International System of Units

Quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Temperature	kelvin	K
Number of moles (of substance)	mole	mol
Electric current	ampere	A
Luminous intensity	candela	cd

TABLE B.2

Derived Units in SI

Quantity	Unit	Symbol	Definition
Energy	joule	J	$kg\ m^2\ s^{-2}$
Force	newton	N	$kg\ m\ s^{-2} = J\ m^{-1}$
Power	watt	W	$kg\ m^2\ s^{-3} = J\ s^{-1}$
Pressure	pascal	Pa	$kg\ m^{-1}\ s^{-2} = N\ m^{-2}$
Electric charge	coulomb	C	A s
Electric potential difference	volt	V	$kg\ m^2\ s^{-3}\ A^{-1} = J\ C^{-1}$

uct of mass and the square of the velocity. Therefore, it is measured in units of kilogram square meters per square seconds ($kg\ m^2\ s^{-2}$), and 1 $kg\ m^2\ s^{-2}$ is called a *joule*. Other derived units, such as the pascal for measuring pressure, appear in Table B.2. Although these names provide a useful shorthand, it is important to remember their meanings in terms of the base units.

Because scientists work on scales ranging from the microscopic to the astronomical, there is a tremendous range in the magnitudes of measured quantities. Consequently, a set of **prefixes** has been incorporated into the International System of Units to simplify the description of small and large quantities (Table B.3). The prefixes specify various powers of 10 times the base and derived units. Some of them are quite familiar in everyday use: the kilometer, for example, is 10^3 m. Others may sound less familiar—for instance, the femtosecond (1 fs = 10^{-15} s) or the gigapascal (1 GPa = 10^9 Pa).

In addition to base and derived SI units, several units that are not officially sanctioned are used in this book. The first is the liter (abbreviated L), a very convenient size for volume measurements in chemistry; a liter is 10^{-3} m^3, or 1 cubic decimeter (dm^3):

$$1\ L = 1\ dm^3 = 10^{-3}\ m^3 = 10^3\ cm^3$$

Second, we use the *angstrom* (abbreviated Å) as a unit of length for atoms and molecules:

$$1\ Å = 10^{-10}\ m = 100\ pm = 0.1\ nm$$

This unit is used simply because most atomic sizes and chemical bond lengths fall in the range of one to several angstroms, and the use of either picometers or nanometers is slightly awkward. Next, we use the *atmosphere* (abbreviated atm) as a unit of pressure. It is not a simple power of 10 times the SI unit of the pascal, but rather is defined as follows:

$$1\ atm = 101{,}325\ Pa = 0.101325\ MPa$$

TABLE B.3

Prefixes in SI

Fraction	Prefix	Symbol	Factor	Prefix	Symbol
10^{-1}	*deci-*	d	10	*deca-*	da
10^{-2}	*centi-*	c	10^2	*hecto-*	h
10^{-3}	*milli-*	m	10^3	*kilo-*	k
10^{-6}	*micro-*	μ	10^6	*mega-*	M
10^{-9}	*nano-*	n	10^9	*giga-*	G

This unit is used because most chemistry procedures are carried out at pressures near atmospheric pressure, for which the pascal is too small a unit to be convenient. In addition, expressions for equilibrium constants (see Chapter 14) are simplified when pressures are expressed in atmospheres.

The non-SI temperature units require special mention. The two most important temperature scales in the United States are the Fahrenheit scale and the Celsius scale, which employ the Fahrenheit degree (°F) and the Celsius degree (°C), respectively. The *size* of the Celsius degree is the same as that of the SI temperature unit, the kelvin, but the two scales are shifted relative to each other by 273.15°C:

$$T_K = \frac{1\ K}{1°C}(t°C) + 273.15\ K$$

The size of the degree Fahrenheit is $\frac{5}{9}$ the size of the Celsius degree. The two scales are related by

$$t°C = \frac{5°C}{9°F}(t°F - 32°F) \qquad \text{or} \qquad t°F = \frac{9°F}{5°C}(t°C) + 32°F$$

The advantage of a unified system of units is that if all the quantities in a calculation are expressed in SI units, the final result must come out in SI units. Nevertheless, it is important to become familiar with the ways in which units are interconverted because units other than SI base units often appear in calculations. The **unit conversion method** provides a systematic approach to this problem.

As a simple example, suppose the mass of a sample is measured to be 64.3 g. If this is to be used in a formula involving SI units, it should be converted to kilograms (the SI base unit of mass). To do this, we use the fact that 1 kg = 1000 g and write

$$\frac{64.3\ g}{1000\ g\ kg^{-1}} = 0.0643\ kg$$

Note that this is, in effect, division by 1; because 1000 g = 1 kg, 1000 g kg^{-1} = 1, and we cancel units between numerator and denominator to obtain the final result. This unit conversion could also be written as

$$64.3\ g\left(\frac{1\ kg}{1000\ g}\right) = 0.0643\ kg$$

In this book we use the more compact first version of the unit conversion. Instead of *dividing* by 1000 g kg^{-1}, we can equally well *multiply* by 1 = 10^{-3} kg g^{-1}:

$$(64.3\ g)(10^{-3}\ kg\ g^{-1}) = 0.0643\ kg$$

Other unit conversions may involve more than just powers of 10, but they are equally easy to carry out. For example, to express 16.4 inches in meters, we use the fact that 1 inch = 0.0254 m (or 1 = 0.0254 m $inch^{-1}$), so

$$(16.4\ inches)(0.0254\ m\ inch^{-1}) = 0.417\ m$$

More complicated combinations are possible. For example, to convert from liter-atmospheres to joules (the SI unit of energy), two separate unit conversions are used:

$$(1\ L\ atm)(10^{-3}\ m^3\ L^{-1})(101{,}325\ Pa\ atm^{-1}) = 101.325\ kg\ m^2\ s^{-2}$$
$$= 101.325\ Pa\ m^3 = 101.325\ J$$

When doing chemical calculations, it is very important to write out units explicitly and cancel units in intermediate steps to obtain the correct units for the final result. This practice is a way of checking to make sure that units have not been incorrectly mixed without unit conversions or that an incorrect formula has not been used. If a result that is supposed to be a temperature comes out with units of $m^3\ s^{-2}$, then a mistake has been made!

B.2 BACKGROUND IN PHYSICS

Although physics and chemistry are distinct sciences with distinct objectives and methods of investigation, concepts from one can aid investigations in the other. Physical reasoning aids chemical understanding in cases where applied forces move chemical systems to new positions—or change their sizes and shapes—and change their energy. These energy changes can have chemical consequences, as shown in two specific examples. First, the total energy content of a system increases when the system is compressed by externally applied pressure. Second, when significant forces exist between molecules, the mutual energy of a pair of molecules changes as the molecules are pushed closer together. Intermolecular forces profoundly influence the organization of matter into solid, liquid, and gaseous states, as well as the effectiveness of molecular collisions in causing chemical reactions. Specific illustrations appear at many places in this book. This section reviews general aspects of motion, forces, and energy as background for these specific applications. For simplicity, we limit the discussion to a **point mass,** which is an object characterized only by its total mass m. We do not inquire into the internal structure of the object. In various contexts, we represent planets, projectiles, molecules, atoms, nuclei, or electrons by this model to predict their response to applied forces.

Describing the Motion of an Object

Our goal here is to find a precise way to describe how an object changes its location and how that change occurs at various rates. We need several definitions. First, we define the position of the object precisely by stating its **displacement** x from a selected reference point. For example, an automobile could be located 1.5 miles north of the intersection of Wilshire and Westwood boulevards in Los Angeles. The electron in a hydrogen atom could be located 5×10^{-11} m from the nucleus. Displacement has dimensions of length (L). The rate of change of location is given by the **average velocity** v, defined over the time interval t_1 to t_2 as $v = [x_2 - x_1]/[t_2 - t_1]$. Both the displacement and the average velocity are defined relative to the selected reference point and therefore possess direction as well as magnitude. The **average speed** s gives the magnitude of the average velocity but not its direction. For example, an automobile can have average velocity of 35 mph southbound from Wilshire and Westwood, while its average speed is 35 mph. Both velocity and speed have dimension of length per time ($L\ t^{-1}$). The **momentum** p of a body is defined as $p = mv$. The momentum indicates the ability of a moving body to exert impact on another body upon collision. For example, a slow-moving automobile "packs a bigger wallop" than a fast-moving bicycle. Momentum has dimensions of $M\ L\ t^{-1}$. The rate at which the velocity changes is given by the **acceleration** a, defined as $a = [v_2 - v_1]/[t_2 - t_1]$. Acceleration has direction as well as magnitude and has dimensions of $L\ t^{-2}$.

Forces Change the Motion of an Object

Force is defined as the agent that changes the motion of an object. This restatement of our daily experience that pushing or pulling an object causes it to move is the basis of Sir Isaac Newton's first law of motion:

> *Every object persists in a state of rest or of uniform motion in a straight line unless compelled to change that state by forces impressed upon it.*

We determine the properties of a force experimentally in the laboratory by measuring the consequences of applying the force. Suppose we have arbitrarily selected a standard test object of known mass m_1. We apply a force F_1 and, by making the distance and time measurements described earlier, determine the acceleration $a_{1,1}$ imparted to the object by the force. Experience shows that a different force

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

F_2 imparts different acceleration $a_{1,2}$ to the test object. Forces can be ranked by the magnitude of the acceleration they impart to the standard test object. Now suppose we choose a second test object of mass m_2. Applying the original force F_1 to this object produces acceleration $a_{2,1}$, which is different from the acceleration $a_{1,1}$ that it gave to the first test object. The results of such experiments are summarized in Newton's second law of motion:

> *The acceleration imparted to an object by an applied force is proportional to the magnitude of the force, parallel to the direction of the force, and inversely proportional to the mass of the object.*

In mathematical form this statement becomes

$$F = ma \quad \text{or} \quad a = F/m$$

This equation demonstrates that force must have dimensions of M L t^{-2}. In SI units, force is expressed in newtons (N).

One familiar example is the force caused by gravity at the surface of the earth. Measurements show this force produces a downward acceleration (toward the center of the earth) of constant magnitude 9.80665 m s^{-2}, conventionally denoted by *g*, the gravitational constant. The gravitational force exerted on a body of mass *m* is

$$F = mg$$

Another familiar example is the restoring force exerted on an object by a spring. In chemistry this is a useful model of the binding forces that keep atoms together in a chemical bond or near their "home" positions in a solid crystal. Imagine an object of mass *m* located on a smooth tabletop. The object is connected to one end of a coiled metallic spring; the other end of the spring is anchored to a post in the tabletop. At rest, the object is located at position x_0. Now suppose the object is pulled away from the post in a straight line to a new position *x* beyond x_0 so the spring is stretched. Measurements show that at the stretched position *x* the magnitude of the force exerted on the object by the spring is directly proportional to the displacement from the rest position:

$$|F| = K(x - x_0)$$

In the preceding equation, *K* is a constant whose magnitude must be determined empirically in each case studied. Clearly, this force is directed back toward the rest position, and when the object is released, the recoiling spring accelerates the object back toward the rest position. Because the displacement is directed *away* from the rest position and the restoring force is directed *toward* the rest position, we insert a minus sign in the equation:

$$F(x) = -K(x - x_0)$$

When studying the dependence of force on position, we must pay careful attention to how displacement is defined in each particular problem. The force and the acceleration at any point are parallel to each other, but the displacement (defined relative to some convenient origin of coordinates in each particular case) may point in a different direction. In applications concerned with the height of an object above the earth, the gravitational force is usually written as

$$F(y) = -mg$$

to emphasize that the vertical displacement *y* is positive and pointing away from the surface of the earth, while the gravitational force is clearly directed toward the earth.

Once a force has been determined, the motion of the object under that force can be predicted from Newton's second law. If a constant force (that is, a force with

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

constant acceleration) is applied to an object initially at rest for a period of time starting at t_1 and ending at t_2, the velocity at t_2 is given by

$$v(t_2) = a(t_2 - t_1)$$

and the position at t_2 is given by

$$x(t_2) = x(t_1) + \tfrac{1}{2}\, a(t_2 - t_1)^2$$

If the force depends on position, predicting the motion is slightly more complicated and requires the use of calculus. We merely quote the results for the linear restoring force. Under this force, the object oscillates about the rest position x_0 with a period τ given by

$$\frac{1}{\tau} = \frac{1}{2\pi}\left(\frac{K}{m}\right)^{1/2}$$

The frequency ν of the oscillation (the number of cycles per unit time) is given by $\nu = \tau^{-1}$. If we represent the motion in terms of the angular frequency $\omega = 2\pi\nu$, which has dimensions radians s^{-1}, the position of the oscillating object is given by

$$x(t) - x_0 = A \cos(\omega t + \delta)$$

where the amplitude A and the phase factor δ are determined by the initial position and velocity of the object.

Forms of Energy

The concept of **energy** originated in the science of mechanics and was first defined as the capacity to perform work, that is, to move an object from one position to another. It is now understood that energy appears in many different forms, each of which can cause particular kinds of physical and chemical changes. From daily experience, we recognize the kinetic energy due to the speed of an onrushing automobile. To stop the automobile, its *kinetic energy* must be overcome by work performed by its brakes. Otherwise, the automobile will crash into other objects and expend its kinetic energy by deforming these objects, as well as itself. The *potential energy* of a mass of snow on a ski slope becomes the kinetic energy of an avalanche. The *electrical energy* stored in a battery can move objects by driving motors, or warm objects through electric heaters. The chemical energy stored in gasoline can move objects by powering an internal combustion engine. The *thermal energy* of hot steam can move objects by driving a steam engine.

Each of these forms of energy plays a role in chemistry, and each is described at the appropriate point in this textbook. Here we concentrate on the nature of potential and kinetic energy and their interconversion. The understanding we gain here is essential background for understanding these other forms of energy.

The **kinetic energy** of a moving object is defined by

$$\mathcal{T} = \frac{1}{2}\, mv^2$$

where m is the mass of the object and v is its speed. A stationary object has no kinetic energy. In the SI systems of units (see Appendix B.1), energy is expressed in joules (J). Thus, 0.5 joule is the kinetic energy of an object with mass 1 kg moving at a speed of 1 m s^{-1}. Experience shows that applying a force to a moving object changes the kinetic energy of the object. If the force is applied in the same direction as the velocity of the object, the kinetic energy is increased; if the force is opposed to the velocity, the kinetic energy is decreased.

Potential energy is the energy stored in an object due to its location relative to a specified reference position. Potential energy therefore depends explicitly on the position x of the object and is expressed as a mathematical function $V(x)$. The

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

change in potential energy when an object is moved from position x_1 to position x_2 by a constant force is equal to the work done in moving the object:

$$\text{change in } V(x) = \text{force} \times \text{displacement} = \text{force} \times (x_2 - x_1)$$

To lift an object of mass m from the surface of the earth to the height h, some agency must perform work in the amount mgh against the downward-directed force of gravity, which has constant acceleration denoted by g. The change in potential energy is mgh. Potential energy is expressed in joules in the SI system of units.

Conservation of Energy

The science of mechanics deals with idealized motions of objects in which friction does not occur. The motions of an object interconvert its potential and kinetic energy subject to the restriction that their sum always remains constant. For example, consider a soccer ball rolling down the side of a steep gully at the edge of the playing field, and assume there is no friction between the ball and the surface on which it rolls. The ball rolls down one side, goes across the bottom, climbs partway up the opposite side, then stops and reverses direction. This pattern is repeated many times as the ball continues to oscillate back and forth across the bottom of the gully. On each downward leg of its journey, the ball loses potential energy and gains kinetic energy, but their sum remains constant. On each upward leg, the ball loses kinetic energy and gains potential energy, but their sum remains constant.

The description in the previous paragraph is clearly an idealization, because eventually the ball comes to rest at the bottom of the gully. In reality, the ball loses some of its kinetic energy through friction with the surface of the gully on each upward leg and on each downward leg of its journey. Both the ball and the gully surface become slightly warmer as a result. The energy lost from the purely mechanical motion is added to the *internal energy* of the ball and the gully surface. The total amount of energy has not changed; we have neither created nor destroyed energy in this process. Rather, we have identified a new mode of energy storage (called internal energy) to interpret the new effects beyond those explained by basic mechanics. Internal energy, heat, and friction are discussed in detail in Chapter 12 as part of the science of thermodynamics.

Similar arguments have extended the law of conservation of energy from the idealized motions of mechanics to include a broad variety of phenomena in which several different forms of energy are involved. This law is one of the securest building blocks in scientific reasoning. It provides the starting point for interpreting and relating a great variety of superficially different processes. In chemistry this law provides the foundation for studying complex processes in which kinetic, potential, electrical, chemical, and thermal energy are interconverted without net loss or gain.

Representing Energy Conservation by Potential Energy Curves

Consider again the soccer ball rolling down the walls of the gully. This process is shown schematically in Figure B.1, where the curve $V(x)$ suggests a "cross-sectional" sketch of the gully. The curve $V(x)$ actually represents the potential energy of the ball relative to its value at the bottom of the gully. The x coordinate locates the distance of the ball from the bottom of the gully to a position along its side. Suppose the ball is held in place at the position x_1. It possesses only potential energy, which we represent by the value E_1. If the ball is released, it falls down the slope and passes across the bottom, where its potential energy is zero and its kinetic energy is E_1. It then climbs the opposite side until it rises to position $-x_1$, where its kinetic energy is zero. The ball promptly reverses direction and retraces its path back to position x_1, where its total energy E_1 is all potential energy.

FIGURE B.1 Sketch of the potential energy of a soccer ball rolling down the sides of a gully. The ball is released at position x_1 with total energy E_1. In idealized motion, it continues to oscillate back and forth across the bottom of the gully. The net force on the ball is always in the direction in which the potential energy is decreasing. In real systems there is sufficient friction between the ball and the gully to bring the ball to rest at the bottom of the gully.

Potential Energy Curves, Force, and Stability

One very important application of the potential energy function in this textbook is to provide a way to qualitatively predict the motion of an object without solving Newton's second law. The method determines the direction of the force applied to an object from knowledge of the potential energy curve as shown in Figure B.1. In preparation for this method, let's examine the potential energy curves for some familiar forces.

The value of the potential energy at a general point x is always stated relative to its value at a specially selected reference point x_0. The value $V(x_0)$ is a constant and is usually assigned the value zero, and the point x_0 is frequently selected as the origin of coordinates for specifying the location of the object.

In the presence of a particular force F, the potential energy of the object at x is defined as the work required to move the object to x from the reference position x_0. Since the work done by a constant force in moving an object is defined as (force) $\times$ (displacement), the definition of potential energy in mathematical terms is

$$V(x) - V(x_0) = (F)(x - x_0)$$

Note carefully that the displacement referred to in the definition of potential energy starts at x_0 and ends at x. For example, the potential energy of an object of mass m at height h above the surface of the earth is the work done by a force $+mg$ opposing gravity in lifting the object from h_0 to h:

$$\begin{aligned} V(h) - V(h_0) &= mg(h - h_0) \\ &= mgh - mgh_0 \\ &= mgh \end{aligned}$$

where the value $V(h_0)$ has been set to zero. For a variable force, the definition of potential energy becomes slightly more complicated and requires explicit use of calculus. The potential energy for the linear restoring force is

$$V(x) = \tfrac{1}{2} K(x)^2$$

where the value $V(x_0)$ has been set to 0 and x_0 has been selected as the origin of coordinates.

It is instructive to plot these two potential energy functions as graphs (see Appendix C). The gravitational potential energy function is a straight line through the origin with slope mg, while the potential energy function for the linear restoring force is a parabola. In each case the potential energy of the object increases as the distance from the reference point x_0 increases.

Knowledge of the potential energy curve as a function of position lets us predict the direction of the net force on the object at each position. For example in Figure B.1, from either side the force is directed toward the bottom; the force is always in the direction in which the potential energy is decreasing. From the definition of potential energy stated earlier, it can be shown that

$$\text{force} = -(\text{slope of PE})$$

The net force drives the object toward the position where the potential energy is a minimum and its slope is zero. For both the gravitational force and the linear restoring force, the object experiences negative forces that attract it back toward the center of force.

The minimum of the potential energy curve shown in Figure B.1 is called a point of **stable equilibrium** because the net force (that is, the slope of the potential energy curve) at that point is zero. As the ball tries to climb the wall on either side of the minimum, the restoring force always drives it back toward this position of stable equilibrium. This qualitative interpretation predicts that the ball will oscillate about the equilibrium position, as predicated by the exact solution to Newton's second law quoted earlier.

We use similar potential energy diagrams to represent the interaction between a pair of objects, such as Earth–moon, Earth–Mars, electron–nucleus, electron–electron, nucleus–nucleus, atom–atom, or molecule–molecule. We construct such diagrams at several points in this textbook and use them to interpret the relative motions of the pair of objects. These methods are extremely important in describing the formation of chemical bonds, the states of matter, and the role of molecular collisions in chemical reactions.

Electrical Forces

The concepts summarized so far in this section also are used to describe the mutual interactions and the motions of electrically charged particles. The only new features are to identify the force that represents electrical interactions and to obtain the corresponding potential energy function. Positive and negative charges and the electrical forces between them were first quantified by Charles Coulomb late in the 18th century. In his honor the unit of charge in SI units is the **coulomb** (C). Electrical charge is fundamentally quantized in units of the charge carried by a single electron *e,* which is equal to 1.60218×10^{-19} C. The coulomb is thus an inconveniently large unit for chemical reasoning. Nonetheless, for consistency and for quantitative accuracy, physical equations involving charge use SI units.

Suppose a charge of magnitude q_1 is held at the origin of coordinates and another charge of magnitude q_2 is brought near it, at the distance r from the origin. The magnitude of the acceleration imparted to the charge q_2 by the charge q_1 fixed at the origin can be determined as described earlier for uncharged objects. From such measurements, Coulomb determined that the magnitude of the force was directly proportional to the magnitudes of the two charges and inversely proportional to the distance between them:

$$F \propto \frac{q_1 q_2}{r^2}$$

The radial displacement variable r has its origin at the same location as charge q_1, and its value increases in the outward direction. If the charges have the same sign, the acceleration pushes them apart in the same direction as r. Consequently, the force between charges is **repulsive** and defined to be **positive.** If the charges have opposite signs, the acceleration pulls them together in the direction opposite to the displacement variable r. In this case the force between charges is **attractive** and defined to be **negative.** It is instructive to sketch the results graphically in these two

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

cases. The quantitative form of Coulomb's law with force expressed in newtons (N) and charge in coulombs (C) is

$$F = \frac{q_1 q_2}{4\pi\ \epsilon_0 r^2}$$

where ϵ_0, called the permittivity of the vacuum, is a constant with value $8.854 \times 10^{-12}\ \mathrm{C^2\ J^{-1}\ m^{-1}}$. In this and related equations, the symbol q for each charge represents the magnitude and carries implicitly the sign of the charge.

The **Coulomb potential energy** corresponding to this force is

$$V(r) = \frac{q_1 q_2}{4\pi\ \epsilon_0 r}$$

Note that the force varies as r^{-2} while the potential energy varies as r^{-1}. Note also that if the charges have the same sign, the potential energy is positive and repulsive; if the charges have opposite sign, the potential energy is negative and attractive. If we know the potential energy curve between two charged particles, we can predict the direction of their relative motion.

The Coulomb potential energy function holds great importance in chemistry for examining the structure of atoms and molecules. In 1912, Ernest Rutherford proposed that an atom of atomic number Z comprises a dense, central nucleus of positive charge with magnitude Ze surrounded by a total of Z individual electrons moving around the nucleus. Thus, each individual electron has a potential energy of interaction with the nucleus given by

$$V(r) = -\frac{Ze^2}{4\pi\ \epsilon_0 r}$$

which is clearly negative and attractive. Each electron has a potential energy of interaction with every other electron in the atom given by

$$V(r) = \frac{e^2}{4\pi\ \epsilon_0 r}$$

which is clearly positive and repulsive. Rutherford's model of the atom, firmly based on experimental results, was completely at odds with the physical theories of the day. Attempts to reconcile these results with theory led to the development of the new theory called quantum mechanics.

Circular Motion and Angular Momentum

An object executing uniform circular motion about a point (for example, a ball on the end of a rope being swung in circular motion) is described by position, velocity, speed, momentum, and force, just as defined earlier for objects in linear motion. It is most convenient to describe this motion in polar coordinates r and θ, which represent, respectively, the distance of the object from the center and its angular displacement from the x-axis in ordinary cartesian coordinates. Because r is constant for circular motion, the motion variables depend directly on θ. The angular velocity during the time interval from t_1 to t_2 is given by

$$\omega = \frac{\theta_2 - \theta_1}{t_2 - t_1}$$

and the angular acceleration is given by

$$\alpha = \frac{\omega_2 - \omega_1}{t_2 - t_1}$$

In linear motion, we are concerned with the momentum $p = mv$ of an object as it heads toward a particular point; the linear momentum measures the impact that

the object can transfer in a collision as it arrives at the point. To extend this concept to circular motion, we define the **angular momentum** of an object as it revolves around a point as $L = mvr$. This is in effect the *moment* of the linear momentum over the distance r, and it is a measure of the torque felt by the object as it executes angular motion. The angular momentum of an electron around a nucleus is a crucial feature of atomic structure, which is discussed in Chapter 5.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G.

SI Units and Unit Conversions

1. Rewrite the following in scientific notation, using only the base units of Table B.1, without prefixes.
(a) 65.2 nanograms
(b) 88 picoseconds
(c) 5.4 terawatts
(d) 17 kilovolts

2. Rewrite the following in scientific notation, using only the base units of Table B.1, without prefixes.
(a) 66 μK
(b) 15.9 MJ
(c) 0.13 mg
(d) 62 GPa

3. Express the following temperatures in degrees Celsius.
(a) 9001°F
(b) 98.6°F (the normal body temperature of human beings)
(c) 20°F above the boiling point of water at 1 atm pressure
(d) −40°F

4. Express the following temperatures in degrees Fahrenheit.
(a) 5000°C
(b) 40.0°C
(c) 212°C
(d) −40°C

5. Express the temperatures given in problem 3 in kelvins.

6. Express the temperatures given in problem 4 in kelvins.

7. Express the following in SI units, either base or derived.
(a) 55.0 miles per hour (1 mile = 1609.344 m)
(b) 1.15 g cm^{-3}
(c) 1.6×10^{-19} C Å
(d) 0.15 mol L^{-1}
(e) 5.7×10^{3} L atm day^{-1}

8. Express the following in SI units, either base or derived.
(a) 67.3 atm
(b) 1.0×10^{4} V cm^{-1}
(c) 7.4 Å $year^{-1}$
(d) 22.4 L mol^{-1}
(e) 14.7 lb $inch^{-2}$ (1 inch = 2.54 cm; 1 lb = 453.59 g)

9. The kilowatt-hour (kWh) is a common unit in measurements of the consumption of electricity. What is the conversion factor between the kilowatt-hour and the joule? Express 15.3 kWh in joules.

10. A car's rate of fuel consumption is often measured in miles per gallon (mpg). Determine the conversion factor between miles per gallon and the SI unit of meters per cubic decimeter (1 gallon = 3.785 dm^3, and 1 mile = 1609.344 m). Express 30.0 mpg in SI units.

11. A certain V-8 engine has a displacement of 404 in^3. Express this volume in cubic centimeters (cm^3) and in liters.

12. Light travels in a vacuum at a speed of 3.00×10^{8} m s^{-1}.
(a) Convert this speed to miles per second.
(b) Express this speed in furlongs per fortnight, a little-used unit of speed. (A furlong, a distance used in horse racing, is 660 ft; a fortnight is exactly 2 weeks.)

The Concept of Energy: Forms, Measurements, and Conservation

13. After being spiked, a volleyball travels with speed near 100 miles per hour. Calculate the kinetic energy of the volleyball. The mass of a volleyball is 0.270 kg.

14. The fastball of a famous pitcher in the National League has been clocked in excess of 95 mph. Calculate the work done by the pitcher in accelerating the ball to that speed. The mass of a baseball is 0.145 kg.

15. A tennis ball weighs approximately 2 ounces on a postage scale. A student practices his serve against the wall of the chemistry building, and the ball achieves the speed of 98 miles per hour. Calculate the kinetic energy of the ball after the serve. How much work is done on the chemistry building in one collision?

APPENDIX C

MATHEMATICS FOR GENERAL CHEMISTRY

Mathematics is an essential tool in chemistry. This appendix reviews some of the most important mathematical techniques for general chemistry.

C.1 USING GRAPHS

In many situations in science, we are interested in how one quantity (measured or predicted) depends on another quantity. The position of a moving car depends on the time, for example, or the pressure of a gas depends on the volume of the gas at a given temperature. A very useful way to show such a relation is through a **graph,** in which one quantity is plotted against another.

The usual convention in drawing graphs is to use the horizontal axis for the variable over which we have control and use the vertical axis for the measured or calculated quantity. After a series of measurements, the points on the graph frequently lie along a recognizable curve, and that curve can be drawn through the points. Because any experimental measurement involves some degree of uncertainty, there will be some scatter in the points, so there is no purpose in drawing a curve that passes precisely through every measured point. If there is a relation between the quantities measured, however, the points will display a systematic trend and a curve can be drawn that represents that trend.

The curves plotted on graphs can have many shapes. The simplest and most important shape is a straight line. A straight line is a graph of a relation such as

$$y = 4x + 7$$

or, more generally,

$$y = mx + b$$

where the variable y is plotted along the vertical axis and the variable x along the horizontal axis (Fig. C.1). The quantity m is the **slope** of the line that is plotted, and b is the **intercept**—the point at which the line crosses the y axis. This can be demonstrated by setting x equal to 0 and noting that y is then equal to b. The slope is a measure of the steepness of the line; the greater the value of m, the steeper the line. If the line goes up and to the right, the slope is positive; if it goes down and to the right, the slope is negative.

The slope of a line can be determined from the coordinates of two points on the line. Suppose, for example, that when $x = 3$, $y = 5$, and when $x = 4$, $y = 7$. These two points can be written in shorthand notation as (3, 5) and (4, 7). The slope of the line is then defined as the "rise over the run"—the change in the y coordinate divided by the change in the x coordinate:

$$\text{slope} = m = \frac{\Delta y}{\Delta x} = \frac{7 - 5}{4 - 3} = \frac{2}{1} = 2$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

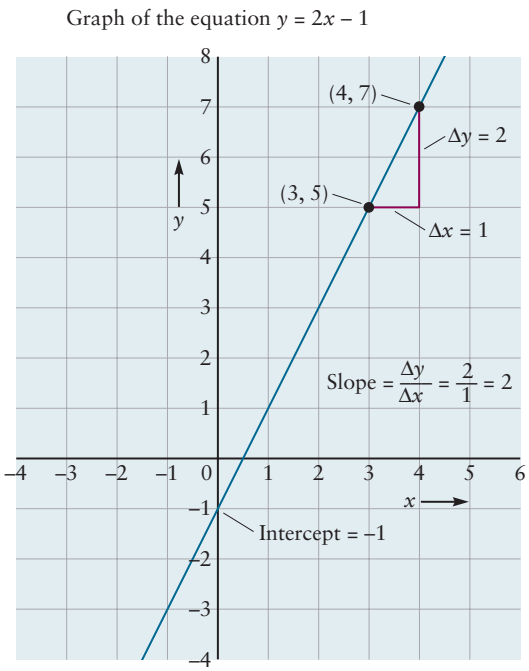

FIGURE C.1 A straight-line, or linear, relationship between two experimental quantities is a very desirable result because it is easy to graph and easy to represent mathematically. The equation of this straight line ($y = 2x - 1$) fits the general form $y = mx + b$. The line's y intercept is -1 and its slope is 2.

The symbol Δ (capital Greek delta) indicates the change in a quantity—the final value minus the initial value. In chemistry, if the two quantities being graphed have dimensions, the slope has dimensions as well. If a graph of distance traveled (in meters) against time (in seconds) is a straight line, its slope has dimensions of meters per second (m s^{-1}).

C.2 SOLUTION OF ALGEBRAIC EQUATIONS

In chemistry it is often necessary to solve an algebraic equation for an unknown quantity, such as a concentration or a partial pressure in an equilibrium-constant expression. Let us represent the unknown quantity with the symbol x. If the equation is linear, the method of solution is straightforward:

$$5x + 9 = 0$$

$$5x = -9$$

$$x = -\frac{9}{5}$$

or, more generally, if $ax + b = 0$, then $x = -b/a$.

Nonlinear equations are of many kinds. One of the most common in chemistry is the quadratic equation, which can always be rearranged into the form

$$ax^2 + bx + c = 0$$

where each of the constants (a, b, and c) may be positive, negative, or 0. The two solutions to a quadratic equation are given by the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

As an example, suppose that the equation

$$x = 3 + \frac{7}{x}$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

arises in a chemistry problem. Multiplying by x and rearranging the terms gives

$$x^2 - 3x - 7 = 0$$

Inserting $a = 1$, $b = -3$, and $c = -7$ into the quadratic formula gives

$$x = \frac{-(-3) \pm \sqrt{(-3)^2 - 4(1)(-7)}}{2} = \frac{3 \pm \sqrt{9 + 28}}{2} = \frac{3 \pm \sqrt{37}}{2}$$

The two roots of the equation are

$$x = 4.5414 \qquad \text{and} \qquad x = -1.5414$$

In a chemistry problem, the choice of the proper root can frequently be made on physical grounds. If x corresponds to a concentration, for example, the negative root is unphysical and can be discarded.

The solution of cubic or higher order algebraic equations (or more complicated equations involving sines, cosines, logarithms, or exponentials) becomes more difficult, and approximate or numerical methods must be used. As an illustration, consider the equation

$$x^2\left(\frac{2.00 + x}{3.00 - x}\right) = 1.00 \times 10^{-6}$$

If x is assumed to be small relative to both 2.00 and 3.00, we obtain the simpler approximate equation

$$x^2\left(\frac{2.00}{3.00}\right) \approx 1.00 \times 10^{-6}$$

which leads to the roots $x = \pm 0.00122$. We immediately confirm that the solutions obtained in this way *are* small compared with 2.00 (and 3.00) and that our approximation was a good one. When a quantity (x in this case) is added to or subtracted from a larger quantity in a complicated equation, it is usually worthwhile, in solving the equation, to simply neglect the occurrence of the small quantity. Note that this tactic works only for addition and subtraction, never for multiplication or division.

Suppose now that the equation is changed to

$$x^2\left(\frac{2.00 + x}{3.00 - x}\right) = 1.00 \times 10^{-2}$$

In this case the equation that comes from neglecting x compared with 2.00 and 3.00 is

$$x^2\left(\frac{2.00}{3.00}\right) \approx 1.00 \times 10^{-2}$$

which is solved by $x \approx \pm 0.122$. The number 0.122 is smaller than 2.00 and 3.00, but not so small that it can be ignored. In this case more precise results can be obtained by **iteration.** Let us simply add and subtract the approximate positive root $x \approx +0.122$ as specified inside the parentheses and solve again for x:

$$x^2\left(\frac{2.00 + 0.122}{3.00 - 0.122}\right) = 1.00 \times 10^{-2}$$

$$x = 0.116$$

This new value can again be inserted into the original equation and the process repeated:

$$x^2\left(\frac{2.00 + 0.116}{3.00 - 0.116}\right) = 1.00 \times 10^{-2}$$

$$x = 0.117$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Once the successive values of x agree to within the desired accuracy, the iteration can be stopped. Another root of the equation is obtained in a similar fashion if the iterative procedure starts with $x = -0.122$.

In some cases iteration fails. Suppose, for example, we have the equation

$$x^2\left(\frac{2.00 + x}{3.00 - x}\right) = 10.0$$

There is no particular reason to believe that x should be small compared with 2.00 or 3.00, but if we nevertheless assume that it is, we find $x = \pm\sqrt{15} = \pm 3.873$. Putting $x = +3.873$ back in for an iterative cycle leads to the equation

$$x^2 = -1.49$$

which has no real solutions. Starting with $x = -3.873$ succeeds no better; it gives

$$x^2 = -36.7$$

One way to overcome these difficulties is to solve the original equation graphically. We plot the left side of the equation against x and see at which values it becomes equal to 10 (the right side). We might initially calculate

x	$x^2\left(\frac{2.00 + x}{3.00 - x}\right)$
0	0
1	1.5
2	16

We observe that for $x = 1$ the left side is less than 10, whereas for $x = 2$ it is greater than 10. Somewhere in between there must be an x for which the left side is *equal to* 10. We can pinpoint it by selecting values of x between 1 and 2; if the left side is less than 10, x should be increased, and if it is greater than 10, x should be decreased.

x	$x^2\left(\frac{2.00 + x}{3.00 - x}\right)$
1.5	5.25
Increase to 1.8	10.26
Decrease to 1.75	9.19
Increase to 1.79	10.04

Thus, 1.79 is quite close to a solution of the equation. Improved values are easily obtained by further adjustments of this type.

C.3 POWERS AND LOGARITHMS

Raising a number to a power and the inverse operation, taking a logarithm, are important in many chemical problems. Although the ready availability of electronic calculators makes the mechanical execution of these operations quite routine, it remains important to understand what is involved in such "special functions."

The mathematical expression 10^4 implies multiplying 10 by itself 4 times to give 10,000. Ten, or any other number, when raised to the power 0 always gives 1:

$$10^0 = 1$$

Negative powers of 10 give numbers less than 1 and are equivalent to raising 10 to the corresponding *positive* power and then taking the reciprocal:

$$10^{-3} = 1/10^3 = 0.001$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

We can extend the idea of raising to a power to include powers that are not whole numbers. For example, raising to the power $\frac{1}{2}$ (or 0.5) is the same as taking the square root:

$$10^{0.5} = \sqrt{10} = 3.1623\ldots$$

Scientific calculators have a 10^x (or INV LOG) key that can be used for calculating powers of 10 in cases where the power is not a whole number.

Numbers other than 10 can be raised to powers, as well; these numbers are referred to as **bases.** Many calculators have a y^x key that lets any positive number y be raised to any power x. One of the most important bases in scientific problems is the transcendental number called e (2.7182818 . . .). The e^x (or INV LN) key on a calculator is used to raise e to any power x. The quantity e^x also denoted as $\exp(x)$, is called the **exponential** of x. A key property of powers is that a base raised to the sum of two powers is equivalent to the product of the base raised separately to these powers. Thus, we can write

$$10^{21+6} = 10^{21} \times 10^6 = 10^{27}$$

The same type of relationship holds for any base, including e.

Logarithms also occur frequently in chemistry problems. The logarithm of a number is the exponent to which some base has to be raised to obtain the number. The base is almost always either 10 or the transcendental number e. Thus,

$$B^a = n \qquad \text{and} \qquad \log_B n = a$$

where a is the logarithm, B is the base, and n is the number.

Common logarithms are base-10 logarithms; that is, they are powers to which 10 has to be raised in order to give the number. For example, $10^3 = 1000$, so $\log_{10} 1000 = 3$. We shall frequently omit the 10 when showing common logarithms and write this equation as $\log 1000 = 3$. Only the logarithms of 1, 10, 100, 1000, and so on are whole numbers; the logarithms of other numbers are decimal fractions. The decimal point in a logarithm divides it into two parts. To the left of the decimal point is the *characteristic;* to the right is the *mantissa.* Thus, the logarithm in the equation

$$\log (7.310 \times 10^3) = 3.8639$$

has a characteristic of 3 and a mantissa of 0.8639. As may be verified with a calculator, the base-10 logarithm of the much larger (but closely related) number 7.310×10^{23} is 23.8639. As this case illustrates, the characteristic is determined solely by the location of the decimal point in the number and not by the number's precision, so it is *not* included when counting significant figures. The mantissa should be written with as many significant figures as the original number.

A logarithm is truly an exponent and as such follows the same rules of multiplication and division as other exponents. In multiplication and division we have

$$\log (n \times m) = \log n + \log m$$

$$\log\left(\frac{n}{m}\right) = \log n - \log m$$

Furthermore,

$$\log n^m = m \log n$$

so the logarithm of $3^5 = 243$ is

$$\log 3^5 = 5 \log 3 = 5 \times 0.47712 = 2.3856$$

There is no such thing as the logarithm of a negative number, because there is no power to which 10 (or any other base) can be raised to give a negative number.

A frequently used base for logarithms is the number e ($e = 2.7182818. . . .$). The logarithm to the base e is called the **natural logarithm** and is indicated by $\log_e$ or ln. Base-e logarithms are related to base-10 logarithms by the formula

$$\ln n = 2.3025851 \log n$$

As already stated, calculations of logarithms and powers are inverse operations. Thus, if we want to find the number for which 3.8639 is the common logarithm, we simply calculate

$$10^{3.8639} = 7.310 \times 10^3$$

If we need the number for which the natural logarithm is 2.108, we calculate

$$e^{2.108} = 8.23$$

As before, the number of significant digits in the answer should correspond to the number of digits in the *mantissa* of the logarithm.

C.4 SLOPES OF CURVES AND DERIVATIVES

Very frequently in science, one measured quantity depends on a second one. If the property y depends on a second property x, we can write $y = f(x)$, where f is a function that expresses the dependence of y on x. Often, we are interested in the effect of a small change Δx on the dependent variable y. If x changes to $x + \Delta x$, then y will change to $y + \Delta y$. How is Δy related to Δx? Suppose we have the simple linear relation between y and x

$$y = mx + b$$

where m and b are constants. If we substitute $y + \Delta y$ and $x + \Delta x$, we find

$$y + \Delta y = m(x + \Delta x) + b$$

Subtracting the first equation from the second leaves

$$\Delta y = m\Delta x$$

or

$$\frac{\Delta y}{\Delta x} = m$$

The change in y is proportional to the change in x, with a proportionality constant equal to the slope of the line in the graph of y against x.

Suppose now we have a slightly more complicated relationship such as

$$y = ax^2$$

where a is a constant. If we substitute $y = y + \Delta y$ and $x = x + \Delta x$ here, we find

$$\begin{aligned} y + \Delta y &= a(x + \Delta x)^2 \\ &= ax^2 + ax\ \Delta x + (\Delta x)^2 \end{aligned}$$

Subtracting as before leaves

$$\Delta y = 2ax\ \Delta x + (\Delta x)^2$$

Here we have a more complicated, nonlinear relationship between Δy and Δx. If Δx is small enough, however, the term $(\Delta x)^2$ will be small relative to the term proportional to Δx, and we may write

$$\Delta y \approx 2ax\ \Delta x \qquad (\Delta x \text{ small})$$

$$\frac{\Delta y}{\Delta x} \approx 2ax \qquad (\Delta x \text{ small})$$

TABLE C.1

Derivatives of Simple Functions

Function $f(x)$	Derivative $\frac{df}{dx}$
$mx + b$	m
ax^2	$2ax$
$\frac{a}{x} = ax^{-1}$	$-\frac{a}{x^2} = -ax^{-2}$
ax^n	nax^{n-1}
e^{ax}	ae^{ax}
$\ln ax$	$\frac{1}{x}$
$\sin ax$	$a \cos ax$
$\cos ax$	$-a \sin ax$

The constants *a, b, m,* and *n* may be positive or negative.

How do we indicate this graphically? The graph of y against x is no longer a straight line, so we need to generalize the concept of slope. We define a **tangent line** at the point x_0 as the line that touches the graph of $f(x)$ at $x = x_0$ without crossing it.[1] If Δy and Δx are small (Fig. C.2), the slope of the tangent line is

$$\frac{\Delta y}{\Delta x} = 2ax_0 \quad \text{at} \quad x = x_0$$

for the example just discussed. Clearly, the slope is not constant but changes with x_0. If we define the slope at each point on the curve by the slope of the corresponding tangent line, we obtain a *new* function that gives the slope of the curve $f(x)$ at each point x. We call this new function the **derivative** of $f(x)$ and represent it with df/dx. We have already calculated the derivatives of two functions:

$$f(x) = mx + b \Rightarrow \frac{df}{dx} = m$$

$$f(x) = ax^2 \Rightarrow \frac{df}{dx} = ax$$

Table C.1 shows derivatives of several other functions that are important in basic chemistry.

The derivative gives the slope of the tangent line to $f(x)$ at each point x and can be used to approximate the response to a small perturbation Δx in the independent variable x:

$$\Delta y \approx \frac{df}{dx}\Delta x$$

As an example, consider 1.00 mol of an ideal gas at 0°C that obeys the law

$$P(\text{atm}) = \frac{22.414 \text{ L atm}}{V(\text{L})}$$

[1]This is an intuitive, rather than a rigorously mathematical, definition of a tangent line.

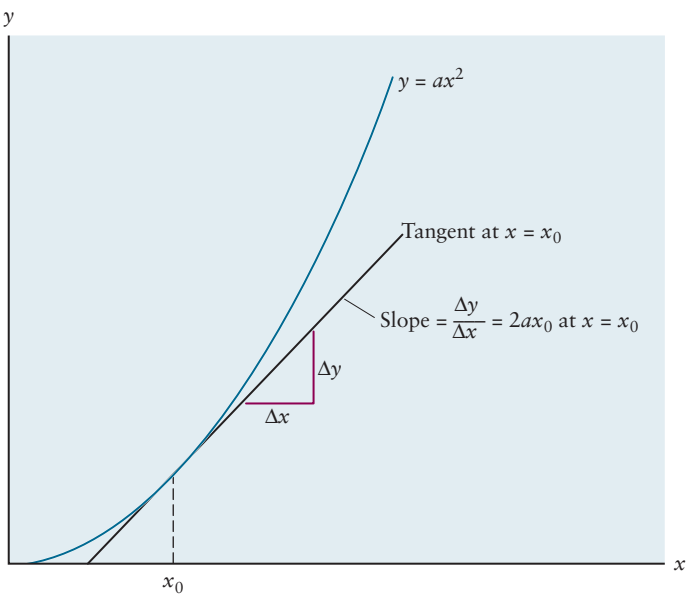

FIGURE C.2 The slope of a curve at a point.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Suppose V is 20.00 L. If the volume V is changed by a small amount ΔV at fixed T and number of moles, what will be the corresponding change ΔP in the pressure? We write

$$P = f(V) = \frac{22.414}{V} = \frac{a}{V}$$

$$\frac{dP}{dV} = \frac{df}{dV} = -\frac{a}{V^2} = -\frac{22.414}{V^2} \qquad \text{(from Table C.1)}$$

$$\Delta P \approx \frac{dP}{dV}\Delta V = -\frac{22.414}{V^2}(\Delta V)$$

If $V = 20.00$ L, then

$$\Delta P \approx -\frac{22.414 \text{ L atm}}{(200.00 \text{ L})^2}\Delta V = -(0.0560 \text{ atm L}^{21})\,\Delta V$$

C.5 AREAS UNDER CURVES AND INTEGRALS

Another mathematical operation that arises frequently in science is the calculation of the area under a curve. Some areas are those of simple geometric shapes and are easy to calculate. If the function $f(x)$ is a constant,

$$f(x) = a$$

then the area under a graph of $f(x)$ between the two points x_1 and x_2 is that of a rectangle (Fig. C.3a) and is easily calculated as

$$\text{area} = \text{height} \times \text{base} = a(x_2 - x_1) = [ax_2] - [ax_1]$$

If $f(x)$ is a straight line that is neither horizontal nor vertical,

$$f(x) = mx + b$$

then the area is that of a trapezoid (Fig. C.3b) and is equal to

$$\begin{aligned}\text{area} &= \text{average height} \times \text{base}\\ &= \tfrac{1}{2}(mx_1 + b + mx_2 + b)(x_2 - x_1)\\ &= [\tfrac{1}{2}mx_2^2 + bx_2] - [\tfrac{1}{2}mx_1^2 + bx_1]\end{aligned}$$

Suppose now that $f(x)$ is a more complicated function, such as that shown in Figure C.3c. We can estimate the area under this graph by approximating it with a series of small rectangles of width Δx and varying heights. If the height of the ith rectangle is $y_i = f(x_i)$, then we have, approximately,

$$\begin{aligned}\text{area} &\approx f(x_1)\,\Delta x + f(x_2)\,\Delta x + \ldots\\ &= \sum_i f(x_i)\,\Delta x\end{aligned}$$

As the widths of the rectangles Δx become small, this becomes a better approximation. We *define* the area under a curve $f(x)$ between two points as the limiting value of this sum as Δx approaches 0, called the **definite integral:**

$$\text{area} = \int_{x_1}^{x_2} f(x)\,dx$$

We have already worked out two examples of such integrals:

$$f(x) = a \Rightarrow \int_{x_1}^{x_2} a\,dx = [ax_2] - [ax_1]$$

$$f(x) = ax + b \Rightarrow \int_{x_1}^{x_2} (ax + b)\,dx = [\tfrac{1}{2}ax_2^2 + bx_2] - [\tfrac{1}{2}ax_1^2 + bx_1]$$

FIGURE C.3 The integral as the area under a curve.

These integrals have an interesting form, which can be generalized to other cases as well: some function F evaluated at the upper limit (x_2) minus that function F evaluated at the lower limit (x_1).

$$\int_{x_1}^{x_2} f(x)\,dx = F(x_2) - F(x_1)$$

F is called the **antiderivative** of f because, for reasons we shall not go into here, it is obtained by the inverse of a derivative operation. In other words, if F is the antiderivative of f, then f is the derivative of F:

$$\frac{dF}{dx} = f(x)$$

To calculate integrals, therefore, we invert the results of Table C.1, because we need to find those functions $F(x)$ whose derivatives are equal to $f(x)$. Table C.2 lists several of the most important integrals for basic chemistry.

Several additional mathematical properties of integrals are important at this point. If a function is multiplied by a constant c, then the integral is multiplied by the same constant:

$$\int_{x_1}^{x_2} cf(x)\,dx = c\int_{x_1}^{x_2} f(x)\,dx$$

The reason is self-evident: if a function is multiplied everywhere by a constant factor, then the area under its graph must be increased by the same factor. Second, the integral of the sum of two functions is the sum of the separate integrals:

$$\int_{x_1}^{x_2} [f(x) + g(x)]\,dx = \int_{x_1}^{x_2} f(x)\,dx + \int_{x_1}^{x_2} g(x)\,dx$$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

TABLE C.2

Integrals of Simple Functions

Function $f(x)$	Antiderivative $F(x)$	Integral $\int_{x_1}^{x_2} f(x)\,dx$
a	ax	$ax_2 - ax_1$
$mx + b$	$\frac{1}{2}mx^2 + bx$	$[\frac{1}{2}mx_2^2 + bx_2] - [\frac{1}{2}mx_1^2 - bx_1]$
$x^n\ (n \neq -1)$	$\dfrac{1}{n+1}x^{n+1}$	$\dfrac{1}{n+1}(x_2^{n+1} - x_2^{n+1})$
$\dfrac{1}{x} = x^{-1}\ (x > 0)$	$\ln x$	$(\ln x_2 - \ln x_1) = \ln \dfrac{x_2}{x_1}$
$\dfrac{1}{x^2} = x^{-2}$	$-\dfrac{1}{x}$	$-\left(\dfrac{1}{x^2} - \dfrac{1}{x_1}\right)$
e^{ax}	$\dfrac{e^{ax}}{a}$	$\dfrac{1}{a}(e^{ax_2} - e^{ax_1})$

The constants a, b, m, and n may be positive or negative.

Finally, if the upper and lower limits of integration are reversed, the sign of the integral changes as well. This is easily seen from the antiderivative form:

$$\int_{x_1}^{x_2} f(x)\,dx = F(x_1) - F(x_2) = -[F(x_2) - F(x_1)] = -\int_{x_1}^{x_2} f(x)\,dx$$

C.6 PROBABILITY

Many applications in chemistry require us to interpret—and even predict—the results of measurements where we have only limited information about the system and the process involved. In such cases the best we can do is identify the possible outcomes of the experiment and assign a *probability* to each of them. Two examples illustrate the issues we face. In discussions of atomic structure, we would like to know the position of an electron relative to the nucleus. The principles of quantum mechanics tell us we can never know the exact location or trajectory of an electron; the most information we can have is the probability of finding an electron at each point in space around the nucleus. In discussing the behavior of a macroscopic amount of helium gas confined at a particular volume, pressure, and temperature we would like to know the speed with which an atom is moving in the container. We do not have experimental means to "tag" a particular atom, track its motions in the container, and measure its speed. The best we can do is estimate the probability that some typical atom is moving with each possible speed.

Everyone is familiar with the common sense concept of probability as a way to assess the likelihood of a desirable outcome in a game of chance. The purpose of this section is to give a brief introduction to probability in a form suited for scientific work.

Random Variable

The first step in setting up a probability model of a statistical experiment is to define the **random variable *X*,** the measurable quantity whose values *fluctuate,* or change, as we carry out many repetitions of the experiment. While defining the random variable, we also identify the **outcomes** of the statistical experiment, the possible values that X can take as we carry out many repetitions. If the experiment consists of flipping a coin, then X is simply the label on the side of the coin facing up, and the only possible outcomes are H for "heads" and T for "tails." If the ex-

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

periment consists of rolling a die, X is the number of dots on the side facing up, with integral values from 1 to 6. If the experiment is rolling a pair of dice, X is the sum of the number of dots on the two sides facing up, with integral values from $1 + 1 = 2$ to $6 + 6 = 12$. If the experiment is to find the position of an electron in an atom, X is then r, the distance from the nucleus to the electron, and it can range from 0 to infinity. If the experiment is to find the speed of an atom in a sample of gas, X is then u, the speed of the atom, which can range from 0 to some large value.

Probability and Probability Functions

It is convenient to set up a graphical representation of the probability model. We represent the random variable X along the horizontal axis of an ordinary Cartesian graph. The possible outcomes of measuring X are shown as points along the horizontal axis. We see from the earlier examples that these can be either discrete or continuous values, depending on the nature of X. Along the vertical axis we want to plot $P(X)$, the probability of observing the random variable to have the value X, for each of the possible outcomes.

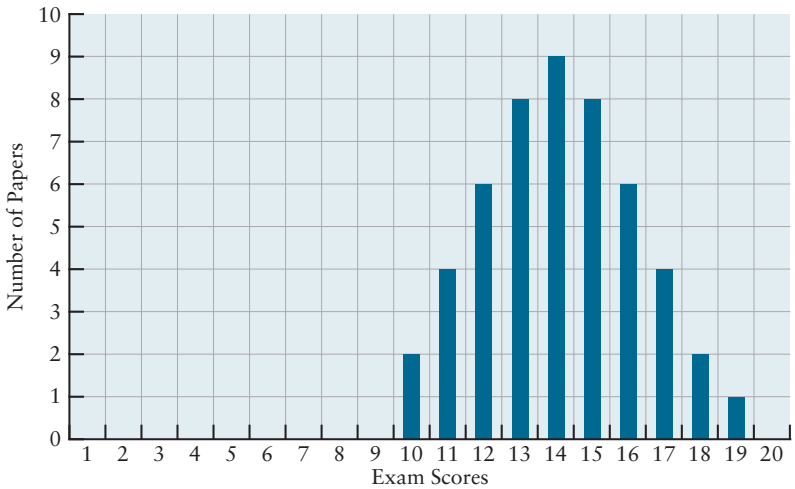
The **probability function *P(X)*** is generated by making multiple measurements of the random variable X and recording the results in a histogram. The performance of a chemistry class with 50 students on a quiz with maximum score 20 is a good example of a statistical experiment. Here the random variable X is the score a student achieves, and the possible outcomes are the integers from 0 to 20. The set of graded papers constitute 50 repetitions of the statistical experiment, and the results are summarized in Figure C.4. We define the probability that a particular score was achieved on the exam to be the fraction of the papers with that score:

$$P(X_i) = \frac{n_i(X_i)}{N}$$

where $n_i(X_i)$ is the number of papers with score X_i and N is the total number of papers. Figure C.5 shows the probability function generated from the data in Figure C.4. The function has a maximum at $X = 14$, which is labeled the **most probable value X_{mp}**. This is the value that appears most often in the experimental data. Probability is a pure number; it does not have physical dimensions. Probability cannot be determined from a single measurement; many repetitions of the statistical experiment are required for the definition of probability.

The probability function has the interesting property that its sum over all the possible outcomes is 1:

$$P_0 + P_1 + \ldots + P_{19} + P_{20} = \frac{1}{50}(n_0 + n_1 + \ldots + n_{19} + n_{20}) = \frac{50}{50} = 1$$



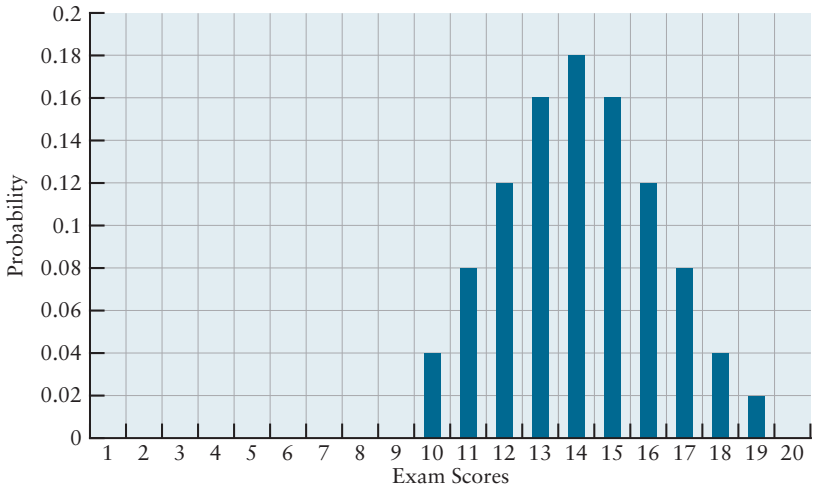


FIGURE C.4 Distribution of exam scores in a class of 50 students.

FIGURE C.5 Probability function for the exam scores in Figure C.4.

We represent this long sum in the following compact way where the uppercase Greek sigma means "add up all the terms," and the running index i indicates the term for each possible outcome from 0 to 20:

$$\sum_{i=0}^{20} P_i = \frac{1}{50}\sum_{i=0}^{20} n_i = \frac{50}{50} = 1$$

A probability function with this property is said to be **normalized.** Normalization signifies that we have accounted for all the possible outcomes: the probability that *some* score is achieved is 1. We should always check that a probability function is normalized before using it in further calculations.

Average Values of the Random Variable

The probability function is used in numerous statistical analyses of the experiment, only one of which we describe here. We calculate $\overline{X}$, the *mean,* or average, value of the random variable, by multiplying each possible outcome by its probability and summing over all the possible outcomes. In our compact form this operation for the probability function in Figure C.5 is

$$\overline{X} = \sum_{i=0}^{20} X_i P(X_i) = \frac{1}{50}\sum_{i=0}^{20} X_i n_i = 14.7$$

The mean value is one way to convey the essence of the probability function in a single number: Is the overall class performance on the exam good, fair, or poor? Another way is to state the most probable value X_{mp}. In this example the mean value is slightly larger than the most probable value because the distribution slightly favors the high end of the range, courtesy of the student who scored 19 of 20! The mean and most probable values coincide only when the distribution is perfectly symmetrical about the maximum. The complete probability function gives much more insight into the results of the experiment than the mean or most probable values standing alone.

Probability Density: Continuous Random Variables and Probability Functions

When the random variable is continuous, as in the case of the position of the electron and speed of the helium atom referred to earlier, we must consider every point of the X axis—not just the integers—as a possible outcome. Therefore, we cannot define the probability of observing a specific value, which we call X_0. Rather, we define the probability that X falls within a narrow, infinitesimal interval between X_0 and $X_0 + dX$. When the interval dX is sufficiently small, the probability will be

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

proportional to the width of the interval, and we define the probability as follows:

$$[\text{Probability of } X \text{ falling in the interval between } X_0 \text{ and } X_0 + dX] = \mathcal{P}(X_0)dX$$

Because this analysis is required at each point X, we drop the subscript 0, and discuss the properties of $\mathcal{P}(X)$ in general. The function $\mathcal{P}(X)$, called the **probability density function** for X, is plotted as a continuous function above the X-axis. It is defined for all points in an interval (a, b) whose end points depend on the nature of X. In some cases the end points can include $+\infty, -\infty$, or both. Note that $\mathcal{P}(X)$ has physical dimensions of X^{-1}, since the product $\mathcal{P}(X)dX$ must be dimensionless.

The probability density plays the same role for continuous variables as does $P(X)$ for discrete random variables. The normalization condition becomes

$$\int_a^b \mathcal{P}(X)dX = 1$$

and the mean value of X is calculated as

$$\overline{X} = \int_a^b X \cdot \mathcal{P}(X)dX$$

The symmetry of the probability density function determines whether the most probable and mean values of X coincide. We use a special symbol here to distinguish probability density from probability. In the main portion of the textbook we do not always make that distinction in symbols. But, it is always clear from context whether we are discussing a probability function or a probability density function.

Experimental Tests of Theoretical Probability

Theoretical probability identifies the possible outcomes of a statistical experiment, and uses theoretical arguments to predict the probability of each. Many applications in chemistry take this form. In atomic and molecular structure problems, the general principles of quantum mechanics predict the probability functions. In other cases the theoretical predictions are based on assumptions about the chemical or physical behavior of a system. In all cases, the validity of these predictions must be tested by comparison with laboratory measurements of the behavior of the same random variable. A full determination of experimental probability, and the mean values that come from it, must be obtained and compared with the theoretical predictions. A theoretical prediction of probability can never be tested or interpreted with a single measurement. A large number of repeated measurements is necessary to reveal the true statistical behavior.

PROBLEMS

Answers to problems whose numbers are boldface appear in Appendix G.

Using Graphs

1. A particular plot of distance traveled against time elapsed is found to be a straight line. After an elapsed time of 1.5 hours, the distance traveled was 75 miles, and after an elapsed time of 3.0 hours, the distance traveled was 150 miles. Calculate the slope of the plot of distance against time, and give its units.

2. The pressure of a gas in a rigid container is measured at several different temperatures, and it is found that a plot of pressure against temperature is a straight line. At 20.0°C the pressure is 4.30 atm, and at 100.0°C the pressure is 5.47 atm. Calculate the slope of the plot of pressure against temperature and give its units.

3. Rewrite each of the following linear equations in the form $y = mx + b$, and give the slope and intercept of the corresponding plot. Then draw the graph.
(a) $y = 4x - 7$
(b) $7x - 2y = 5$
(c) $3y + 6x - 4 = 0$

4. Rewrite each of the following linear equations in the form $y = mx + b$, and give the slope and intercept of the corresponding plot. Then draw the graph.
(a) $y = -2x - 8$
(b) $-3x + 4y = 7$
(c) $7y - 16x + 53 = 0$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5. Graph the relation

$$y = 2x^3 - 3x^2 + 6x - 5$$

from $y = -2$ to $y = +2$. Is the plotted curve a straight line?

6. Graph the relation

$$y = \frac{8 - 10x - 3x^2}{2 - 3x}$$

from $x = -3$ to $x = +3$. Is the plotted curve a straight line?

Solution of Algebraic Equations

7. Solve the following linear equations for x.
(a) $7x + 5 = 0$
(b) $-4x + 3 = 0$
(c) $-3x = -2$

8. Solve the following linear equations for x.
(a) $6 - 8x = 0$
(b) $-2x - 5 = 0$
(c) $4x = -8$

9. Solve the following quadratic equations for x.
(a) $4x^2 + 7x - 5 = 0$
(b) $2x^2 = -3 - 6x$
(c) $2x + \dfrac{3}{x} = 6$

10. Solve the following quadratic equations for x.
(a) $6x^2 + 15x + 2 = 0$
(b) $4x = 5x^2 - 3$
(c) $\dfrac{1}{2 - x} + 3x = 4$

11. Solve each of the following equations for x using the approximation of small x, iteration, or graphical solution, as appropriate.
(a) $x(2.00 + x)^2 = 2.6 \times 10^{-6}$
(b) $x(3.00 - 7x)(2.00 + 2x) = 0.230$
(c) $2x^3 + 3x^2 + 12x = -16$

12. Solve each of the following equations for x using the approximation of small x, iteration, or graphical solution, as appropriate.
(a) $x(2.00 + x)(3.00 - x)(5.00 + 2x) = 1.58 \times 10^{-15}$
(b) $x\dfrac{(3.00 + x)(1.00 - x)}{2.00 - x} = 0.122$
(c) $12x^3 - 4x^2 + 35x = 10$

Powers and Logarithms

13. Calculate each of the following expressions, giving your answers the proper numbers of significant figures.
(a) $\log (3.56 \times 10^4)$
(b) $e^{-15.69}$
(c) $10^{8.41}$
(d) $1n (6.893 \times 10^{-22})$

14. Calculate each of the following expressions, giving your answers the proper numbers of significant figures.
(a) $10^{-16.528}$
(b) $\ln (4.30 \times 10^{13})$
(c) $e^{14.21}$
(d) $\log (4.983 \times 10^{-11})$

15. What number has a common logarithm of 0.4793?

16. What number has a natural logarithm of -15.824?

17. Determine the common logarithm of 3.00×10^{121}. It is quite likely that your calculator will *not* give a correct answer. Explain why.

18. Compute the value of $10^{-107.8}$. It is quite likely that your calculator will *not* give the correct answer. Explain why.

19. The common logarithm of 5.64 is 0.751. Without using a calculator, determine the common logarithm of 5.64×10^7 and of 5.64×10^{-3}.

20. The common logarithm of 2.68 is 0.428. Without using a calculator, determine the common logarithm of 2.68×10^{192} and of 2.68×10^{-289}.

21. Use the graphical method and a calculator to solve the equation

$$\log \ln x = -x$$

for x. Give x to four significant figures.

22. Use a calculator to find a number that is equal to the reciprocal of its own natural logarithm. Report the answer to four significant figures.

Slopes of Curves and Derivatives

23. Calculate the derivatives of the following functions.
(a) $y = 4x^2 + 4$
(b) $y = \sin 3x + 4 \cos 2x$
(c) $y = 3x + 2$
(d) $y = \ln 7x$

24. Calculate the derivatives of the following functions.
(a) $y = 6x^{19}$
(b) $y = 7x^2 + 6x + 2$
(c) $y = e^{-6x}$
(d) $y = \cos 2x + \dfrac{7}{x}$

Areas under Curves and Integrals

25. Calculate the following integrals.
(a) $\displaystyle\int_2^4 (3x + 1)dx$
(b) $\displaystyle\int_0^5 x^6 dx$
(c) $\displaystyle\int_1^4 e^{-2x} dx$

26. Calculate the following integrals.
(a) $\displaystyle\int_{-1}^3 4\, dx$
(b) $\displaystyle\int_2^{100} \frac{1}{x} dx$
(c) $\displaystyle\int_2^4 \frac{5}{x^2} dx$

APPENDIX D

STANDARD CHEMICAL THERMODYNAMIC PROPERTIES

This table lists standard enthalpies of formation ΔH_f°, standard third-law entropies $S°$, standard free energies of formation ΔG_f°, and molar heat capacities at constant pressure, C_P, for a variety of substances, all at 25°C (298.15 K) and 1 atm. The table proceeds from the left side to the right side of the periodic table. Binary compounds are listed under the element that occurs to the left in the periodic table, except that binary oxides and hydrides are listed with the other element. Thus, KCl is listed with potassium and its compounds, but ClO_2 is listed with chlorine and its compounds.

Note that the *solution-phase* entropies are not absolute entropies but are measured relative to the arbitrary standard $S°(H^+(aq)) = 0$. Consequently, some of them (as well as some of the heat capacities) are negative.

Most of the thermodynamic data in these tables were taken from the *NBS Tables of Chemical Thermodynamic Properties* (1982) and changed, where necessary, from a standard pressure of 0.1 MPa to 1 atm. The data for organic compounds $C_nH_m(n > 2)$ were taken from the *Handbook of Chemistry and Physics* (1981).

APPENDIX E

STANDARD REDUCTION POTENTIALS AT 25°C

Half-Reaction	$E°$ (volts)
$F_2(g) + 2\ e^- \longrightarrow 2\ F^-$	2.87
$H_2O_2 + 2\ H_3O^+ + 2\ e^- \longrightarrow 4\ H_2O$	1.776
$PbO_2(s) + SO_4^{2-} + 4\ H_3O^+ + 2\ e^- \longrightarrow PbSO_4(s) + 6\ H_2O$	1.685
$Au^+ + e^- \longrightarrow Au(s)$	1.68
$MnO_4^- + 4\ H_3O^+ + 3\ e^- \longrightarrow MnO_2(s) + 6\ H_2O$	1.679
$HClO_2 + 2\ H_3O^+ + 2\ e^- \longrightarrow HClO + 3\ H_2O$	1.64
$HClO + H_3O^+ + e^- \longrightarrow Cl_2(g) + 2\ H_2O$	1.63
$Ce^{4+} + e^- \longrightarrow Ce^{3+}$ (1 M HNO_3 solution)	1.61
$2\ NO(g) + 2\ H_3O^+ + 2\ e^- \longrightarrow N_2O(g) + 3\ H_2O$	1.59
$BrO_3^- + 6\ H_3O^+ + 5\ e^- \longrightarrow Br_2(\ell) + 9\ H_2O$	1.52
$Mn^{3+} + e^- \longrightarrow Mn^{2+}$	1.51
$MnO_4^- + 8\ H_3O^+ + 5\ e^- \longrightarrow Mn^{2+} + 12\ H_2O$	1.491
$ClO_3^- + 6\ H_3O^+ + 5\ e^- \longrightarrow Cl_2(g) + 9\ H_2O$	1.47
$PbO_2(s) + 4\ H_3O^+ + 2\ e^- \longrightarrow Pb^{2+} + 6\ H_2O$	1.46
$Au^{3+} + 3\ e^- \longrightarrow Au(s)$	1.42
$Cl_2(g) + 2\ e^- \longrightarrow 2\ Cl^-$	1.3583

APPENDIX G

ANSWERS TO ODD-NUMBERED PROBLEMS

CHAPTER 1

1. Mercury is an element; water and sodium chloride are compounds. The other materials are mixtures: seawater and air are homogeneous; table salt and wood are heterogeneous. Mayonnaise appears homogeneous to the naked eye, but under magnification shows itself as water droplets suspended in oil.

3. Substances

5. 16.9 g

7. (a) 2.005 and 1.504 g
(b) 2.005/1.504 5 1.333 5 4/3; SiN (or a multiple)

9. 2, 3, 4, 5

11. (a) HO (or any multiple, such as H_2O_2)
(b) All would give H_2 and O_2 in 1:1 ratio.

13. 2.0 L N_2O, 3.0 L O_2

15. 28.086

17. 11.01

19. (a) 145/94 = 1.54
(b) 94 electrons

21. 95 protons, 146 neutrons, 95 electrons

CHAPTER 2

1. 2.107298×10^{-22} g

3. (a) 283.89 (b) 115.36 (c) 164.09 (d) 158.03 (e) 132.13

5. The total count of 2.52×10^{9} atoms of gold has a mass of only 8.3×10^{-13} g, which is far too small to detect with a balance.

7. 1.041 mol

9. 2540 cm^3 = 2.54 L

11. 7.03×10^{23} atoms

83. (a) Copper(I) sulfide and copper(II) sulfide (b) Sodium sulfate
(c) Tetraarsenic hexaoxide (d) Zirconium(IV) chloride
(e) Dichlorine heptaoxide (f) Gallium(I) oxide

CHAPTER 4

1. 0.66 m s^{-1}

3. 3.04 m

5. (a) 5.00×10^5 s^{-1} (b) 4.4 min

7. $\lambda = 1.313$ m; time = 0.0873 s

9. 2.7 K

11. Red

13. 550 nm, green

15. (a) 3.371×10^{-19} J (b) 203.0 kJ mol^{-1} (c) 4.926×10^{-3} mol s^{-1}

17. 5.895×10^{-7} m

19. $r_3 = 0.0952$ nm, $E_3 = 26.06 \times 10^{-18}$ J, energy per mole = 3.65×10^3 kJ mol^{-1}, $\nu = 1.14 \times 10^{16}$ s^{-1}, $\lambda = 2.63 \times 10^{-8}$ m = 26.3 nm

21. 72.90 nm, ultraviolet

23. Blue

25. Part of the yellow light, together with green and blue light, will eject electrons from cesium. No visible light will eject electrons from selenium; ultraviolet light is required.

27. (a) 7.4×10^{-20} J (b) 4.0×10^5 m s^{-1}

29. (a) 100 cm, 33 cm (b) two nodes

31. (a) 7.27×10^{-7} m (b) 3.96×10^{10} m (c) 2.2×10^{-34} m

35. (a) 5.8×10^4 m s^{-1} (b) 7.9 m s^{-1}

37. $E_1 = 3.36 \times 10^{-18}$ J; $E_2 = 1.34 \times 10^{-17}$ J; $E_3 = 3.02 \times 10^{-17}$ J; $\lambda = 1.97 \times 10^8$ m

39. (a) $\tilde{\Psi}_{21} = \tilde{\Psi}_{12}$ because the x- and y-axes are equivalent in a square box.
(b) Exchanging x and y corresponds to a 90-degree rotation.
(c) Exchanging labels cannot change the energy of the particle, a physically observable quantity.

CHAPTER 5

1. Only (b) is allowed.

3. (a) $4p$ (b) $2s$ (c) $6f$

5. (a) 2 radial, 1 angular (b) 1 radial, 0 angular (c) 2 radial, 3 angular

7. $R_{pz}^2 \propto \cos^2 q = 0$ for $= 5\ p/2$; d_{xz} nodal planes are the y–z and x–y planes; $d_{x^2-y^2}$ nodal planes are two planes containing the z-axis at 45° from the x- and y-axes.

9. 3.17 Å, 2.64 Å

11. $\varepsilon_{2s} = -0.397$ Ry $= -521$ kJ mol^{-1}

13. −1 Ry exactly, −0.397 Ry, −0.376 Ry

15. (a) $1s^2 2s^2 2p^2$ (b) $[Ar]3d^{10}4s^2 4p^4$ (c) $[Ar]3d^6 4s^2$

17. Be^+: $1s^2 2s^1$; C^-: $1s^2 2s^2 2p^3$; Ne^{2+}: $1s^2 2s^2 2p^4$; Mg^+: $[Ne]3s^1$; P^{2+}: $[Ne]3s^2 3p^1$; Cl^-: $[Ne]3s^2 3p^6$; As^+: $[Ar]3d^{10}4s^2 4p^2$; I^-: $[Kr]4d^{10}5s^2 5p^6$. All except Cl^- and I^- are paramagnetic.

19. (a) In (b) S^{2-} (c) Mn^{4+}

21. 117

23. First "noble gases" at $Z = 1, 5, 9$

25. 9.52 eV or 1.52×10^{-18} J

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

29. (a) $Z_{\text{eff},1s} = 7.12$ (b) $Z_{\text{eff},2s}$ approx equal 3.2 (c) $Z_{\text{eff},2p}$ approx equal 1.9

31. (a) K (b) Cs (c) Kr (d) K (e) Cl^-

33. (a) S^{2-} (b) Ti^{2+} (c) Mn^{2+} (d) Sr^{2+}

35. (a) For definition see Section 3.4. Helium has two electrons in the 1*s* orbital, which has the smallest radius. Moreover, each electron only partially screens the other from the nucleus, which has charge +2. Therefore, removal of the first electron requires considerable energy.
(b) Li, because Li^+ is essentially like He and explanation in (a) applies.
(c) 50.4 nm

37. (a) Start with Ca^{2+} and Ar, which are isoelectronic; that is, they have the same number of electrons. Ca^{2+} has the higher nuclear charge and is therefore smaller. Mg is above Ca in Group 2, so its 2+ ion is smaller than that of Ca. Br^- is larger than Cl^- in Group 7, which is, in turn, larger than Ar. Therefore, $Mg^{2+} < Ca^{2+} < Ar < Br^2$.
(b) Na has one *s* electron, well shielded from the nucleus; Ne and Na^+ are isoelectronic, but Na+ has a net positive charge; O has an unfilled shell, but no special stability relative to Ne. Therefore, Na < O < Ne < Na+.
(c) Al is metallic, and thus electropositive; electronegativity sequence of others follows their relative horizontal positions in the periodic table. Therefore, Al < H < O < F.

39. 318.4 nm, near ultraviolet

CHAPTER 6

1. 0, 1, 2, 3, 2, 3 (6 σ orbitals in order of increasing energy)

3. All circles.

5. The $1\sigma_g$ MO

7. State (b) has higher energy because it has two electrons in the anti-bonding MO.

9. H_2

11. He_2^+

15. Smaller bond energy; larger bond length

17. (a) F_2: $(\sigma_{g2s})^2(\sigma^*_{u2s})^2(\sigma_{g2p})^2(\pi_{u2p})^4(\pi^*_{g2p})^4$; F_2^+ : $(\sigma_{g2s})^2(\sigma^*_{u2s})^2(\sigma_{g2p})^2(\pi_{u2p})^4(\pi^*_{g2p})^3$
(b) F_2: 1, F_2^+ : $\frac{3}{2}$
(c) F_2^+ should be paramagnetic.
(d) $F_2 < F_2^+$

19. $(\sigma_{g3s})^2(\sigma^*_{u3s})^2(\sigma_{g3pz})^2(\pi_{u3p})^4(\pi^*_{g3p})^2$ bond order = 2; paramagnetic

21. (a) F, 1 (b) N, $2\frac{1}{2}$ (c) O, $1\frac{1}{2}$

23. (a) is diamagnetic; (b) and (c) are paramagnetic.

25. Bond order $2\frac{1}{2}$, paramagnetic

27. The outermost electron in CF is in a π^*_{2p} molecular orbital. Removing it gives a stronger bond.

29. $(\sigma_{1s})^2(\sigma^*_{1s})^2$ bond order = 0. It should be unstable.

31. Ground state electronic configurations

CF: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\pi_{2px}, \pi_{2py})^4(\sigma_{2pz})^2(\pi^*_{2px}, \pi^*_{2py})^1$

CH: $(\sigma^{nb})^2\sigma^1(\pi^{nb}_x, \pi^{nb}_y)^2$

CH^+: $(\sigma^{nb})^2\sigma^1(\pi^{nb}_x, \pi^{nb}_y)^1$

CN^-: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\pi_{2px}, \pi_{2py})^4(\sigma_{2pz})^2$

CF, CH, and CH^+ have unpaired electrons

33. Ground state electronic configurations and bond orders:

CF^+: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\pi_{2px}, \pi_{2py})^4(\sigma_{2pz})^2$ BO = (0.5)(8 − 2) = 3

CF^-: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\pi_{2px}, \pi_{2py})^4(\sigma_{2pz})^2(\pi^*_{2px}, \pi^*_{2py})^2$ BO = (0.5)(8 − 4) = 2

NO: $(\sigma_{2s})^2(\sigma^*_{2s})^2(\pi_{2px}, \pi_{2py})^4(\sigma_{2pz})^2(\pi^*_{2px}, \pi^*_{2py})^1$ BO = (0.5)(8 − 3) = 2.5

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Bond dissociation energies are ranked $CF^+ > NO > CF^-$ because bond dissociation energy correlates with bond order.

35. (a) IE = 15.6 eV, from σ_{g2pz}, which is highest occupied level.
(b) IE = 16.7 eV, from π_{u2pxy}, which is second-highest occupied level.

39. 11.88 eV: the $4p_x$ or the $4p_y$ orbital; 15.2 eV: the σ orbital

41. Li_2: $\psi_\sigma^{bond}\ (1, 2; R_{AB}) = c_1[2s^A(1)2s^B(2)\ 1\ 2s^A(2)2s^B(1)]$

C_2: $\psi_\pi^{bond}\ (1, 2, 3, 4; R_{AB}) = c_1R_{AB}[2\ p_y^A\ (1)\ 2\ p_y^B\ (2)][2\ p_x^A\ (3)\ 2\ p_x^B\ (4)] + c_1R_A$ $[2\ p_y^A\ (2)\ 2\ p_y^B\ (1)][2\ p_x^A\ (4)\ 2\ p_x^B\ (3)]$

43. Because the ground state of Be has no unpaired electrons, the simple VB model predicts that a bond will not form between two Be atoms. The same result is predicted by the LCAO approach. Two of the valence electrons in Be_2 occupy a bonding molecular orbital, but the other two must occupy an antibonding molecular orbital, leading to bond order zero.

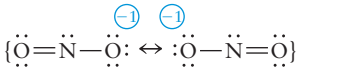
45. $\psi_\sigma^{bond}\ (1, 2; R_{BH}) = C_1[1s^H(1)2\ p_z^B\ (2)] + C_2[1s^H(2)2\ p_z^B\ (1)]$

The simple VB model predicts a diatomic molecule BH. This is incorrect. The correct prediction is BH_3.

47. N has one unpaired electron in each of its 2*p* orbitals. Each of these can overlap with H 1*s* to form an s bond whose wave function has the form $\psi_\sigma = C_1[2\ p_a^N\ (1)1s^H(2)] + C_2[2\ p_a^N\ (2)1s^H(1)]$ where *a* is *x*, *y*, or *z*.

Because the 2*p* orbitals are mutually perpendicular, the simple VB model predicts a trigonal pyramid with angles of 90 degrees.

49. sp^3 hybridization of central N^- bent molecular ion



51. (a) sp^3 on C, tetrahedral
(b) *sp* on C, linear
(c) sp^3 on O, bent
(d) sp^3 on C, pyramidal
(e) *sp* on Be, linear

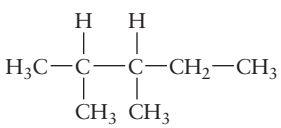
53. sp^2 hybrid orbitals. ClO_3^+ is trigonal planar, ClO_2^+ is bent.

55. sp^3 hybrid orbitals, tetrahedral

59. Sixteen electrons, so molecule is linear; *sp* hybridization of central N gives two σ bonds, with $2p_z$ orbitals on outer nitrogen atoms (four electrons). Lone pairs on both 2*s* orbitals on outer nitrogen atoms (four atoms). π system as in Figure 6.22: $(\pi)^4(\pi^{nb})^4$ with eight electrons. Total bond order = 4; bond order 2 per N^- bond. N_3 and N_3^+ should be bound. N_3 and N_3^+ are paramagnetic.

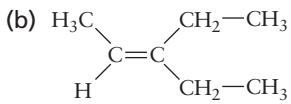
61.

$SN = 3$, sp^2 hybridization, bent molecule. The $2p_z$ orbitals perpendicular to the plane of the molecule can be combined into a π molecular orbital containing one pair of electrons. This orbital adds bond order 1/2 to each N—O bond, for a total bond order of 3/2 per bond.



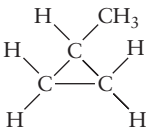
CHAPTER 7

1. Yes, if the amount of knocking is less than that of iso-octane. Examples are the BTX compounds.

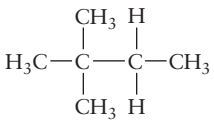


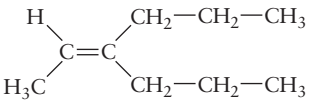
3. Ethane; $2\ C_2H_6(g) + 7\ O_2(g) \longrightarrow CO_2(g) + 6\ H_2O(\ell)$

5. (a) $C_{10}H_{22} \longrightarrow C_5H_{10} + C_5H_{12}$
(b) Two: 1-pentene and 2-pentene



7. (a)





(b)

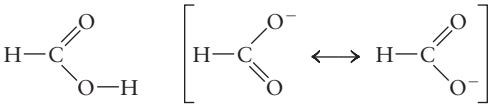
(b) All sp^2
(c) sp^2, sp^2; all others sp^3
(d) sp^3, sp^3, sp, sp, sp^3, sp^3

15. 30 double bonds; on the bonds shared by two hexagonal faces

17. 11.2%; 4.49×10^9 kg

19. (a) $CH_3CH_2CH_2CH_2OH + CH_3COOH \longrightarrow CH_3COOCH_2CH_2CH_2CH_3 + H_2O$
(b) $NH_4CH_3COO \longrightarrow CH_3CONH_2 + H_2O$
(c) $CH_3CH_2CH_2OH \longrightarrow CH_3CH_2CHO$ (propionaldehyde) $+ H_2$
(d) $CH_3(CH_2)_5CH_3 + 11\ O_2 \longrightarrow 7\ CO_2 + 8\ H_2O$



21. (a) $CH_2{=}CH_2 + Br_2 \longrightarrow CH_2BrCH_2Br$; $CH_2BrCH_2Br \longrightarrow CH_2 = CHBr + HBr$
(b) $CH_3CH_2CH = CH_2 + H_2O \longrightarrow CH_3CH_2CH(OH)CH_3$ (using H_2SO_4)
(c) $CH_3CH = CH_2 + H_2O \longrightarrow CH_3CH(OH)CH_3$ (using H_2SO_4);
$CH_3CH(OH)CH_3 \longrightarrow CH_3COCH_3 + H_2$ (copper or zinc oxide catalyst)

23. 

25. 79.9 L

27. $-CH_3$ carbon sp^3, other carbon sp^2. A π orbital with two electrons bonds the second carbon atom with the oxygen atom. The three groups around the second carbon form an approximately trigonal planar structure, with bond angles near 120 degrees. The geometry about the first carbon atom is approximately tetrahedral, with angles near 109.5 degrees.

29. The Lewis diagrams for HCOOH and $HCOO^-$ are

One resonance form is given for HCOOH, but two are given for the formate anion $HCOO^-$. In formic acid, one oxygen atom is doubly bonded to the carbon atom, and

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the other is singly bonded. In the anion, there is some double-bond character in both C—O bonds. The carbon atom in HCOOH is sp^2 hybridized (*SN* 3), and the OH oxygen atom is sp^3 hybridized (*SN* 4). The immediate surroundings of the carbon atom have trigonal planar geometry, and the C—O—H group is bent. In the $HCOO^-$, the carbon atom and both oxygen atoms are sp^2 hybridized (*SN* 3), possessing a three-center four-electron *p* system. In HCOOH, *p* overlap occurs between orbitals on the carbon atom and only one oxygen atom. Both the C— to —O bond lengths in the formate ion should lie somewhere between the value for the single bond (1.36 Å) and the value for the double bond (1.23 Å).

31. (a) Alcohol: $CH_3CH(OH)CH_3$, isopropyl alcohol; carboxylic acid: $CH_3C(CH_3)(OCH_3)(CH_2)_3CH(CH_3) = CH_2CH = CHC(CH_3) = CHCOOH$
(b) 3,7,11-Trimethyl-2,4-dodecadiene

33. (a) $C_9H_8O_4$ (b) 1.80×10^{-3} mol

35. Dehydrogenate to make C—O bond from C—OH bond on first ring; move C—C bond from first to second ring; insert C=O group on third ring; remove hydrocarbon side chain on fourth ring together with hydrogen atom and replace it with an —OH group and a $-COCH_2OH$ group.

CHAPTER 8

1. (a) PtF_4 (b) PtF_6

3. $V_{10}O_{28}^{6-} + 16\ H_3O^+ \longrightarrow 10\ VO_2^+ + 24\ H_2O + 5$ state, V_2O_5

5. $2\ TiO_2 + H_2 \longrightarrow Ti_2O_3 + H_2O$ Titanium(III) oxide

7. +2, +4, +3, +7, mixed +2 and +3, +7

9. Small ligands with large charge densities, such as F^-, can stabilize the higher oxidation states of a given transition metal.

11. Al^{3+} is a hard acid that prefers to pair with the hard base O^{2-}, whereas Ni^{2+} and Cu^{2+} are borderline acids that prefer to pair with the soft base S^{2-}.

13. Melting and boiling points. $TiCl_4$ is predicted to be a covalent compound because Ti^{4+} is a high oxidation state cation that can accept electrons from Cl^- ions to form covalent (dative) bonds.

15. Monodentate, at the N-atom lone pair

17. +2, +2, +2, 0

19. (a) $Na_2[Zn(OH)_4]$ (b) $[Co(en)_2Cl_2]NO_3$
(c) $[Pt(H_2O)_3Br]Cl$ (d) $[Pt(NH_3)_4(NO_2)_2]Br_2$

21. (a) Ammonium diamminetetraisothiocyanatochromate(III)
(b) Pentacarbonyltechnetium(I) iodide
(c) Potassium pentacyanomanganate(IV)
(d) Tetra-ammineaquachlorocobalt(III) bromide

23. $[Cu(NH_3)_2Cl_2] < KNO_3 < Na_2[PtCl_6] < [Co(NH_3)_6]Cl_3$

25. (a) $[Pt(NH_3)_2BrCl]$ has two isomers, (*cis* and *trans*). Neither is optically active.
(b) $[Co(CN)_3(H_2O)_2Cl]^-$ has three possible isomers. None of the three isomers is optically active.
(c) $[V(C_2O_4)_3]^{3-}$ is enantiomeric with two possible optical isomers.

27. Three isomeric $[Fe(en)_2Cl_2]^+$ complexes exist.

29. (a) Strong: 1, weak: 5 (b) Strong or weak: 0
(c) Strong or weak: 3 (d) Strong: 2, weak: 4
(e) Strong: 0, weak: 4

31. $[Fe(CN)_6]^{3-}$: 1 unpaired, CFSE = $-2\ \Delta_o$; $[Fe(H_2O)_6]^{3+}$: = unpaired, CFSE = 0

33. d^3 gives half-filled and d^8 filled and half-filled shells for metal ions in an octahedral field. d^5 will be half-filled and stable for high spin (small Δ_o), and d^6 will be a filled subshell and stable for low spin (large Δ_o).

35. This ion does not absorb any significant amount of light in the visible range.

37. $\lambda \approx 480$ nm; $\Delta_o \approx 250$ kJ mol^{-1}

39. -500 kJ mol^{-1}

41. (a) Orange–yellow
(b) Approximately 600 nm (actual: 575 nm)
(c) Decrease, because CN^- is a strong-field ligand and will increase Δ_o.

43. (a) Pale, because F^- is an even weaker field ligand than H_2O, so it should be high-spin d^5. This is a half-filled shell and the complex will absorb only weakly.
(b) Colorless, because Hg(II) is a d^{10} filled-subshell species.

45. $[AuBr_4]^-$ is a low-spin, d^8 square planar complex, the square planar geometry being favored for larger cations. $[NiBr_4]^{2-}$ is high-spin, d^8 tetrahedral complex, the tetrahedral geometry being favored for smaller cations.

CHAPTER 9

1. $NH_4HS(s) \longrightarrow NH_3(g) + H_2S(g)$

3. $NH_4Br(s) + NaOH(aq) \longrightarrow NH_3(g) + H_2O(\ell) + NaBr(aq)$

5. 10.3 m

7. 1.40×10^4 ft

9. 1697.5 atm, 1.7200×10^3 bar

11. 0.857 atm

13. 8.00 L

15. 14.3 gill

17. 134 L

19. 35.2 psi

21. (a) 19.8 atm (b) 23.0 atm

23. The mass of a gas in a given volume changes proportionately to the absolute temperature. This statement will be true only at -19.8°C.

25. (a) $2\ Na(s) + 2\ HCl(g) \longrightarrow 2\ NaCl(s) + H_2(g)$ (b) 4.23 L

27. 3.0×10^6 L

29. 24.2 L

31. (a) 932 L H_2S (b) 1.33 kg, 466 L SO_2

33. $X_{SO_3} = 0.135$; $P_{SO_3} = 0.128$ atm

35. $X_{N_2} = 0.027$; $P_{N_2} = 1.6 \times 10^{-4}$ atm

37. (a) $X_{CO} = 0.444$ (b) $X_{CO} = 0.33$

39. (a) 5.8×10^{17} (b) 520 L

41. (a) 1.93×10^3 m s^{-1} = 1.93 km s^{-1} (b) 226 m s^{-1}

43. 6100 m s^{-1} (6000 K), 790 m s^{-1} (100 K)

45. Greater. As T increases, the Maxwell–Boltzmann distribution shifts to higher speeds.

47. 162 atm = 2.38×10^3 psi

49. (a) 27.8 atm (b) 24.6 atm; attractive forces dominate.

51. 6.1×10^{-9} m

53. 92.6 g mol^{-1}

55. 1830 stages

57. 7.4×10^{-7} atm; 20 m^2 s^{-1}

CHAPTER 10

1. Gas

3. (a) Condensed (b) 10.3 cm^3 mol^{-1}

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5. Condensed

7. The liquid water has vaporized to steam.

9. Harder, because forces binding the particles in NaCl are stronger and resist deformation better.

11. In all three phases, the diffusion constant should decrease as its density is increased. At higher densities, molecules are closer to each other. In gases, they will collide more often and travel shorter distances between collisions. In liquids and solids, there will be less space for molecules to move around each other.

13. Both involve the interaction of an ion with a dipole. In the first case, the dipole is permanent (preexisting), whereas in the second, it is induced by the approach of the ion. Induced dipole forces are weaker than ion–dipole forces. Examples: Na^+ with HCl (ion–dipole); Na^+ with Cl_2 (induced dipole).

15. **(a)** *Ion–ion,* dispersion **(b)** *Dipole–dipole,* dispersion
(c) Dispersion **(d)** Dispersion

17. Bromide ion

19. **(a)** 2.0×10^{-10} m; 2.5×10^{-10} m
(b) KCl has a longer bond yet lower potential energy (greater bond strength).

21. Heavier gases have stronger attractive forces, favoring the liquid and solid states.

23. Ne < NO < NH_3 < RbCl; nonpolar < polar < hydrogen-bonded < ionic

25. An eight-membered ring of alternating H and O atoms is reasonable. The ring is probably not planar.

27. The two have comparable molar masses, but the hydrogen-bonding in hydrazine should give it a higher boiling point.

29. 6.7×10^{25}

31. 6.16 L; several times smaller than the volume of 1 mol at standard temperature and pressure (22.4 L mol^{-1})

33. 7.02×10^{13} atoms cm^{-3}

35. 0.9345 g L^{-1}

37. 2.92 g $CaCO_3$

39. 0.69 atm; 31% lies below

41. Iridium. Its higher melting and boiling points indicate that the intermolecular forces in iridium are stronger than those in sodium.

43. No phase change will occur.

47. **(a)** Liquid **(b)** Gas **(c)** Solid **(d)** Gas

49. **(a)** Above. If gas and solid coexist at −84.0°C, their coexistence must extend upward in temperature to the triple point.
(b) The solid will sublime at some temperature below −84.0°C.

51. The meniscus between gas and liquid phases will disappear at the critical temperature, 126.19 K.

CHAPTER 11

1. **(a)** 5.53×10^{-3} M **(b)** 5.5×10^{-3} molal **(c)** 3.79 L

3. Molarity = 12.39 M in HCl; mole fraction of HCl = 0.2324; molality 16.81 molal in HCl

5. 8.9665 molal

7. 0.00643 g H_2O

9. **(a)** 1.33 g mL^{-1} **(b)** 164 mL

11. 1.06 M in NaOH

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

13. (a) $Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$
(b) $K_2CO_3(s) + 2\ H^+(aq) \longrightarrow 2\ K^+(aq) + CO_2(g) + H_2O(\ell)$
(c) $2\ Cs(s) + 2\ H_2O(\ell) \longrightarrow 2\ Cs^+(aq) + 2\ OH^-(aq) + H_2(g)$
(d) $2\ MnO_4^-(aq) + 16\ H^+(aq) + 10\ Cl^-(aq) \longrightarrow 5\ Cl_2(g) + 2\ Mn^{2+}(aq) + 8\ H_2O(\ell)$

15. 16.8 mL of 7.91 M HNO_3

17. 6.74×10^3 L $CO_2(g)$

19. (a) $Ca(OH)_2(aq) + 2\ HF(aq) \longrightarrow CaF_2(aq) + 2\ H_2O(\ell)$
Hydrofluoric acid, calcium hydroxide, calcium fluoride
(b) $2\ RbOH(aq) + H_2SO_4(aq) \longrightarrow Rb_2SO_4(aq) + 2\ H_2O(\ell)$
Sulfuric acid, rubidium hydroxide, rubidium sulfate
(c) $Zn(OH)_2(s) + 2\ HNO_3(aq) \longrightarrow Zn(NO_3)_2(aq) + 2\ H_2O(\ell)$
Nitric acid, zinc hydroxide, zinc nitrate
(d) $KOH(aq) + CH_3COOH(aq) \longrightarrow KCH_3COO(aq) + H_2O(\ell)$
Acetic acid, potassium hydroxide, potassium acetate

21. Sodium sulfide

23. (a) $PF_3 + 3\ H_2O \longrightarrow H_3PO_3 + 3\ HF$
(b) $[H_3PO_3] = 0.0882$ M; $[HF] = 0.265$ M

25. 0.04841 M HNO_3

27. (a) $2\ \overset{+3}{P}F_2\ I(\ell) + 2\ \overset{0}{Hg}(\ell) \rightarrow \overset{+2}{P}_2\ F_4(g) + \overset{+1}{Hg}_2\ I_2(s)$
(b) $2K\overset{+5}{Cl}\overset{-2}{O}_3(s) \rightarrow 2K\overset{-1}{Cl}(s) + 3\ \overset{0}{O}_2(g)$
(c) $4\ \overset{-3}{N}H_3(g) + 5\ \overset{0}{O}_2(g) \longrightarrow 4\ \overset{+2}{N}\overset{-2}{O}(g) + 6H_2\overset{-2}{O}(g)$
(d) $2\ \overset{0}{As}(s) + 6Na\overset{+1}{O}H(\ell) \longrightarrow 2Na_3\overset{+3}{As}O_3(s) + 3\ \overset{0}{H}_2(g)$

29. $2\ \overset{0}{Au}(s) + 6H_2\overset{+6}{Se}O_4 \longrightarrow \overset{+3}{Au}_2(\overset{+6}{Se}O_4)_3(aq) + 3H_2\overset{+4}{Se}O_3(aq) + 3H_2O_6(\ell)$

Au is oxidized

H_2SeO_4 is reduced (half of it)

31. (a) $2\ VO_2^+(aq) + SO_2(g) \longrightarrow 2\ VO^2(aq) + SO_4^{2-}(aq)$
(b) $Br_2(\ell) + SO_2(g) + 6\ H_2O(\ell) \longrightarrow 2\ Br^-(aq) + SO_4^{2-}(aq) + 4\ H_3O^+(aq)$
(c) $Cr_2O_7^{2-}(aq) + 3\ Np^{4+}(aq) + 2\ H_3O^+(aq) \longrightarrow 2\ Cr^{3+}(aq) + 3\ NpO_2^{2+}(aq) + 3\ H_2O(\ell)$
(d) $5\ HCOOH(aq) + 2\ MnO_4^-(aq) + 6\ H_3O^+(aq) \longrightarrow 5\ CO_2(g) + 2\ Mn^{2+}(aq) + 14\ H_2O(\ell)$
(e) $3\ Hg_2HPO_4(s) + 2\ Au(s) + 8\ Cl^-(aq) + 3\ H_3O^+(aq) \longrightarrow 6\ Hg(\ell) + 3\ H_2PO_4^-(aq) + 2\ AuCl_4^-(aq) + 3\ H_2O(\ell)$

33. (a) $2\ Cr(OH)_3(s) + 3\ Br_2(aq) + 10\ OH^-(aq) \longrightarrow 2\ CrO_4^{2-}(aq) + 6\ Br^-(aq) + 8\ H_2O(\ell)$
(b) $ZrO(OH)_2(s) + 2\ SO_3^{2-}(aq) \longrightarrow Zr(s) + 2\ SO_4^{2-}(aq) + H_2O(\ell)$
(c) $7\ HPbO_2^-(aq) + 2\ Re(s) \longrightarrow 7\ Pb(s) + 2\ ReO_4^-(aq) + H_2O(\ell) + 5\ OH^-(aq)$
(d) $4\ HXeO_4^-(aq) + 8\ OH^-(aq) \longrightarrow 3\ XeO_6^{4-}(aq) + Xe(g) + 6\ H_2O(\ell)$
(e) $N_2H_4(aq) + 2\ CO_3^{2-}(aq) \longrightarrow N_2(g) + 2\ CO(g) + 4\ OH^-(aq)$

35. (a) $Fe^{2+}(aq) \longrightarrow Fe^{3+}(aq) + e^-$ oxidation
$H_2O_2(aq) + 2\ H_3O^+(aq) + 2\ e^- \longrightarrow 4\ H_2O(\ell)$ reduction
(b) $5\ H_2O(\ell) + SO_2(aq) \longrightarrow HSO_4^-(aq) + 3\ H_3O^+(aq) + 2\ e^-$ oxidation
$Mn_4^-(aq) + 8\ H_3O^+(aq) + 5\ e^- \longrightarrow Mn^{2+}(aq) + 12\ H_2O(\ell)$ reduction
(c) $ClO_2^-(aq) \longrightarrow ClO_2(g)\ 1\ e^-$ oxidation
$ClO_2^-(aq) + 4\ H_3O^+(aq) + 4\ e^- \longrightarrow Cl^-(aq) + 6\ H_2O(\ell)$ reduction

37. $3\ HNO_2(aq) \longrightarrow NO_3^-(aq) + 2\ NO(g) + H_3O^+(aq)$

39. 7.175×10^{-3} M $Fe^{2+}(aq)$

41. 0.2985 atm

43. 3.34 K kg mol^{-1}

45. 340 g mol^{-1}

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

47. 1.7×10^2 g mol^{-1}

49. −2.8°C. As the solution becomes more concentrated, its freezing point decreases further.

51. 2.70 particles (complete dissociation of Na_2SO_4 gives 3 particles)

53. 1.88×10^4 g mol^{-1}

55. 7.46×10^3 g mol^{-1}

57. (a) 0.17 mol CO_2
(b) Because the partial pressure of CO_2 in the atmosphere is much less than 1 atm, the excess CO_2 will bubble out from the solution and escape when the cap is removed.

59. 4.13×10^2 atm

61. 0.774

63. (a) 0.491 (b) 0.250 atm (c) 0.575

CHAPTER 12

1. -2.16×10^4 L atm $= -2.19 \times 10^6$ J

3. 86.6 m

5. 24.8, 28.3, 29.6, 31.0, and 32.2 J K^{-1} mol^{-1}, respectively; extrapolating gives about 33.5 J K^{-1} mol^{-1} for Fr.

7. 26.1, 25.4, 25.0, 24.3, 25.4, and 27.6 J K^{-1} mol^{-1}

9. (a) w is zero, q is positive, and ΔU is positive.
(b) w is zero, q is negative, and ΔU is negative.
(c) $(w_1 + w_2)$ is zero. $(\Delta U_1 + \Delta U_2) = (q_1 + q_2)$. The latter two sums could be any of three possibilities: both positive, both negative, or both zero.

11. 0.468 J K^{-1} g^{-1}

13. $q_1 = Mc_{s1}\Delta T_1 = -q_2 = -Mc_{s2}\Delta T_2$ $\qquad \dfrac{C_{s1}}{C_{s2}} = \dfrac{\Delta T_2}{\Delta T_1}$

15. 314 J g^{-1} (modern value is 333 J g^{-1})

17. $w = -323$ J; $\Delta U = -393$ J; $q = -70$ J

19. (a) 38.3 L
(b) $w = -1.94 \times 10^3$ J; $q = 0$; $\Delta U = -1.94 \times 10^3$ J
(c) 272 K

21. $\Delta U = +11.2$ kJ; $q = 0$; $w = +11.2$ kJ

23. For HI:

The measured value is $c_P = 29.16$ J mol^{-1} K^{-1}. (Appendix D)

The vibrational contribution = 29.16 − 29.10 = 0.06 J mol^{-1} K^{-1}.

Per Cent of c_P for HI due to vibration = (0.06/29.16) × 100 = 0.2%

For I_2:

The measured value is $c_P = 36.90$ J mol^{-1} K^{-1}. (Appendix D)

The vibrational contribution = 36.02 − 29.10 = 7.80 J mol^{-1} K^{-1}.

Per cent of c_P for I_2 due to vibration = (7.80/36.90) × 100 = 21.1 %

25. (a) for Argon $\Delta H = 11.4$ kJ
(b) for C_2H_4 $\Delta H = 73.2$ kJ

27. (a) −6.68 kJ (b) +7.49 kJ (c) +0.594 kJ

29. 41.3 kJ

31. +513 J

33. 10.4°C

35. −623.5 kJ

37. A pound of diamonds. (This is recommended as a source of heat only as a last resort, however!)

39. -555.93 kJ

41. (a) -878.26 kJ (b) -1.35×10^7 kJ of heat absorbed

43. (a) -81.4 kJ (b) 55.1°C

45. $\Delta H_f^\circ = -152.3$ kJ mol^{-1}

47. (a) $C_{10}H_8(s) + 12\ O_2(g) \longrightarrow 10\ CO_2(g) + 4\ H_2O(\ell)$
(b) -5157 kJ (c) -5162 kJ (d) $+84$ kJ mol^{-1}

49. -264 kJ mol^{-1}

51. -1.58×10^3 kJ

53. Each side of the equation has three B—Br and three B—Cl bonds.

55. $w = -6.87$ kJ; $q = +6.87$ kJ; $\Delta U = \Delta H = 0$

57. $T_f = 144$ K; $w = \Delta U = 23.89$ kJ; $\Delta H = 26.48$ kJ

59. $N_{high}/N_{low} = 0.91$

61. 5.3×10^{-4}

63. 2.42×10^{-9}

CHAPTER 13

1. (a) The system is all the matter participating in the reaction $NH_4NO_3(s) \longrightarrow NH_4^+(aq) + NO_3^-(aq)$. This includes solid ammonium nitrate, the water in which it dissolves, and the aquated ions that are the products of the dissolution process. The surroundings include the flask or beaker in which the system is held, the air above the system, and other neighboring materials. The dissolution of ammonium nitrate is spontaneous after any physical separation (such as a glass wall or a space of air) between the water and the ammonium nitrate has been removed.

(b) The system is all the matter participating in the reaction $H_2(g) + O_2(g) \longrightarrow$ products. The surroundings are the walls of the bomb and other portions of its environment that might deliver heat or work or absorb heat or work. The reaction of hydrogen with oxygen is spontaneous. Once hydrogen and oxygen are mixed in a closed bomb, no constraint exists to prevent their reaction. It is found experimentally that this system gives products quite slowly at room temperature (no immediate explosion). It explodes instantly at higher temperatures.

(c) The system is the rubber band. The surroundings consist of the weight (visualized as attached to the lower end of the rubber band), a hanger at the top of the rubber band, and the air in contact with the rubber band. The change is spontaneous once a constraint such as a stand or support underneath the weight is removed.

(d) The system is the gas contained in the chamber. The surroundings are the walls of the chamber and the moveable piston head. The process is spontaneous if the force exerted by the weight on the piston exceeds the force exerted by the collisions of the molecules of the gas on the bottom of the piston. (The forces due to the mass of the piston itself and friction between the piston and the walls within which it moves are neglected.)

(e) The system is the drinking glass in the process glass $\longrightarrow$ fragments. The surroundings are the floor, the air, and the other materials in the room. The change is spontaneous. It occurs when the constraint, which is whatever portion of the surroundings holds the glass above the floor, is removed.

3. (a) $6 \times 6 = 36$ (b) 1 in 36

5. The tendency for entropy to increase

7. $10^{-3.62 \times 10^{23}}$ (that is, 1 part in $10^{+3.62 \times 10^{23}}$)

9. (a) $\Delta S > 0$ (b) $\Delta S > 0$ (c) $\Delta S < 0$

11. 9.61 J K^{-1} mol^{-1}

13. 29 kJ mol^{-1}

15. $\Delta U = \Delta H = 0$; $w = -1.22 \times 10^4$ J; $q = +1.22 \times 10^4$ J; $\Delta S = +30.5$ J K^{-1}

17. $\Delta S_{sys} = +30.2$ J K^{-1}; $\Delta S_{surr} = -30.2$ J K^{-1}; $\Delta S_{univ} = 0$

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

19. $\Delta S_{Fe} = -8.24\ J\ K^{-1}$; $\Delta S_{H_2O} = +9.49\ J\ K^{-1}$; $\Delta S_{tot} = +1.25\ J\ K^{-1}$

21. (a) $-116.58\ J\ K^{-1}$ (b) Lower (more negative)

23. $\Delta S° = -162.54, -181.12, -186.14, -184.72, -191.08\ J\ K^{-1}$. The entropy changes in these reactions become increasingly negative with increasing atomic mass, except that the rubidium reaction is out of line.

25. ΔS_{surr} must be positive and greater in magnitude than $44.7\ J\ K^{-1}$.

27. $\Delta S_{sys} > 0$ because the gas produced (oxygen) has many possible microstates.

29. (a) +740 J (b) 2.65 kJ (c) No (d) 196 K

31. $q = +38.7$ kJ; $w = -2.92$ kJ; $\Delta U = +35.8$ kJ; $\Delta S_{sys} = +110\ J\ K^{-1}$; $\Delta G = 0$

33. Overall reaction: $2\ Fe_2O_3(s) + 3\ C(s) \longrightarrow 4\ Fe(s) + 3\ CO_2(g)$ $\Delta G = +840\ J + 3(-400)\ J = -360\ J < 0$

35. (a) $0 < T < 3000$ K
(b) $0 < K < 1050$ K
(c) Spontaneous at all temperatures

37. $WO_3(s) + 3\ H_2(g) \longrightarrow W(s) + 3\ H_2O(g)$
$\Delta H° = 117.41$ kJ; $\Delta S° = 131.19\ J\ K^{-1}$; $\Delta G < 0$ for $T > \Delta H°/\Delta S° = 895$ K

39. (a) 0.333 (b) $q = -1000$ J (c) $w = -500$ J

CHAPTER 14

1. (a) $\dfrac{P_{H_2O}^2}{P_{H_2}^2 P_{O_2}} = K$ (b) $\dfrac{P_{XeF_6}}{P_{Xe}P_{F_2}^3} = K$ (c) $\dfrac{P_{CO_2}^{12} P_{H_2O}^6}{P_{C_6H_6}^2 P_{O_2}^{15}} = K$

3. $P_4(g) + 6\ Cl_2(g) + 2\ O_2(g) \rightleftharpoons 4\ POCl_3(g)$ $\dfrac{P_{POCl_3}^4}{P_{P_4}P_{Cl_2}^6 P_{O_2}^2} = K$

5. (a) $\dfrac{P_{CO_2}P_{H_2}}{P_{CO}P_{H_2O}} = K$ (b) 0.056 atm

7. (a) The graph is a straight line passing through the origin.
(b) The experimental K's range from 3.42×10^{-2} to 4.24×10^{-2}, with a mean of 3.84×10^{-2}.

9. (a) $\dfrac{(P_{H_2S})^8}{(P_{H_2})^8} = K$

(b) $\dfrac{(P_{COCl_2})(P_{H_2})}{(P_{Cl_2})} = K$

(c) $P_{CO_2} = K$

(d) $\dfrac{1}{(P_{C_2H_2})^3} = K$

11. (a) $\dfrac{[Zn^{2+}]}{[Ag^+]^2} = K$

(b) $\dfrac{[VO_3(OH)^{2-}[OH^-]}{[VO_4^{3-}]} = K$

(c) $\dfrac{[HCO_3^-]^6}{[As(OH)_6^{3-}]^2 P_{CO_2}^6} = K$

13. $\Delta G° = -550.23$ kJ; $K = 2.5 \times 10^{96}$

15. (a) 2.6×10^{12} $\dfrac{P_{SO_3}}{(P_{SO_2})(P_{O_2})^{1/2}} = K$
(b) 5.4×10^{-35} $(P_{O_2})^{1/2} = K$
(c) 5.3×10^3 $[Cu^{-1}][Cl^-]^2 = K$

17. $K_1 = (K_2)^3$

19. K_2/K_1

21. 1.04×10^{-4}

71. 76

73. (a) $K_1 = 1.64 \times 10^{-2}$; $K_2 = 5.4$ (b) 330

CHAPTER 15

1. (a) Cl^- cannot act as a Brønsted–Lowry acid.
(b) SO_4^{2-}
(c) NH_3
(d) NH_2^-
(e) OH^-

3. HCO_3^- serves as the base.

5. (a) $CaO(s) + H_2O(\ell) \longrightarrow Ca(OH)_2(s)$
(b) The CaO acts as a Lewis base, donating a pair of electrons (located on the oxide ion) to one of the hydrogen ions (the Lewis acid) of the water molecule.

7. (a) Fluoride acceptor (b) Acids: BF_3, TiF_4; bases: ClF_3O_2, KF

9. (a) Base, $Mg(OH)_2$ (b) Acid, HOCl
(c) Acid, H_2SO_4 (d) Base, CsOH

11. $SnO(s) + 2\ HCl(aq) \longrightarrow Sn^{2+}(aq) + 2\ Cl^-(aq) + H_2O(\ell)$;
$SnO(s) + NaOH(aq) + H_2O(\ell) \longrightarrow Sn(OH)_3^-(aq) + Na^+(aq)$

13. 3.70

15. $3 \times 10^{-7}\ M < [H_3O^+] < 3 \times 10^{-6}\ M$; $3 \times 10^{-9}\ M < [OH^-] < 3 \times 10^{-8}\ M$

17. $[H_3O^+] = 1.0 \times 10^{-8}\ M$; $[OH^-] = 1.7 \times 10^{-6}\ M$

19. The first reaction is more likely to be correct. In the second case, the reactant H_3O^+ would be present at very low concentration (10^{-7} M) and would give neither a fast nor a vigorous reaction.

21. (a) $C_{10}H_{15}ON(aq) + H_2O(\ell) \rightleftharpoons C_{10}H_{15}ONH^+(aq) + OH^-(aq)$
(b) 7.1×10^{-11}
(c) Stronger

23. $K = 24$; $HClO_2$ is the stronger acid and NO_2^- the stronger base.

25. (a) Methyl orange (b) 3.8 to 4.4

27. 2.35

29. (a) 2.45 (b) 0.72 mol

31. 1.2

33. 1.2×10^{-6}

35. 10.4

37. 0.083 M

39. The reaction gives a base of moderate strength, the acetate ion, in solution, so the pH > 7.

41. $HCl < NH_4Br < KI < NaCH_3COO < NaOH$

43. 8.08

45. (a) 4.36 (b) 4.63

47. *m*-Chlorobenzoic acid

49. 639 mL

51. 13.88, 11.24, 7.00, 2.77

53. 2.86, 4.72, 8.71, 11.00

55. 11.89, 11.52, 10.79, 8.20, 6.05, 3.90, 1.95

57. 0.97 g

59. 0.0872 g, pH = 6.23 if no approximations are made, bromothymol blue

79. pK_{a1} should be smaller than 4.9; pK_{a2} should be larger.

CHAPTER 16

1. 4.65 L

3. About 48°C

5. $Fe_2(SO_4)_3(s) \rightleftharpoons 2\ Fe^{3+}(aq) + 3\ SO_4^{2-}(aq)$ $[Fe^+]^2[SO_4^{2-}]^3 = K_{sp}$

7. 0.0665 g per 100 mL water

9. 14.3 g L^{-1}

11. $[I^-] = 6.2 \times 10^{-10}$ M, $[Hg_2^{2+}] = 3.1 \times 10^{-10}$ M

13. 1.9×10^{-12}

15. 1.6×10^{-8}

17. Yes. The initial reaction quotient is $6.2 \times 10^{-10} > K_{sp}$.

19. Yes

21. $[Pb^{2+}] = 2.3 \times 10^{-10}$ M; $[IO_3^-] = 0.033$ M

23. $[Ag^+] = 1.8 \times 10^{-2}$ M; $[CrO_4^{2-}] = 6.2 \times 10^{-9}$ M

25. 2.4×10^{-8} mol L^{-1}

27. **(a)** 3.4×10^{-6} M **(b)** 1.6×10^{-14} M

29. 9.1×10^{-3} M

31. In pure water: 1.2×10^{-4} M; at pH 7: 0.15 M

33. **(a)** Unchanged **(b)** Increase **(c)** Increase

35. 5.3

37. $K_a = 9.6 \times 10^{-10}$

39. In the first case, solid $Pb(OH)_2$ will precipitate; $[Pb^{2+}] = 4.2 \times 10^{-13}$ M, $[Pb(OH)_3^-] = 0.17$ M. In the second case, solid $Pb(OH)_2$ will not precipitate; $[Pb^{2+}] = 1 \times 10^{-13}$ M, $[Pb(OH)_3^-] = 0.050$ M.

41. **(a)** 8.6×10^{-4} M, Pb^{2+} in solid **(b)** 3.1×10^{-7}

43. $[I^-] = 5.3 \times 10^{-4}$ M

45. 2×10^{-13} M

47. pH = 2.4; $[Pb^{2+}] = 6 \times 10^{-11}$ M

49. $[Cu(NH_3)_4^{2+}] = 0.10$ M; $[Cu^{2+}] = 7 \times 10^{-14}$ M

51. $[K^+] = 0.0051$ M and $[Na^+] = 0.0076$ M

53. More will dissolve in 1 M NaCl (3×10^{-5} versus 1.3×10^{-5} mol L^{-1}). Less will dissolve in 0.100 M NaCl (3×10^{-6} versus 1.3×10^{-5} mol L^{-1}).

55. $Cu^{2+}(aq) + 2\ H_2O(\ell) \rightleftharpoons CuOH^+(aq) + H_3O^+(aq)$ or
$Cu(H_2O)_4^{2+}(aq) + H_2O(\ell) \rightleftharpoons Cu(H_2O)_3OH^+(aq) + H_3O^+(aq)$

CHAPTER 17

1. Electrons flow from the left electrode to the right as Cr(II) is oxidized to Cr(III). In the salt bridge, negative ions flow from right to left and positive ions from left to right.

The overall reaction is represented $2\ Cr^{2+}(aq) + Cu^{2+}(s) \longrightarrow 2\ Cr^{3+}(aq) + Cu(s)$

3. 0.180 mol

5. (a) $Zn(s) + Cl_2(g) \longrightarrow Zn^{2+}(aq) + 2\ Cl^-(aq)$
(b) 1.20×10^3 C; 1.24×10^{-2} mol e^-
(c) Decreases by 0.407 g (d) 0.152 L Cl_2 consumed

7. +2

9. (a) Anode: $Cl^- \longrightarrow \frac{1}{2}Cl_2(g) + e^-$; cathode: $K^+ + e^- \longrightarrow K(\ell)$
total: $Cl^- + K^+ \longrightarrow K(\ell) + \frac{1}{2}\ Cl_2(g)$
(b) Mass K = 14.6 g; mass Cl_2 = 13.2 g

11. $\Delta G° = -921$ J; $w_{max} = +921$ J

13. (a) Anode: $Co \longrightarrow Co^{2+} + 2\ e^-$; cathode: $Br_2 + 2\ e^- \longrightarrow 2\ Br^2$;
total: $Co + Br_2 \longrightarrow Co^{2+} + 2\ Br^-$
(b) 1.34 V

15. (a) Anode: $Zn \longrightarrow Zn^{2+} + 2\ e^-$; cathode: $In^{3+} + \times e^- \longrightarrow In$
(b) −0.338 V

17. Reducing agent

19. Br_2 less effective than Cl_2

21. (a) BrO_3^- (b) Cr (c) Co

23. (a) $\mathscr{E} = -0.183$ V (b) It will not disproportionate.

25. (a) No (b) Br^-

27. 0.381 V

29. −0.31 V

31. 5.17

33. (a) 0.31 V (b) 1×10^{-8} M

35. $K = 3 \times 10^{31}$, orange

37. 3×10^6

39. pH = 2.53; $K_a = 0.0029$

41. (a) 1.065 V (b) 1.3×10^{-11} M (c) 7.6×10^{-13}

43. The midpoint between the waves appears at −0.170 V, reflecting the difference between the reduction potentials of the SCE and Ag/AgCl reference electrodes.

45. $E = E_{HOMO} - E_{LUMO} = 2.4$ eV, λ=517 nm, green

47. No, the valence band potential is not sufficiently positive to oxidize water.

49. The redox potential of the HOMO must be more negative than the conduction band of strontium titanate (−0.2 V) in order to inject electrons and that of the LUMO must be more positive than the water oxidation potential (1.229 V) so the minimum HOMO − LUMO gap must be around 1.5 eV.

51. 2.041 V; 12.25 V

53. (a) 9.3×10^6 C (b) 1.1×10^8 J

55. No, because $H_2SO_4(aq)$ is not the only substance whose amount changes during discharge. The accumulated $PbSO_4$ must also be removed and replaced by Pb and PbO_2.

57. 7900 J g^{-1}

59. $\Delta\mathscr{E} = -0.419$ V, not spontaneous under standard conditions (pH 5 14). If $[OH^-]$ is small enough, the equilibrium will shift to the right and the reaction will become spontaneous.

61. According to its reduction potential, yes. In practice, however, the sodium would react instantly and explosively with the water and would therefore be useless for this purpose.

63. $2\ Cl^- \longrightarrow Cl_2(g) + 2\ e^-$ anode
$Na^+ + e^- \longrightarrow Na(\ell)$ cathode

65. 4.4×10^4 kg

67. $2\ Mg + TiCl_4 \longrightarrow Ti + 2\ MgCl_2$; 102 kg

69. 42.4 min

71. (a) Ni
(b) 21.9 g (provided the electrolyte volume is very large)
(c) H_2

CHAPTER 18

1. 5.3×10^{-5} mol L^{-1} s^{-1}

3. $$\text{rate} = -\frac{\Delta[N_2]}{\Delta t} = -\frac{1}{3}\frac{\Delta[H_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[NH_3]}{\Delta t}$$

5. (a) Rate = $k[NO]^2[H_2]$; k has the units L^2 mol^{-2} s^{-1}.
(b) An increase by a factor of 18

7. (a) Rate = $k[C_5H_5N][CH_3I]$ (b) $k = 75$ L mol^{-1} s^{-1}
(c) 7.5×10^{-8} mol L^{-1} s^{-1}

9. 3.2×10^4 s

11. 0.0019 atm

13. 5.3×10^{-3} s^{-1}

15. 2.3×10^{-5} M

17. 2.9×10^{-6} s

19. (a) Bimolecular, rate = $k[HCO][O_2]$
(b) Termolecular, rate = $k[CH_3][O_2][N_2]$
(c) Unimolecular, rate = $k[HO_2NO_2]$

21. (a) The first step is unimolecular; the others are bimolecular.
(b) $H_2O_2 + O_3 \longrightarrow H_2O + 2\ O_2$
(c) O, ClO, CF_2Cl, Cl

23. 0.26 L mol^{-1} s^{-1}

25. (a) $A + B + E \longrightarrow D + F$ $\quad \text{rate} = \dfrac{k_1k_2[A][B][E]}{k_{-1}[D]}$

(b) $A + D \longrightarrow B + F$ $\quad \text{rate} = \dfrac{k_1k_2k_3}{k_{-1}k_{-2}}\dfrac{[A][D]}{[B]}$

27. Only mechanism (b)

29. Only mechanism (a)

31. $\text{rate} = \dfrac{k_2k_1[A][B][E]}{k_2[E] + k_{-1}[D]}$ When $k_2[E] \ll k_{-1}[D]$

33. $$\frac{d[Cl_2]}{dt} = \frac{k_1k_2[NO_2Cl]^2}{k_{-1}[NO_2] + k_2[NO_2Cl]}$$

35. (a) 4.25×10^5 J (b) 1.54×10^{11} L mol^{-1} s^{-1}

37. (a) 1.49×10^{-3} L mol^{-1} s^{-1} (b) 1.30×10^3 s

39. (a) 4.3×10^{-3} s^{-1} (b) 1.7×10^5 s^{-1}

41. 70.3 kJ mol^{-1}

43. 6.0×10^9 L mol^{-1} s^{-1}

45. The rate constant is much smaller than that expected for a diffusion-controlled reaction so it is limited by a large activation energy.

47. (a) 1×10^{-3} mol L^{-1} s^{-1} (b) 5×10^{-5} M

CHAPTER 19

1. 16.96 MeV

3. (a) $^{39}_{17}\text{Cl} \longrightarrow {}^{39}_{18}\text{Ar} + {}^{0}_{-1}e^{-} + \tilde{\nu}$
(b) $^{22}_{11}\text{Na} \longrightarrow {}^{22}_{10}\text{Ne} + {}^{0}_{-1}e^{+} + \nu$
(c) $^{224}_{88}\text{Ra} \longrightarrow {}^{220}_{86}\text{Rn} + {}^{4}_{2}\text{He}$
(d) $^{82}_{38}\text{Sr} + {}^{0}_{-1}e^{-} \longrightarrow {}^{82}_{37}\text{Rb} + \nu$

5. ^{19}Ne decays to ^{19}F by positron emission; ^{23}Ne decays to ^{23}Na by beta decay.

7. An electron, 0.78 MeV

9. $^{30}_{14}\text{Si} + {}^{1}_{0}n \longrightarrow {}^{31}_{14}\text{Si} \longrightarrow {}^{31}_{15}\text{P} + {}^{0}_{-1}e^{-} + \tilde{\nu}$

11. $^{210}_{84}\text{Po} \longrightarrow {}^{206}_{82}\text{Pb} + {}^{4}_{2}\text{He}$ $\quad$ $^{4}_{2}\text{He} + {}^{9}_{4}\text{Be} \longrightarrow {}^{12}_{6}\text{C} + {}^{1}_{0}n$

13. (a) $2\,{}^{12}_{6}\text{C} \longrightarrow {}^{23}_{12}\text{Mg} + {}^{1}_{0}n$
(b) $^{15}_{7}\text{N} + {}^{1}_{1}\text{H} \longrightarrow {}^{12}_{6}\text{C} + {}^{4}_{2}\text{He}$
(c) $2\,{}^{3}_{2}\text{He} \longrightarrow {}^{4}_{2}\text{He} + 2\,{}^{1}_{1}\text{H}$

15. (a) 3.300×10^{10} kJ mol^{-1} = 342.1 MeV total; 8.551 MeV per nucleon
(b) 7.312×10^{10} kJ mol^{-1} = 757.9 MeV total; 8.711 MeV per nucleon
(c) 1.738×10^{11} kJ mol^{-1} = 1801.7 MeV total; 7.570 MeV per nucleon

17. The two ^{4}He atoms are more stable, with a mass lower than that of one ^{8}Be atom by 9.85×10^{-5} u.

19. 3.7×10^{10} min^{-1}

21. (a) 1.0×10^{6} $\quad$ (b) 5.9×10^{4}

23. 1.6×10^{18} disintegrations s^{-1}

25. 4200 years

27. 3.0×10^{9} years

29. 5.9×10^{9} years

31. $^{11}_{6}\text{C} \longrightarrow {}^{11}_{5}\text{B} + {}^{0}_{1}e^{+} + n$; $\;{}^{15}_{8}\text{O} \longrightarrow {}^{15}_{7}\text{N} + {}^{0}_{1}e^{+} + n$

33. Exposure from ^{15}O is greater by a factor of 1.72/0.99 = 1.74.

35. (a) 2.3×10^{10} Bq
(b) 0.025 mGy
(c) Yes. A dose of 5 Gy has a 50% chance of being lethal; this dose is greater than 8.5 Gy in the first 8 days.

37. (a) $^{90}_{38}\text{Sr} \longrightarrow {}^{90}_{40}\text{Zr} + 2\,{}^{0}_{-1}e^{-} + 2\tilde{\nu}$
(b) 2.8 MeV
(c) 5.23×10^{12} disintegrations s^{-1}
(d) 4.44×10^{11} disintegrations s^{-1}

39. Increase (assuming no light isotopes of U are products of the decay)

41. 7.59×10^{7} kJ g^{-1}

CHAPTER 20

1. Use the Beer-Lambert law in the form $I = I_0 \exp[-(N/V)\sigma\ell]$ and rearrange it to solve for ℓ to get

$$\begin{aligned}\ell &= -\sigma^{-1}(N/V)^{-1}\ln(I/I_0)\\ &= (5 \times 10^{-20}\ \text{cm}^2\ \text{molecule}^{-1})^{-1}(5 \times 10^{12}\ \text{molecules cm}^{-3})\ln(0.9)\\ &= 4.2 \times 10^{5}\ \text{cm} = 4.2\ \text{km}\end{aligned}$$

3. $N_{\nu=1}/N_{\nu=0} = \exp(-\Delta\varepsilon/k_\text{B}T) = 0.188$

5. 6.736×10^{-23} J = 40.56 J mol^{-1}

7. (a) 1.45×10^{-46} kg m^2
(b) $E_1 = 7.65 \times 10^{-23}$ J; $E_2 = 2.30 \times 10^{-22}$ J; $E_3 = 4.59 \times 10^{-22}$ J
(c) 1.13 Å

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

9. $I = h/(8\pi^2 c\tilde{B}) = 1.929 \times 10^{-46}$ kg m^2

11. (a) 5.12 (b) 6.80×10^{-2} (c) 3.23×10^{-6}

13. 25.4 kg s^{-2}

15. 5.1×10^2 kg s^{-2}

17. 5.3×10^{-4}

19. Rearranging Equation 20.9 to solve for k, with vibrational frequencies given in cm^{-1}, and substituting the values given for each molecule we find that k = 966.0 N m^{-1} (^{1}H^{19}F), 516.3 N m^{-1} (^{1}H^{35}Cl), 351.7 N m^{-1} (^{1}H^{81}Br), 313.7 N m^{-1} (^{1}H^{127}I). $\mu \approx 1$ for all of these molecules so the vibrational frequency is most sensitive to differences in the force constants.

21. $(\nu_{CD})/(\nu_{CH}) \approx \sqrt{k_{CH}/k_{CD}}$ so $\upsilon_{CD} \approx 2165$ cm^{-1}

23. NH_3 (6); C_2H_4 (12); CCl_2F_2 (12); CH_3CH_2OH (21)

25. The top spectrum is that of nonane and the bottom spectrum is that of 1-hexanol. Prominent bands in the nonane spectrum include those due to aliphatic C—H stretching modes around 2,900 cm^{-1}, —CH_2 and —CH_3 bending modes near 1,450 and 1,375 cm^{-1}, respectively. Prominent bands in the 1-hexanol spectrum include the broad O—H stretch around 3,400 cm^{-1} characteristic of hydrogen-bonded alcohols, —CH_2 and —CH_3 bending modes near 1,450 and 1,375 cm^{-1} similar to those in nonane, and the C—O stretch around 1,075 cm^{-1}, also characteristic of alcohols.

27. 2, 3:2; 1; 2, 6:1

29. There are three sets of equivalent protons. The 9 protons with $\delta = 1.01$ are characteristic of a *t*-butyl group. The two sets of protons with $\delta = 2.11$ and 2.32 are characteristic of protons adjacent to a carbonyl group, three protons belonging to a —CH_3 group and two protons belonging to a —CH_2 group. The molecule is 4,4-Dimethyl-2-pentanone.

31. (a) A = 0.699 (b) $\varepsilon = 1 \times 10^3$ L mol^{-1} cm^{-1}

33. $c_A = 0.000368$ mol L^{-1}

$c_B = 0.00157$ mol L^{-1}

35. Decrease, because the electron will enter a π^* antibonding orbital

37. In the blue range, around 450 nm

39. Shorter; the π bonding is localized in cyclohexene.

41. 474 nm

43. 2.72×10^{-7} m

45.

SN = 3, sp^2 hybridization, bent molecule

Two electrons in a π orbital formed from the three $2p_z$ orbitals perpendicular to the molecular plane, total bond order of $\frac{3}{2}$ for each O—O bond.

47. 8 molecules

CHAPTER 21

1. (b), (c), and (d)

3. Two mirror planes, one 2-fold rotation axis

5. 3.613 Å

7. 102.9°

9. ±49.87° and ±115.0°

11. (a) 5.675×10^6 Å^3 (b) 5×10^{14}

13. 4.059 g cm^{-3}

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

15. (a) 1.602×10^{-22} cm^3 (b) 3.729×10^{-22} g
(c) 4.662×10^{-23} g (d) 6.025×10^{23} (in error by 0.05%)

17. 8

19. ReO_3

21. (a) 2.48 Å (b) 2.87 Å (c) 1.24 Å

23. (a) 2 (b) 0.680

25. 0.732

27. (a) Ionic (b) Covalent (c) Molecular (d) Metallic

29. CO < $BaCl_2$ < Co < SiC

33. 8, 6, 12

35. Not by a significant amount because each vacancy is accompanied by an interstitial. In large numbers, such defects could cause a small bulging of the crystal and a decrease in its density.

37. (a) $Fe_{0.9352}O$ (b) 13.86% of the iron

39. 664 kJ mol^{-1}

41. (a) 1041 kJ mol^{-1} (b) 1205 kJ mol^{-1}

CHAPTER 22

1. The structures of $P_2O_7^{4-}$ and $S_2O_7^{2-}$ have the same number of electrons and are found by writing "P" or "S" in place of "Si" and adjusting the formal charges. The chlorine compound is Cl_2O_7, dichlorine heptaoxide.

3. (a) Tetrahedra; Ca: +2, Fe: +3, Si: +4, O: −2
(b) Infinite sheets; Na: +1, Zr: +2, Si: +4, O: −2
(c) Pairs of tetrahedra; Ca: −2, Zn: +2, Si: +4, O: −2
(d) Infinite sheets; Mg: +2, Si: +4, O: −2, H: +1

5. (a) Infinite network; Li: +1, Al: +3, Si: +4, O: −2
(b) Infinite sheets; K: 11, Al: +3, Si: +4, O: −2, H: +1
(c) Closed rings or infinite single chains; Al: +3, Mg: +2, Si: +4, O: −2

7. $Mg_3Si_4O_{10}(OH)_2(s) \longrightarrow 3\ MgSiO_3(s) + SiO_2(s)\ 6\ H_2O(g)$

9. 234 L

11. 0.418 mol Si, 0.203 mol Na, 0.050 mol Ca, 0.0068 mol Al, 0.002 mol Mg, 0.0005 mol Ba

13. −113.0 kJ

15. $\frac{7}{3}$

17. (a) $SiO_2(s) + 3\ C(s) \longrightarrow SiC(s) + 2\ CO(g)$
(b) +624.6 kJ mol^{21}
(c) Low conductivity, high melting point, very hard

19. −1188.2 kJ, unstable

21. 24 (Ω m)$^{-1}$ or 24 S m^{-1}

23. 1.26 C V^{-1} s^{-1} m^{-1} or 1.26 (Ω m)$^{-1}$ or 1.26 S m^{-1}

25. 1.5 electrons per Cu atom

27. 2.16×10^{-19} J

29. 6.1×10^{-27} electrons; that is, no electrons

31. (a) Electron movement (*n*-type)
(b) Hole movement (*p*-type)

33. 680 nm, red

35. Decrease

CHAPTER 23

1. $n\ CCl_2=CH_2 \longrightarrow -(CCl_2-CH_2-)_n$

3. Formaldehyde, $CH_2=O$

5. (a) H_2O (b) $-(NH-CH_2-CO-)$

7. 646 kg adipic acid and 513 kg hexamethylenediamine

9. 3.49×10^{12} L $= 3.49 \times 10^{9}$ m^3 $= 3.49$ km^3

11. The isotropic phase has higher entropy and higher enthalpy.

13. A micelle (containing hydrocarbon in the interior and water on the outside)

15. 5 chiral centers

17. 27

19. In octane, because the side groups are all hydrocarbon

21. C_9H_9NO; 119 units

APPENDIX A

1. (a) 5.82×10^{25} (b) 1.402×10^{3} (c) 7.93
(d) -6.59300×10^{3} (e) 2.530×10^{-3} (f) 1.47

3. (a) 0.000537 (b) 9,390,000 (c) -0.00247
(d) 0.00620 (e) 20,000

5. 746,000,000 kg

7. (a) The value is 135.6 (b) 111.34 g (c) 0.22 g, 0.23 g

9. That of the mass in problem 7

11. (a) 5 (b) 3 (c) Either two or three (d) 3 (e) 4

13. (a) 14 L (b) -0.0034°C (c) 340 lb $= 3.4 \times 10^{2}$ lb
(d) 3.4×10^{2} miles (e) 6.2×10^{-27} J

15. 2,997,215.55

17. (a) -167.25 (b) 76 (c) 3.1693×10^{15} (d) -7.59×10^{-25}

19. (a) -8.40 (b) 0.147 (c) 3.24×10^{-12} (d) 4.5×10^{13}

21. $A = 337$ cm^2

APPENDIX B

1. (a) 6.52×10^{-11} kg (b) 8.8×10^{-11} s (c) 5.4×10^{12} kg m^2 s^{-3}
(d) 1.7×10^{4} kg m^2 s^{-3} A^{-1}

3. (a) 4983°C (b) 37.0°C (c) 111°C (d) -40°C

5. (a) 5256 K (b) 310.2 K (c) 384 K (d) 233 K

7. (a) 24.6 m s^{-1} (b) 1.51×103 kg m^{-3} (c) 1.6×10^{-29} A s m
(d) 1.5×10^{2} mol m^{-3} (e) 6.7 kg m^2 s^{-3} $= 6.7$ W

9. 1 kW-hr $= 3.6 \times 10^{6}$ J; 15.3 kW-hr $= 5.51 \times 10^{7}$ J

11. 6620 cm^3 or 6.62 L

13. 3×10^{2} J

15. (a) 55 J
(b) O (No work was done because no displacement was achieved.)

INDEX/GLOSSARY

Page numbers followed by "f" denote figures; those followed by "t" denote tables. Page numbers preceded by "A" indicate Appendix page numbers.

Absolute zero The theoretical minimum of temperature, at which the entropy of a crystalline pure substance becomes equal to zero, 404
Absorbance, 975
Acceleration The rate at which the velocity of an object changes in response to an applied force, A.12
Accuracy of result The extent to which a measurement gives the true value of a quantity by reducing systematic errors, A.5
Acid A substance capable of donating hydrogen ions, 353–355, 670
Acid anhydride A compound that forms an acid upon addition of water, 675
Acid ionization constant The equilibrium constant that relates the concentration of an acid to the concentrations of the products of its ionization, 681, 682t
Acid–base equilibria, 669–670, 719–720
  amphoteric equilibria, 717–718
  Arrhenius acids and bases, 670–671, 676
  autoionization of water, 677–678
  Brønsted–Lowry acids and bases, 671–673, 676, 677–680
  buffer solutions, 694–699
  classification of, 670–676
  exact treatment of, 714–719
  hydrolysis, 692–693
  indicators, 687–689
  Lewis acids and bases, 674–676
  molecular structure and acid strength, 685–687
  organic acids and bases, 710–714
  pH, 679–681
  polyprotic acids, 704–707, 718–719
  properties of in aqueous solutions, 677–680
  strength of acid and base, 681–689
  strong acids and bases, 678–679
  titration curves, 699–703
  weak acids, 689–692
  weak bases, 687, 689, 691–692
Acid–base titrations, 481–484
Actinide element An element from Ac to Lr in the periodic table of the elements, 70, 71f
Action, 166
Activated complex or transition state A transient species formed by the collision of reacting molecules that can break apart to form products; the activated complex lies at the maximum in a plot of energy *versus* progress along the reaction path, 858–859, 865
Activation energy (E_a) The energy term in the Arrhenius equation that gives the temperature dependence of the rate constant; E_a is obtained from the slope of a plot of ln k against $1/T$; interpreted as the minimum collision energy in an encounter between molecules for reaction to ensue, 857
Activation-energy-controlled, 868
Active site of enzyme, 872
Activity, 628–630
Activity [1] (a_i) For a dilute gas, the ratio of the partial pressure to a reference pressure of 1 atm; for a dilute solute species, the ratio of the concentration to a reference concentration of 1 M, 628
Activity [2] A The disintegration rate of a collection of unstable nuclei, 910
Activity coefficient (γ_i) A correction factor that relates the activity of a nonideal gaseous species to its partial pressure, or the activity of a species in a nonideal solution to its concentration, 628
Actual yield The amount of a product of a chemical reaction that is found to form experimentally, 50
Addition polymerization A reaction in which monomers react to form polymers without net loss of atoms, 1106
Adiabatic process A process occurring in a system that is thermally insulated from its surroundings, so $q = 0$, 551, 553–556, 576
Adiabatic walls Boundaries that separate thermodynamic systems from their surroundings or from other systems and block the flow of thermal energy, 521
Adjacent atoms, 163
Affinity, 15
Air, composition of, 396t
Alchemists, 4
Alcohol An organic compound characterized by the functional group —OH, 325–328
Aldehyde An organic compound characterized by the

functional group, 329–330
Algebraic equations, solving, A.22–A.24

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

Alkali halide A compound formed by reaction of an element from Group I of the periodic table with an element from Group VII, 72
Alkali metal An element of Group I of the periodic table, 72
Alkaline dry cell A primary cell having an alkaline electrolyte and using the reaction $Zn(s) + 2\ MnO_2(s) + H_2O(\ell) \rightarrow Zn(OH)_2(s) + Mn_2O_3(s)$ to generate a voltage, 802
Alkaline-earth metal An element of Group II of the periodic table, 72
Alkanes
branched-chain alkanes, 312–314
cyclic alkanes, 311–312
normal alkanes, 309–311
Alkene A hydrocarbon with one or more double bonds between carbon atoms, 314–319
Alkyl halide An organic compound the molecules of which have a halogen atom bonded to an alkyl group, 325
Alkyne A hydrocarbon containing one or more triple bonds, 314–319
Allotrope, 72
Alloy A macroscopically homogeneous mixture of two or more metals, 1056
Alloy steels, 1056
Alpha decay (α-decay), 900
Alpha helix (α-helix), 1124
Alumina The compound Al_2O_3, which appears in several different crystalline forms, 1082
Aluminosilicate A mineral containing aluminum, silicon, and oxygen, 1072–1073
Aluminum and electrometallurgy, 811–813
Amide, 334
Amine, 334
Amino acids, 1122–1126
Ammeter An instrument used to measure the direction and magnitude of flow of an electric current, 765
Ammonia's structure, 118f
Ammonium perchlorate, 434
Amorphous solid A solid that lacks long-range order in the arrangement of its atoms, 1053–1054, 1056
Amphiphiles Molecules that are both hydrophilic and hydrophobic, 1118
Amphoteric Exhibiting the properties of either an acid or a base, depending on reaction conditions, 352, 672, 717–718
Amphoterism, 672
Amplitude The distance from center to crest or center to trough of a standing or traveling wave, 141
Analgesics, 337–338
Analysis, 6
Angle strain Additional contribution to the total potential energy of a molecule arising from distortion of bond angles away from their equilibrium values, 312
Angular momentum In circular motion, the product of the radius of the circle described by the moving particle, its mass, and its velocity; $L = mvr$, 154, A.19
circular motion and, A.18–A.19
Angular momentum quantum number A quantum number for a one-electron atom that governs the shape of the orbital; takes integer values from $\ell = 0$ to $\ell = n - 1$, where n is the principal quantum number, 196
Angular node A surface in a wave function at which the electron density equals zero and across which the wave function changes sign, 204
Anion A negatively charged ion, 79, 121t
Annealing The slow cooling of a piece of material to allow the release of internal stresses by shortrange diffusion of atoms, 1079
Anode The site at which oxidation occurs in an electrochemical cell, 17, 765
Antibacterial agents, 339
Antibonding molecular orbital (σ^*) A molecular orbital in which the occupation by electrons results in a reduction of bond strength, 246
Antiderivative A new function obtained from another function by the operation of integration, which is the inverse of the derivative operation, A.29
Approximate molecular orbitals, 254
Aqueous solution Containing water, as in "aqueous solution," or dissolved in water as in "aqueous ions," 478, 793
electrolysis of, 816–818
of ionic species, 479–481
of molecular species, 476–478
oxidation-reduction equations, balancing, 486–489
Argon, 216–219
Aromatic hydrocarbon A compound of hydrogen and carbon, the molecules of which contain one or more rings with conjugated π electron systems, 319–321, 322f
Arrhenius acids and bases, 670–671, 676
Artificial photosynthesis, 798
Asbestos A fibrous material, formerly used for thermal insulation, that is composed of double-chain and rolled-up layered silicates, 1072
Atactic form Polymer structure in which side groups are randomly positioned along the backbone chain, 1114
Atmosphere, 993–994
Atmospheric chemistry, 992–1009
Atomic force microscopy A form of scanning probe microscopy that images the surfaces of samples by measuring the strength of the force between the sample and the tip of the microscope at each location as the tip is scanned systematically across the sample surface, 27
Atomic mass, 23, 895
Atomic mass unit (u) A unit of mass defined as exactly $\frac{1}{12}$ of the mass of a single atom of ^{12}C, 895–896
Atomic number (Z) The number of electrons in the neutral atom; also, the number of protons in the nucleus of the atom, 28, 894. *See also* **Relative atomic mass**
Atomic orbitals (AOs) The wave functions that give the probability amplitude for the locations of electrons in atoms, 182, 236
Atomic spectra, 149–151, 151f, 156–157
Atomic theory of matter The postulate that matter is composed of indestructible atoms that combine in whole-number ratios to form compounds, 10–11. *See also* Matter, atomic theory, 12
Atom(s), 193–195
aufbau principle, 215
helium to argon, 216–218
transition-metal elements and beyond, 219, 220f

crystals, atomic packing in, 1044–1046
electronegativity, 88–91
electrons of. *See* **Electron (*e*)**
energy quantization in. *See* **Energy quantization in atoms**
forces and potential energy in, 73–78
Hartree orbitals, 194, 210–211
shielding effects, 212–214, 215f, 215t
sizes and shapes, 211–212
hydrogen atom. *See* **Hydrogen atom**
laws of chemical combination, 9–15
nucleus of, 21–22
protons, 28–29
Rutherford's planetary model of, 22–23
scanning tunneling microscopy imaging, 26–27
shell model of, 82–85
many-electron atoms, 210–214, 215f, 215t
and periodic table, 220–223
size of, 224–225
structure of, 16–29
Attractive force A force that accelerates two objects to move toward each other, A.17
Aufbau principle, 215
helium to argon, 216–218
transition-metal elements and beyond, 219, 220f
Autoionization of water The spontaneous reaction of molecules of a substance to give pairs of ions; the autoionization of water to give H_3O^+ plus OH^- ions, although slight in extent, is great in importance, 677–678
Average reaction rate The change in the concentration of a product of a reaction divided by the time interval over which the change occurs and also divided by the coefficient of the product in the chemical equation for the reaction, 837
Average speed For a single object, the value of the instantaneous speed averaged over a period of time. For a collection of objects, such as the molecules in a gas, the average value of the instantaneous speed of all the molecules, 415, A.12
Average value In a series of measurements, the sum of all the values observed divided by the number of measurements, A.3
Average velocity The rate of change of the location of an object defined over a time interval as opposed to the instantaneous value, A.12
Avogadro's hypothesis, 14–15
Avogadro's number (N_A) The number of atoms in exactly 12 grams of ^{12}C; equal to 6.022137×10^{23} mol^{-1}, 36
Axial sites Lying along the axis of symmetry perpendicular to the plane that contains the equator; used to describe a type of site for atom or group substitution in a molecule, 117–118

Backbonding A bonding mechanism in which un-occupied π^* orbitals in CO and related molecules accept and de-localize electron density from *d* orbitals in a metal, strengthening the bond between the molecule and the metal, 382
Balanced chemical equations, writing, 43–45
Band gap The energy difference between the top of one band and the bottom of the next higher band, 1092
Band of levels, 780 *See also* **Energy band**
Band theory of conduction, 1090–1093
Barometer A device to measure the pressure of the atmosphere, 398–399
Base A substance that, when dissolved in water, increases the amount of hydroxide ion relative to that present in pure water, 353–355, 483, 670, A.25
Base anhydride A compound that reacts with water to form bases, 675, 677–680
Base solubility, 746
Base units, A.9
Battery A galvanic cell or group of cells used to generate electrical work, 800–805
Battery of cells, 801
Bayer process An industrial process for the purification of aluminum(III) oxide through its selective dissolution in a strongly basic solution, 811
Beer's law Relates the amount of light absorbed by a sample to its concentration, the path length, and its molar extinction coefficient, 975
Berthollides Solids that exist over a small range of compositions, without the definite stoichiometry implied by a single molecular formula, 11
Beta decay (β-decay), 900
Bilayer membranes Structure formed when high concentrations of molecules having both hydrophilic and hydrophobic sections are dissolved in water, 1119
Bimolecular reaction An elementary reaction that occurs through collision of two molecules, 847
Binary compounds, 8
Binary covalent compounds, 125
Binding energy (E_B) The energy required to separate a nucleus into its component protons and neutrons; also, the energy required to remove an electron from a specific orbital in an atom, 906
nuclear, 906–908
Biology, radiation in, 913–917
Bismuth, 468
Blackbody radiation Electromagnetic radiation emitted from an idealized dark-colored solid with which is in thermal equilibrium with the radiation, 146–149
Blood plasma, buffered, 708–709
Boat conformation Conformation of cyclohexane in which four carbon atoms lie in a plane with two carbon atoms above the plane, 311–312
Body-centered crystals, 1039
Body-centered cubic (bcc) structure A crystalline structure that has one atom located at each point of the bcc lattice. The points at each corner are shared among the 8 unit cells meeting at that corner and together contribute one atom to the unit cell. The total number of atoms in the unit cell is 2, 1042
Body-centered unit cell A solid lattice in which the unit cell has lattice points at each of the 8 corners of the unit cell and one additional point at the center of the cell, 1039
Bohr model, 153–157
Bohr radius (a_0) The radius of the first electron orbit in the Bohr model for the hydrogen atom; equal to 5.29×10^{-11} m, 154
Boiling, 461

Boiling point (T_b) The temperature t which the vapor pressure of a liquid equals the external pressure, 461
Boiling-point elevation The colligative property in which the boiling point of a solvent is raised by the presence of a nonvolatile solute, 492–495
Boltzmann distribution, 945
Boltzmann energy distribution An exponential distribution showing the population over the energy levels of a molecule as a function of temperature, 417, 556–557
Boltzmann's constant (k_B) The universal gas constant divided by Avogadro's number, $R/N_A = 1.38066 \times 10^{-23}$ J K^{-1}, 413, 578
Bomb calorimeters, 532
Bond(s)
classical description of chemical bond, 63–65
coordination chemistry. *See* **Coordination chemistry/complexes**
covalent bonds, 64, 98–107, 674
mechanism of formation, 240–241
polar, 64, 105
crystal field theory. *See* **Crystal field theory**
de-localized bonds. *See* **Linear combination of atomic orbitals (LCAO)**
dipole moment, 105–107, 118–120
double bonds, 108
excess bond energy, 89–90
formation of, 89–90
H_2^+, 242, 243–247
ionic bonds, 64, 94–98
LCAO approximation. *See* **Linear combination of atomic orbitals (LCAO)**
lengths, 100–101, 101t, 105
localized bonds. *See* **Valence bond (VB) theory**
organic molecule bonding. *See* **Organic molecule bonding**
p bonds, 271
percent ionic character, 105–107
polar covalent bonds, 64, 105
quantum picture of, 237–239, 247
Born–Oppenheimer approximation, 239–240
H_2^+, 242, 243–246
s bonds, 271
transition-metal elements. *See* **Transition-metal element**
triple bonds, 108
valence bond model. *See* **Valence bond (VB) theory**
Bond dissociation energy The amount of energy that must be absorbed in order to break a particular chemical bond, 93, 249–250
Bond energy Also called bond dissociation energy; the amount of energy that must be absorbed in order to break a particular chemical bond, 101
Bond enthalpy The enthalpy change ΔH in a reaction in which a chemical bond is broken in the gas phase, 549
Bond force constant A measure of the stiffness of a chemical bond, it correlates with theoretical models of bond order and is measured experimentally using vibrational spectroscopy, 104
Bond order A measure of the strength of a chemical bond; in the Lewis model, defined as the number of shared electron pairs; in the molecular orbital description, defined as one-half the number of electrons in bonding molecular orbitals minus one-half the number of electrons in antibonding ones, 104–105, 252
Bonding molecular orbital (σ) A molecular orbital, the occupation of which by one or two electrons results in an increase in bond strength, 246
Born–Haber cycle A thermodynamic cycle that allows the experimental determination of lattice energies in ionic crystals, 1060
Born–Oppenheimer approximation, 239–240
Boron nitride, 1085
Boron trifluoride, 113f
Bound motion, 77, 78f
Boundary condition Restrictions that must be placed on the solutions to differential equations to reflect certain conditions known in advance about the system, 161, 171
Boyle's law At constant temperature, the product of pressure and volume is a constant for a fixed amount of a gas; $PV = C$ or $P_1V_1 = P_2V_2$, 400–402
Bragg angles, 1041
Bragg law The relationship giving the angle Θ for Bragg diffraction of X-rays of wavelength λ from parallel planes in a crystal separated by the distance *d:* $n\lambda = 2d \sin \Theta$; *n*, an integer, is the *order* of the Bragg reflection, 1041
Branched-chain alkane A saturated hydrocarbon in which one or more carbon atoms are bonded to three or four other carbon atoms, 312–314
Branching chain reaction A chain reaction in which the number of reactive intermediates increases during the propagation steps, 855
Breeder reactor, 921
Brønsted–Lowry acid A substance that can donate a hydrogen ion to a Brønsted–Lowry base, 671–673, 676
Brønsted–Lowry base A substance that can accept a hydrogen ion from a Brønsted–Lowry acid, 671–673, 674, 676, 677–680
Brownian motion The continual random motion of colloidal particles as they undergo collisions with surrounding solvent molecules, 505
Buckminsterfullerene, 322–323
Buffer solution A solution that maintains approximately constant pH upon small additions of acid or base, 694
calculations of buffer action, 694–697
designing buffers, 697–699
Buffered blood plasma, 708–709

Calorimetry Methods for measuring quantitatively the amount of heat (thermal energy) transferred into or out of a thermodynamic system in a process, 527
Canal ray Positively charged particles (ions) in cathode ray tubes, 21
Carbohydrate A compound of general formula $C_n(H_2O)_m$, 1120–1122, 1121f
Carbon and organic molecule bonding. *See* **Organic molecule bonding**
Carbon compounds, 278–280
Carbonylation A reaction in which the C=O group is inserted into a previously existing bond, 330

Carboxylic acid An organic compound the molecules of which contain the —COOH functional group, 330
Carnot cycle, 581, 597–599
Carnot engines, 600–601
Catalysis, 869–873
Catalyst A substance that takes part in a chemical reaction, speeds it up, but itself undergoes no permanent chemical change, 869
Catalytic converter An assembly of catalysts used in automobiles to oxidize hydrocarbons and CO to carbon dioxide and water and to reduce oxides of nitrogen to the elements, 871, 871f
Catalytic cracking The breaking down of long-chain hydrocarbon molecules in petroleum using catalysts, 318
Cathode The site at which reduction occurs in an electrochemical cell; source of electrons in a cathode ray tube, 17, 765
Cathode ray (e^-) An electron; so called when it emanates from the negatively charged electrode to carry the current in a low-pressure gas-discharge tube, 17
Cation A positively charged ion, 79
Cell constants The three edges and three angles that describe the size and shape of the unit cell of a crystalline solid, 1038
Cell potential The electrical potential difference between two half-cells, 770
  and the Gibbs free energy, 770–780
Cell voltage (ΔE), 767
Cements, 1080–1081
Ceramic A synthetic material that has as its essential components inorganic, nonmetallic materials, 1075
  cements, 1080–1081
  composition and structure of, 1075–1076
  glass, 1078–1080
  making, 1076–1077
  nonoxide ceramics, 1084–1086
  nonsilicate ceramics, 1082–1086
  oxide ceramics, 1082–1083
  pottery, 1077–1078
  silicate ceramics, 1077–1081
  structural clay products, 1077–1078
  superconducting ceramics, 1083–1084
Ceramic phase Any portion of the whole body that is physically homogeneous and bounded by a surface that separates it from other parts, 1076
Cesium chloride structure of ionic crystals An ionic crystal structure that consists of two interpenetrating simple cubic lattices: one of cations, and the other of anions, 1047–1048
Chain reaction A reaction that proceeds through a series of linked elementary reactions; the general steps are initiation, propagation, and termination, 855
Chair conformation Conformation of cyclohexane in which four carbon atoms line in a plane with one carbon atom above the plane and one below, 311–312
Chalcogen element An element of Group VI of the periodic table, 72
Charge-to-mass-ratio The charge of an ion divided by its mass
  of electrons, 18–20
  of ions, 16
Charles's law At constant pressure, the volume of a sample of gas is a linear function of its temperature; $V = V_0 + aV_{0t}$, 403–405
Chelate, 357
Chemical equilibrium, 617. *See* also **Equilibrium**
Chemical formula A representation of the chemical composition of a substance; refers to either empirical formula or molecular formula, 12
Chemical kinetics. *See* **Reactions**
Chemical reactions. *See* **Reactions**
Chemical shift (δ), 969
Chemical vapor deposition A method used in the fabrication of ceramics, 1086
Chiral structures, 366–368
Chirality The structural property in which a species is not superimposable on its mirror-image structure, 313–314
Chlorofluorocarbons (CFCs), 992, 999, 1001–1003
Cholesteric A type of liquid crystal in which the ordered arrangement of the molecules shifts from one vertical plane to the next to form a helical array that strongly diffracts light, 1118
Chromatographic separations, 652–654
Chromatography A method of separating substances that exploits the difference in the partition coefficients of solute species between two phases, such as a gas and a liquid absorbed on a porous support, 652
Chromophore Functional groups in molecules that absorb visible light, 795, 973
Circular motion, A.18–A.19
Circular standing wave, 161
Classical description of chemical bond, 63–65
Classical mechanics, 140. *See also* **Quantum mechanics**
Clay A hydrated aluminosilicate produced by the weathering of primary minerals, 1073–1074, 1077–1078
Climate change, 1003–1009
Closed system A thermodynamic system that does not gain or lose matter during a process because it is surrounded by impermeable walls, 521
Cobalt(II) chloride, 41f
Coefficient of thermal expansion (α) A value characterizing the rate at which a substance changes its volume with temperature at constant pressure, 446
Coenzymes, 873
Colligative property A physical property of a solution that depends only on the concentration of a solute species and not on its nature, 492
Collision cross section The effective area of a molecule as a target for collisions with other molecules, 860
Collision theory, 859–864
Colloid A mixture of two or more substances in which one is suspended in the second as tiny particles that nonetheless exceed molecular size, 504
Colloidal suspensions, 504–505
Color center, 1054 *See also* **F-center**
Column chromatography, 652
Combustion, determination of form elemental analysis by, 42–43
Combustion train, 42f

Common logarithms Logarithms expressed in base 10, A.25
Common-ion effect The observation that if a solution and a solid salt to be dissolved in it have an ion in common, the solubility of the salt is depressed, 742–744
Complementary color, 977
Complex ion An ion in which a central metal ion is bound to one or more ligand molecules or ions that are capable of independent existence in solution, 746
  acidity and amphoterism of complex ions, 750–751
  complex-ion equilibria, 746–750
Composite ceramic A ceramic in which one ceramic is reinforced by the admixture before firing of another ceramic, 1086
Compound A substance containing two or more elements, 8
  binary compound, 8
  covalent compounds, 107–108, 125
  ionic compounds, 123–124
  nonstoichiometric compounds, 11
  quaternary compound, 8
  ternary compound, 8
Compressibility The measure of the rate of change of the volume of a substance with pressure, 445
Compressibility factor (*z*) The ratio *PV*/*nRT*, which differs from 1 for a real gas, 418
Concentration (*c*) The amount of a solute present in a given amount of solvent or solution, 474
Concrete A mixture of portland cement, sand, and aggregate in the proportions 1:3.75:5, 1081
Condensation The formation of a liquid or solid from a gas, 459
Condensation polymerization Polymerization via condensation reactions, 1109
Condensation reaction The joining together of two molecules as a third, small molecule is split out, 328
Condensed structural formula Specifies which atoms in a molecule are bonded to each other and by what types of bonds they are connected, 65
Conductance (*G*) Proportionality constant relating current through a sample to the voltage applied to the sample; reciprocal of the resistance, and measured in Siemens (S), 1087
Conducting polymers, 1116–1117
Conduction, 1070, 1086–1090, 1090–1093
Conduction band (CB) A partially filled band of energy levels in a crystal through which the electrons can move easily, 1091–1092
Conductivity (σ) Property that measures the ability of a substance or material to conduct electricity; reciprocal of the resistivity, and measured in $(\Omega m)^{-1}$ or S m^{-1}, 1070, 1087
  measurement of, 1087–1088
  in metals, 1090
  microscopic origins of, 1088–1090
Confidence limit, A.4
Conjugate acid–base pairs A Brønsted–Lowry acid and the base formed when it donates a hydrogen ion, or a Brønsted–Lowry base and the acid formed when it accepts a hydrogen ion, 672
Conjugated π electron system A molecule or portion of a molecule in which double or triple bonds alternate with carbon–carbon single bonds, and electrons are delocalized across several atoms, 318
Consecutive equilibria, 632
Conservation of energy, 5, A.15
Conservation of matter, 5
Constrained, 522
Constraint A portion of the apparatus in a thermodynamic experiment; it holds one of the properties of the system at a constant value throughout the experiment, 522
Constructive interference Interaction of two waves in which their crests are aligned and their sum has greater amplitude than the original waves, 144, 162
Convection The net flow of one region of a fluid with respect to another region, 448
Conversion method, A.11
Coordinate covalent bond A covalent bond in which the shared electrons are both supplied by one of the bonded atoms; results from the interaction of a Lewis base and a Lewis acid, 674
Coordination chemistry/complexes, 385–386
  bonding in, 376–385
  chiral structures, 366–368
  crystal field theory. *See* **Crystal field theory**
  formation of, 355–359
  ligand substitution reactions, 360–361
  linear geometries, 362, 366
  magnetic properties, 372–373
  naming coordination compounds, 359–360
  octahedral geometries, 361–362, 363f
  square-planar geometries, 362, 363f, 366
  tetrahedral geometries, 362, 363f, 366
  valence bond theory, 376–383
Coordination complex A compound in which metal atoms or ions are bonded via coordinate covalent bonds to anions or neutral molecules that supply electron pairs, 355–356, 746
Core electron Electrons that are contained in the inner shells of an atom and do not participate in chemical bonding, 84–85
Correlation diagram A diagram that shows the relative energy of the molecular orbitals in a molecule and their derivation from the atomic orbitals of the constituent atoms, 251
Correspondence principle The requirement that the predictions of quantum mechanics approach the predictions that classical mechanics would make for the same system when the system is sufficiently large or sufficiently excited, 175–176
Corrosion, 808–810
Coulomb (C) The fundamental unit of charge in the SI system of units, A.17
Coulomb potential energy The potential energy of a pair of systems that interact by the Coulomb force law, A.18
Coulomb stabilization energy, 97
Coulomb's law, 73–78
Covalent bond A model of chemical bonding in which electrons are shared between atoms participating in the bond, 64, 98–107, 674
  mechanism of formation, 240–241
  polar, 64, 105

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Covalent compound A compound formed from electron sharing; tends to be low-melting, low-boiling, and nonconducting, 107–108, 125
Covalent crystals, 1051
COX inhibitors, 338
Cracking The degradation of longer chain alkanes to shorter chain alkenes by means of heat or catalysts, 318
Critical point The point in the phase diagram at which the gas–liquid coexistence curve terminates, 463
Crookes tube, 16–17
Crossed molecular beam technique, 867–868
Crystal Solids whose structures are symmetrical and highly ordered over macroscopic distances, 1036, 1056–1057
alloys, 1056
amorphous solids, 1053–1054, 1056
atomic packing in, 1044–1046
cohesion in, 1047–1053
covalent crystals, 1051
defects, 1054
elements, structures of, 1051–1053
glasses, 1056
interstitial sites, 1046–1047
ionic crystals, 1047–1048, 1058–1061
lattice energy, 1057–1061
liquid crystals. *See* **Liquid crystal**
metallic crystals, 1048–1050, 1049f, 1050f
molecular crystals, 1051–1052, 1051f, 1057–1058
nonstoichiometric compounds, 1054–1056
octahedral site, 1046
point defects, 1054
structure, 1042–1047
symmetry, 1036–1042
unit cells, 1038–1039
X-ray scattering by, 1039–1042
Crystal field splitting energy, 369
Crystal field stabilization energy (CFSE) The amount by which the (otherwise equal) energy levels for the *d* electrons of a metal ion are split by the electrostatic field of the surrounding ligands in a coordination complex, 370
Crystal field theory A model for coordination complexes in which the central metal is treated as ionically bonded to surrounding ligands, 367–372, 386
magnetic properties of coordination compounds, 372–373
square-planar complexes, 370–372
tetrahedral complexes, 370–371
Crystal lattice A three-dimensional array of points that embodies the pattern of repetition in a crystalline solid, 1038
Crystallography The branch of science that studies the properties and structures of crystals, 1036
Cubic system A category (one of seven) into which a crystalline solid can be classified on the basis of the symmetry of its diffraction pattern, 1038
Curvature, 169
Curves
areas under, and integrals, A.28–A.30
slopes of, and derivatives, A.26–A.28
Cyclic alkanes, 311–312
Cyclic voltammetry, 791
Cycloalkane A saturated hydrocarbon with one or more closed rings of carbon atoms, 311

***d* orbitals** Atomic orbitals for which the total angular momentum quantum number ℓ has the value 2, 206–209, 208f
Dalton's atomic theory, 11–12
Dalton's law The total pressure of a gas mixture is the sum of the pressures that would be measured separately if each of the components were present by itself, 408
Dative bonds A bond formed by transfer of a pair of electrons from one bonding partner to the other, 352, 674
Davisson-Germer experiment, 163
***d*-block element** The elements from scandium to zinc, whose electron configurations involve filling the *d*-orbitals in the building up process, 219
de Broglie waves, 161–162
Decomposition potential The external voltage that must be impressed across the electrodes of an electrochemical cell in order to make a reaction occur that would otherwise not be spontaneous on thermodynamic grounds, 816
Decomposition potential of water, 816–817
Definite integral, A.28
Degenerate Energy levels that correspond to more than one quantum state, 176
Degenerate quantum states, 196
Degrees of freedom Different types of motions available to molecules (e.g., translation, vibration, rotation, electronic) and the number of coordinates necessary to describe each type of motion, 537
Delocalized bonds, linear combination of atomic orbitals method. *See* **Linear combination of atomic orbitals (LCAO)**
Densification The removal of voids in a ceramic body during drying or firing, leading to shrinking, 1076
Density Mass per unit volume, 38–40
Derivative, A.27
Deshielded Protons having less shielding than those in tetramethylsilane (TMS), the standard NMR reference compound, 970
Destructive interference Interaction of two waves in which the crest of one is aligned with the trough of the other and difference shows cancellation of the original waves, 144–145, 144f, 162
Detailed balance principle At equilibrium the rate of each elementary process is equal to the rate of its reverse process, 849
Detergent A synthetic analog to natural soaps that contains a hydrophobic chain and a hydrophilic end group, 1119
Diagmagnetic shielding Shielding that occurs as a result of electronic currents induced in atoms by magnetic fields, 971
Diamagnetic substance The property of being repelled from an inhomogeneous magnetic field, 217
Diathermal walls In a thermodynamic system, walls that allow transfer of heat or thermal energy into or out of the system during a process, 521
Diatomic molecules A molecule containing two atoms, 12, 948
dipole moment, 106t
heteronuclear. *See* **Heteronuclear diatomic molecule**

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

homonuclear. *See* **Homonuclear diatomic molecule**
ionic character measures, 107f
properties, 100t
rotational spectroscopy, 949–954
vibrational spectroscopy, 955–962
Dielectric constant, 1070, 1086
Differential equation, 169
Diffraction pattern Arrangement of alternating bright and dark spots produced by constructive and destructive interference of two waves, 145
Diffuse Diffusion is the process by which two materials are mixed by random motion of atoms from one into the other, 447
Diffusion, 427, 447–448
Diffusion constant The proportionality constant relating the mean-square displacement of a particle to the elapsed time, 430, 447
Diffusion-controlled reaction A reaction the rate of which is controlled by the rate at which molecules can diffuse toward each other, 868
Dimensions Results of measurements expressed as a combination of pure numbers (magnitudes) and units, A.9
Diol A compound containing two hydroxyl groups, 328–329
Dipeptide molecules, 1122
Dipole moment ($\boldsymbol{\mu}$) A measure of the separation of charge in a molecule; the product of the charge and the distance that separates it from a charge of equal magnitude by opposite sign, 105–107, 118–120
Dipole–dipole forces The interactions among polar molecules, 450
Dip-pen lithography Synthesis of two-dimensional arrays of materials by using scanning probe microscopy tools to "drag" molecules to the desired locations, 27
Disaccharide The result of the condensation (with elimination of water) of two simple sugars, 1121
Disilicate Mineral form in which two SiO_4^{4-} are linked, 1071–1072
Dispersion force, 310, 452
Displacement, A.12
Disproportionation A reaction in which a single species is both oxidized and reduced, 489–490, 777–778
Dissolution reaction A chemical reaction by which a substance dissolves; the reverse of precipitation, 479
Distillation, 501–504
Distillation column, 502
Donor impurity level A band of orbitals in a semiconducting solid containing electrons contributed by an impurity, 1093
Doping The deliberate addition of a small amount of an impurity in order to change the properties of the pure substance, 1093
Double bond Two pairs of electrons shared between two atoms, 108
Downfield Protons in compounds with resonances shifted to weaker magnetic fields than other compounds, including tetramethylsilane (TMS), the standard NMR reference compound, 970
Drift speed, 1089
Drude model, 1048–1049
Dye sensitized solar cells, 798–799
Dynamic charge distribution, 241
Effective charge, 83, 83f
Effective force field, 194
Effective nuclear charge (Z_{eff}) The nuclear charge experienced by an electron in an atom as a consequence of other electrons shielding it from full interaction with the nucleus, 213
Effective potential energy An approximate function that models the potential energy of one electron in an atom as the sum of the electron-nuclear attraction and the average of all the electron-electron repulsions, 82–83
Effective potential energy curve, 238–239
Effective potential energy function, 238
Efficiency ($\boldsymbol{\epsilon}$) For an engine, the ratio of the net work done by the system to the heat added to the system at the higher temperature, 599, 601–603
Einstein radiation relations, 1015–1018
and lasers, 1018–1020
Elasticity Capacity to recover shape when a deforming stress is removed, 447
Elastomer A polymer material that is capable of being elongated to a considerable degree, and that returns to its original shape when released, 1115
Electric current (I) The amount of charge flowing past a point in a circuit per unit time, 769
Electric fields, 142
Electric polarization, 1070, 1086
Electrical conduction, 1070, 1086–1090, 1090–1093
Electrical conductivity, 1070, 1086, 1087
measurement of, 1087–1088
in metals, 1090
microscopic origins of, 1088–1090
Electrical forces, A.17–A.18
Electrical work (w_{elec}) The work required to move a charge through a difference in electrical potential, 770
Electrically conducting polymers, 1116–1117
Electrochemical cell A device in which the passage of electric current through an external circuit is associated with oxidation and reduction half-reactions that occur at the anode and cathode, 764
electrolytic cells, 764, 766–770
Faraday's laws, 768–769
galvanic cells, 764–766, 768
Electrochemistry, 763–764
780-781, 787–800
batteries, 800–805
concentration effects, 781–787
corrosion, 808–810
disproportionation, 777–778
electrochemical cells. *See* **Electrochemical cell**
electrogenerated chemiluminescence, 790–795
electrolysis of water and aqueous solutions, 816–819
electrometallurgy. *See* **Electrometallurgy**
enzyme-based sensors, 788–790
equilibrium constants, measuring, 783–785
fuel cells, 806–808
Gibbs free energy and cell voltage, 770–780
molecular, 787–800
Nernst equation, 781–787
organic synthesis, 788

Electron (*e*), 17–21
acceptors, 88
charge of, 20–21
charge-to-mass-ratio, 18–20
core electrons, 84–85
delocalized density, 254
donors, 88
fast electrons, 239–240
Hartree orbitals, 194, 210–211
shielding effects, 212–214, 215f, 215t
sizes and shapes, 211–212
hydrogen molecular ion, 245–246, 298f–299f
photoelectron spectroscopy, 220–223
shell model for many-electron atoms, 210–214, 215f, 215t
shells and the periodic table, 220–223
structure, 224–227
valence electrons, 64, 84–85
Electron affinity (*EA*) The negative of the energy change that occurs when an electron is added to an atom, 85–87, 227
Electron attachment energy The energy change in a chemical reaction in which an electron is attached to a free gaseous atom to form an anion, 85
Electron capture A nuclear decay process in which an electron outside the nucleus is captured, a neutrino is emitted, and a proton is converted to a neutron inside the nucleus, 902
Electron configuration A representation of the occupancy of orbitals by the electrons in an atom or molecule, 215–216
helium to argon, 216–218
transition-metal elements and beyond, 219, 220f
Electron density functions of H_2^+ orbitals, 295
Electron diffraction, 162–165
Electron volt (eV) A unit of energy equal to the energy required to move one electron through a potential difference of one volt; equal to 1.60216×10^{-19} J, 74, 897
Electronegative Having a relatively large electronegativity, 89
Electronegativity A measure of the tendency of an atom or molecule to draw electrons to itself in a chemical bond, 64, 88–91
organic acids and bases, 712–713
Electroneutrality, 352
Electronic spectroscopy of molecules, 973–983
and excited state relaxation processes, 983–992
lasers, 1018–1020
Electronic wave function, 242, 243–245
Electroplating The deposition of a thin layer of metal on top of another material by electrochemical reaction, 814–815
Electropositive Having a relatively small electronegativity, 89
Electrorefining The purification of substances by electrochemical methods, 814–815
Electrostatic forces and molecular shapes, 284–286
Electrostatic interaction, 241
Electrostatic potential Electrostatic potential energy per unit charge, 766–767
Electrostatic potential energy diagram Representation of the potential energy measured by a small positive text charge as it scans across the surface of the electron density of a molecule. Sign and magnitude of the potential energy are represented by a color scale, 67
Electrostatic potential energy map See definition for electrostatic potential energy diagram. The terms are used interchangeably, 284, 454–455
Elementary particles, 16
Elementary reactions A reaction that occurs in a single step, through collision of reactants and direct formation of products, 846
molecular theories of, 859–868
Elements A substance that cannot be decomposed into simpler substances by chemical means, 8–9, 1051–1053
physical properties of, A.45–A.53
Empirical equilibrium constant (K_P or K_C) The product of reaction product concentrations each raised to a power equivalent to its stoichiometric coefficient in the balanced equation for the reaction, divided by the product of the reactant concentrations each raised to a power equivalent to its stoichiometric coefficient. This ratio is measured at equilibrium, 618
Empirical formula A chemical formula of a compound that expresses the relative chemical amounts of its elements in terms of the smallest integers, 40–41
determination of, from elemental analysis by combustion, 42–43
determination of, from mass composition, 41–42
molecular formula and, 43
and percentage composition, 41
Empirical mass equation, 926
Empirical rate expression Relation between the rate of a reaction and concentration of reactants, determined by experiment, 839
End point The point in a titration at which the indicator signals that a stoichiometric amount of the first reactant has been added to the second reactant, 483
Endothermic reaction A reaction in which heat is taken up, so that ΔH is positive, 542–543, 645

Endpoint The point in a titration at which the indicator signals that a stoichiometric amount of the first reactant has been added to the second reactant, 701
Energy analyzer, 221
Energy band, 1050
Energy (*E*) The capacity for doing work, A.14
activation energy, 857
Bohr model, 153–157
bond dissociation energy, 93
bond energy, 101
conservation of, A.15
Coulomb stabilization energy, 97
discrete energy levels, predicting, 153–157
effective potential energy, 82–83
excess bond energy, 89–90
forms of, A.14–A.15
free energy changes, 647
Hartree orbitals, 212–214, 215f, 215t
hydrogen atom levels, 195–197, 197f
hydrogen molecular ion in linear combination of atomic orbitals approximation, 249–251
internal capacity, molecular contributions to, 537–542
ionization energies, 79–82, 155, 226–227
ionizing energy, 226–227
kinetic energy, 78f, A.14
kinetic molecular theory of matter, 556–558
lattice energy of crystals, 1057–1061
mass-energy relationships, 903–908
particle-in-a-box models. *See also* **Particle-in-a-box models**
in atoms, 73–78
comparison of curves, 453
in molecules, 91–94
potential. *See* **Potential energy** (E_p)
in Schrödinger equation, 170
thermal energy, 520, 527–528
thermodynamics. *See* **Thermodynamics**
vibrational energy distribution, 557–558
zero-point energy, 175
Energy equivalent The amount of energy equivalent to 1 atomic mass unit *u* is 931.494 MeV, 904
Energy quantization in atoms, 145
atomic spectra, 149–151, 156–157
blackbody radiation, 146–149
energy levels of atoms, 152–153
energy states, transitions between, 149–151, 150f
Franck-Hertz experiment, 152–153
Planck's hypothesis, 146–149
Energy states, transitions between, 149–151, 150f
Energy-level diagrams Diagrams in which horizontal lines represent the possible allowed energy values of a system, 148
Enrichment factor (*A*) The factor by which a particular isotope or chemical species is enriched by one stage of effusion or diffusion; $A = (\mathcal{M}_B/\mathcal{M}_A)^{1/2}$, 424
Enthalpy (*H*) A function of state, defined as $H = U + PV$; for changes carried out at constant pressure, the enthalpy change of the system is equal to the heat absorbed: $\Delta H q_p$, 350, 532–533
bond enthalpies, 549–550
Carnot cycle, 581
Gibbs free energy. *See* **Gibbs free energy**
reaction enthalpies, 542–546
standard-state, 546–549
Entropy (*S*) A thermodynamic state function of a system, determined by the number of microstates available to the molecules of the system; changes in entropy, and therefore in the number of available microstates, determine the direction of spontaneous processes, 572, 574–575, 597–599
Carnot engines, 600–601
changes and spontaneity, 586–589
definition of, 581–582
efficiency, 599, 601–603
and heat, 580–581
heat engines, 599–600
ideal gas compression/expansion, 583, 587–589
isothermal processes, 582–584
phase transitions, 583–584
second law of thermodynamics, 580–581
spontaneity, 575–580
changes and, 586–589
spontaneous cooling of a hot body, 586–587
standard-state, 590–592
surroundings, 585–586
temperature changes, processes with, 584–585
thermodynamic efficiency, 600
third law of thermodynamics, 590–591
Enzyme A protein capable of catalyzing a specific chemical reaction, 872, 1125
Enzyme catalysis, 872–873
Enzyme kinetics, 872–877
Enzyme-based electrochemical sensors, 788–790
Enzyme-catalyzed reactions, 876–877
Epoxide A cyclic ether in which an oxygen atom is a member of a three-membered ring, 328
Equation of state An equation relating pressure, temperature, and molar volume of a system, 417, 522
Equatorial sites Lying in the plane that contains the equator; used to describe a type of site for an atom of group substitution in a molecule, 117–118
Equilibrium The condition of a chemical reaction in which all tendency toward chemical change has been exhausted and no further change will occur spontaneously, 459, 522, 613–614, 654
acid–base equilibria. *See* **Acid–base equilibria**
activity, 628–630
approach to, 614–617
calculations for gas-phase and heterogeneous reactions, 632–638
characteristics of state, 617
chromatographic separations, 652–654
compositions calculated when *K* is known, 635–638
concentration of a reactant or product, effects of changing, 643–644
consecutive equilibria, 632
constants evaluated from reaction data, 633–634
direction of change in chemical reactions
empirical description, 639, 642–646
thermodynamic explanation, 646–650

distribution of a single species between immiscible phases, 650–654
expressions, relationships among, 630–632
external effects on *K*, 642–646
extraction processes, 651–652
free energy changes, 647
ideal gases, reactions among, 624–627
kinetics and, 849–850
law of mass action. *See* **Law of mass action**
Le Châtelier's principle, 639, 642–646
reaction quotient, 639
solubility equilibria. *See* **Solubility equilibria**
stable, A.17
temperature, effects of changing, 645
thermodynamic description of, 623–630
volume, effects of changing, 644–645
yield of a reaction, maximizing, 645
Equilibrium bond length, 93
Equilibrium composition, 617
Equilibrium constant A constant relating partial pressures and concentration of the reactants and products of a reaction at chemical equilibrium, 614, 646–647, 648
Equipartition theorem Each quadratic term that appears in the energy of a molecule contributes *RT*/2 to the average energy calculated from the Maxwell–Boltzmann distribution, 539
Equivalence point The point in a titration at which the chemical amount of titrant added is equal to the chemical amount of the substance being titrated, 700
Equivalent volume The volume of titrating solution required to bring a titration to the equivalence point, 700
Ester An organic compound the molecules of which are characterized by the —C(=O)—O— functional group, 330
Ether An organic compound containing the —O— functional group, 328–329
Evaporation The formation of a vapor from a liquid, 459
Excess bond energy Δ The difference between the actual bond energy and (hypothetical) covalent bond energy in a polar AB diatomic molecule; a measure of the electronegativity difference between atoms A and B, 89–90
Excited state relaxation processes, 983–992
Exothermic reaction A reaction in which heat is given off, so that ΔH is negative, 86, 542–543, 645
Experimental error, A.3–A.5
Exponential, A.225
Extensive property A property that is proportional to the size of a system and is therefore the sum of the corresponding properties for each of the subsystems into which the system can be divided, 522
Extraction The removal of a solute from one solvent to another, 651–652
Extractive metallurgy The recovery of metals from their sources in the earth, 810

Face-centered crystals A solid lattice in which the unit cell has lattice points at each of the 8 corners of the unit cell and one additional point at the center of each of the 6 faces, 1039
Face-centered cubic (fcc) structure A crystalline structure that has one atom located at each point of the bcc lattice, and one at the center of each face. The points at each corner are shared among the 8 unit cells meeting at that corner and together contribute one atom to the unit cell. The points in each face are shared by the 2 cells and together contribute 3 atoms to the unit cell. The total number of atoms in the unit cell is four, 1042
Face-centered unit cell, 1039
Faraday constant (*F*) The charge on one mole of electrons; equal to 96,485.3 mol^{-1}, 768
Faraday's laws In an electrochemical cell, the quantities of reactants and products are proportional to the amount of electrical charge passed through the cell; for a given amount of electrical charge, the quantity of a substance produced or consumed at an electrode is proportional to its molar mass divided by the absolute value of the total change in oxidation number required to produce it, 768–770
Fast electrons, 239–240
***f*-block element** In an electrochemical cell, the quantities of reactants and products are proportional to the amount of electrical charge passed through the cell; for a given amount of electrical charge, the quantity of a substance produced or consumed at an electrode is proportional to its molar mass divided by the absolute value of the total change in oxidation number required to produce it, 219
F-center A site at which an electron replaces an anion in an ionic crystal, 1054
Feldspars, 1073
Fermi One femtometer, named for the Italian physicist Enrico Fermi, 896
Fermi level The uppermost occupied energy level in a crystal at the absolute zero of temperature, 1091
Fibers, 1111–1112
Fibrous protein Protein formed by amino acids in regular three-dimensional structures, 1124
First excited state On the energy level diagram of a system, the state immediately above the ground state, 152
First law of thermodynamics The change in the internal energy of a system is equal to the work done on it plus the heat transferred to it: $\Delta U = w + q$, 529–530
heat and work for ideal gases, 536
heat capacities of ideal gases, 534–536
First order reaction A reaction that has a total order of 1, as determined by the sum of the exponents of the concentration terms in the rate law; if a reaction is first order in a single species A, the concentration of A changes with time according to $[A] = [A]_0\, e^{-kt}$, 840, 843–844
Fission Decay of unstable nuclei by splitting into daughter nuclei, 900, 917–922
Flocculation Acceleration of the settling out of a colloid through the addition of salts, 504
Flourier transform (FT NMR) spectroscopy, 948
Fluidity Tendency to flow, 446–447
Fluorescence, 986
Fluorite, 1048
Force constant (k), 956
Forces in atoms, 73–78
Forces in molecules, 91–94

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Formal charge The charge an atom in a molecule would have if the electrons in its Lewis structure were divided equally between the atoms that share them, 109–110
Formalin, 329
Formation constant (K_f) The equilibrium constant for the reaction in which ligands replace water molecules in a complex ion, 747
Formula unit The atoms represented by the empirical formula of a compound, 40–41
Fourier transform (FT), 948
Fractional distillation The separation of two or more components of a liquid solution on the basis of their different boiling points by repeated evaporation and recondensation, 501–502
Fractional saturation The fraction of hemoglobin or myoglobin sites occupied by O2 molecules, 640
Franck-Condon factors Measures of the overlap of the vibrational wavefunctions of a molecule in two different electronic states, 988
Franck-Condon principle An assertion that the most probable transition between electronic states induced by the absorption of electromagnetic radiation leaves the nuclear positions unchanged, 988
Franck-Hertz experiment, 152–153
Free energies, 779
Free radical A species in which one or more valence electrons are unpaired; radicals are often but not always highly reactive; often occurs as an intermediate in reactions, 325
Freezing-point depression Reduction of the freezing point of a pure liquid by solute dissolved in the liquid, 495–497
Frenkel defect A lattice imperfection that consists of a lattice vacancy plus a nearby interstitial atom or ion, 1054
Frequency (ν) The number of cycles of a wave that pass a particular point per unit time, 141
Frontier orbitals The highest occupied and lowest unoccupied molecular orbitals that govern much of the spectroscopy, photochemistry and reactivity of molecules, 974
Frozen orbital approximation Assumption that the orbitals of an atom remain undistorted upon ionization of the atom, 222
Fuel cell, 806–808
Fullerene Any of a class of closed, hollow aromatic carbon compounds that are made up of 12 pentagonal and differing numbers of hexagonal faces, 322–323
Functional group A group of atoms in a molecule (usually organic) that exhibits a characteristic set of reactions, 324
  alcohols, 325–328
  aldehyde, 329–330
  amides, 334
  amines, 334
  carboxylic acids, 330
  esters, 330
  ethers, 328–329
  halides, 325
  ketones, 329–330
  pesticides, 335–337
  pharmaceuticals, 337–340
  phenols, 327
Fundamental The standing wave with the fewest nodes, 161
Fundamental limit, 166

Galvanic cell An electrochemical cell in which oxidation–reduction reactions occur spontaneously, at separated electrodes, leading to the generation of an electric current through an external circuit, 764–766, 768
Gas chromatogram, 654
Gaseous diffusion through a porous barrier Passage of gas through a porous barrier, in which molecules experience numerous collisions with one another and with the barrier during passage, 424–425
Gases, 395–398, 431
  Boyle's law, 400–402
  bulk properties, 443–449
  Charles's law, 403–405
  chemical calculations for, 407–408
  compressibility, 445
  diffusion, 427, 447–448
  fluidity, 446–447
  Graham's law of effusion, 423–424
  ideal gas law, 405–408
  intermolecular forces, 417–422
  kinetic theory of gases. *See* **Kinetic theory of gases**
  mean free path, 427
  mixtures of, 408–410
  molar volume, 444
  molecule-molecule collisions, 426–427
  molecule-wall collisions, 422–425
  phase diagrams, 462–465
  phase equilibrium, 459–460
  phase transitions, 460–462
  pressure, 398–401
  rigidity, 446–447
  surface tension, 448–449
  temperature, 402–405
  thermal expansion, 446
Gas-liquid chromatography, 652, 653f, 654
Geiger counter, 894
Geiger-Müller counter A gas-filled tube in which ionizing particles are accelerated to create additional ions by collision with neutral molecules, causing a current to flow and allowing measurement of the intensity of radiation, 894
Geometric isomer Two or more species that have the same connectivity but differ in geometric structure, 312, 362
Gibbs free energy, 572, 592
  and cell potential, 770–780
  and cell voltage, 770–780
  and chemical reactions, 595–597
  equilibrium, thermodynamic description of, 624
  nature of spontaneous processes at fixed *T* and *P,* 592–593
  and phase transitions, 594–595
  properties of, 593–594
  standard-state free energies, 595–596
  temperature on ΔG, effects of, 596–597
Glass A solid state characterized by noncrystalline atomic structure, 1056, 1078–1780
Glass electrode, 786

Glaze A thin glass layer applied to the surface of the clay in a ceramic, 1078
Global warming, 1003–1009
Globular protein A protein formed from a sequence of amino acids with an irregular folded structure, 1124
Glow discharges, 16–17
Graham's law of effusion The rate of effusion of a gas through a small hole into a vacuum is inversely proportional to the square root of its molar mass, 423–424
Graphs, using, A.21–A.22
Greenhouse effect, 1003–1009
Ground state The state of lowest energy for an atom, molecule, or collection of molecules, 152
Group Elements found in the same column in the periodic table, 70

Half–life ($t_{1/2}$) For a first-order reaction, the time it takes a concentration to decay to one half of its initial value; in nuclear decay processes, the time it takes for half of the radioactive nuclei present initially to decay, 843
Half-reaction Either the oxidation or reduction portion of a redox reaction, 486
Halides, 325
Hall–Héroult process A process for producing aluminum through electrolysis of a solution of bauxite in molten cryolite, 812
Halogen element An element of Group VII of the periodic table, 72
Hardness Resistance to indentation, 447
Harpoon mechanism Model process describing the formation of ionic bonds, 98
Hartree atomic orbital Approximate orbitals used to describe the locations of the electrons in many-electron atoms, 194, 210–211
  shielding effects, 212–214, 215f, 215t
  sizes and shapes, 211–212
Haüy's law Interfacial angles remain the same when crystals are cleaved into smaller crystals, 1036
Heat bath, 585
Heat capacity (C) The amount of heat required to raise the temperature of an object by 1 K, either at constant pressure (C_P), or at constant volume (C_V), 520, 530–531, 534
  internal, molecular contributions to, 537–542
Heat engines, 599–600
Heat (q) A means by which energy is transferred from a hot body to a colder body when the two are placed in thermal contact with one another, 527–528, 536, 580–581
Heat transfer at constant pressure, 532–533
Heat transfer at constant volume, 532
Heavy atom effect The presence of "heavy" atoms ($Z \geq 15$) in organic molecules enhances intersystem crossing and phosphorescence, 991
Heisenberg indeterminacy principle The statement that the product of the uncertainties in the position and the momentum of an object must exceed a lower limit: $(\Delta p)(\Delta x) \geq h/4\pi$, 165–167
Heisenberg uncertainty principle, 167
Helium burning A stage in the evolution of a star during which helium is converted to heavier elements by nuclear fusion, 923
Helium to argon, 216–219
Helix Right-handed coiled structure assumed by protein molecules, 1124
Heme proteins, 364–365
Hemoglobin and oxygen transport, 640–641
Henry's law The vapor pressure P_2 of a volatile solute above a solution is proportional to its mole fraction X_2 in solution at low mole fractions; $P_2 = k_2X_2$, 500
Herbicides, 336–337
Hertz (Hz) The SI unit of frequency; equal to 1 s^{-1}, 141
Hess's law If two or more chemical equations are combined by addition or subtraction to give another equation, then adding or subtracting changes in enthalpies for these equations in the same way gives the enthalpy change associated with the resultant equation, 545
Heteroatoms Atoms other than carbon and hydrogen in organic molecules, the lone pairs of which are important in spectroscopy and chemistry, 974
Heterogeneous Having properties that vary from region to region, 7
Heterogeneous catalysis A catalyst that is present in a different phase than the reactants, 871
Heteronuclear diatomic molecule A molecule formed from more than one type of atom, 109, 252
  linear combination of atomic orbital method, 262–265
Hexagonal close-packed structure A scheme of packing of equal spheres in which each sphere has 12 immediate neighbors and the symmetry of the lattice generated from the positions of the spheres is hexagonal, 1045
High-density polyethylene, 1113
High-spin complex, 369
High-spin configuration Electron configurations with a large number of unpaired spins, 369–370
Hole, 1093
HOMO (highest occupied molecular orbit) The highest energy molecular orbital that is occupied by one or more electrons, 795, 974
Homogeneous Having properties that are uniform throughout, 7
Homogeneous catalysis A catalyst that is present in the same phase as the reactants, 870
Homonuclear diatomic molecule A molecule formed from atoms of the same element, 109, 252
  bonding and antibonding regions, 99f
  linear combination of atomic orbitals method
    first-period atoms, 251–253
    second-period atoms, 253–262, 261f
Hund's rule The statement that when electrons are added to orbitals of equal energy, they will half-fill every orbital, with the spins remaining parallel, before pairing in any orbital, 215
Hybridization The mixing of atomic orbitals into new atomic orbitals with different shapes, 273
  and lone pairs, 278
  organic carbon compounds, multiple bonds in, 278–280

for polyatomic molecules, 273–280
sp hybrid atomic orbitals, 273–274
sp^2 hybrid atomic orbitals, 274–275, 276f
sp^3 hybrid atomic orbitals, 276–277, 278
Hydraulic cement A cement that hardens by chemical reactions that incorporate water into the final body, 1081
Hydrocarbon A substance containing hydrogen and carbon but no other elements, 42, 309, 319–321, 322f
Hydrochlorofluorocarbons (HCFCs), 1003
Hydrodealkylation The replacement of an alkyl group by hydrogen in a hydrocarbon, 321
Hydrogen atom, 195
electron spin, 209–210
energy levels, 195–197, 197f
orbitals, 198–200
d orbitals, 206–209, 208f
p orbitals, 204–206
s orbitals, 200–204
wave functions, 197–198
Hydrogen atomic orbital Wave functions that describe the probability amplitude for the electron in the various states of the hydrogen atom, obtained by exact solution of Schrödinger's equation for the hydrogen atom, 194
Hydrogen bond A strong nonbonding interaction that forms when a hydrogen atom bonded to a strongly electronegative atom also interacts with the lone electron pair of a nearby electronegative atom, 456–457
Hydrogen burning A stage in the evolution of stars during which hydrogen is converted into helium by nuclear fusion reactions, 922
Hydrogen molecular ion, 242
electron density, 245–246, 298f–299f
electronic wave functions for, 243–245
linear combination of atomic orbitals method, 248–251
Hydrogen molecule coordinates, 92f
Hydrogenation The absorption of hydrogen by a substance in a chemical reaction, 331
Hydrolases, 872
Hydrolysis The reaction of a substance with water, in particular the reaction of an ion in which the pH of the water changes from neutral, 692–693
Hydrophilic Having a strong affinity for water, 1118
Hydrophobic Lacking affinity for water, 1118
Hydroxide solubility, 744–745
Hypothesis, 4

Ice calorimeter An instrument used to measure amounts of heat flowing into or out of a system, 527
Ideal gas law A relationship between the pressure, volume, temperature, and number of moles of a gas: $PV = nRT$, 405–408
Ideal gases
compression/expansion, 583, 587–589
equilibrium and reactions, 624–627
heat and work for, 536
heat capacities of, 536
irreversible expansion of, 587–589
reversible processes in, 551–556
Ideal solution A solution that conforms to Raoult's law so that the vapor pressures of its components are proportional to their mole fractions in solution, 491–492
Impact parameter, 861
Impermeable Walls between thermodynamic systems that prevent flow of matter during a process, 521
"In excess" Refers to any reactant in a chemical reaction that is not the limiting reactant, 49–50
Indeterminacy An aspect of quantum mechanics, recognizing that observable properties can be indeterminate, 165
Indeterminacy principle, 165–167
Indeterminate If an observable property does not have a definite value under certain experimental conditions, it is said to be indeterminate, 165
Indicator, acid–base A substance the color of which changes noticeably over a fairly small range of pH, 483, 687–689
Indicator electrode, 786
Induced dipole forces The attraction between an ion and a nonpolar molecule or atom based on the induction of a weak dipole by the ion, 451, 451f, 452f
Induced dipole–induced dipole forces, 452
Inequality of Clausius, 588–589
Inert complex A complex in which the ligands exchange only slowly with other ligands, 360
Inert gas, 72 *See also* Noble gas
Inhibitor A substance that slows the rate of a reaction; a negative catalyst, 870
Initial (reaction) rate The rate of a chemical reaction at the moment that it begins, before any products can start to react in the reverse direction, 838
Initiation The first stage in a chain reaction, 855
Initiator A chemical reagent with bonds weak enough to be broken by heat or light to give radicals that initiate the chain polymerization of monomers, 1106
Inner coordination sphere Arrangement of ligands coordinated to metal atoms in well-defined directions in space, 355
Inner core, 80–81
Inorganic materials, 1069–1070, 1105
aluminosilicates, 1072–1073
band theory of conduction, 1090–1093
ceramics. *See* **Ceramic**
clays, 1073–1074
electrical conduction in materials, 1086–1090
optical displays, 1096–1097
phosphors, 1096–1097
pigments, 1096–1097
semiconductors, 1093–1095, 1096f
silicates, 1070–1072
zeolites, 1074–1075
Insecticides, 335–336
Instantaneous rate (of chemical reaction) The average rate, obtained over progressively shorter time intervals, 838
Insulator A substance that will not conduct electricity because of the large energy band gap between its occupied valance band and unoccupied conduction band, 1092
Integrated rate law A relation that gives the concentration of a reactant or product as a function of time, 843

Intensive property A property that is independent of the size of a system and is therefore the same for each of the subsystems into which the system can be divided, 522
Intercept, A.21
Interference, 162
Intermolecular forces, 417–422
  dipole–dipole forces, 450
  electrostatic potential energy surface, 454–455
  hydrogen bonds, 456–457
  induced dipole forces, 451, 451f, 452f
  induced dipole–induced dipole forces, 452
  ion–dipole forces, 450–451
  ion–ion forces, 450
  in liquids, 455–458
  London dispersion forces, 452
  origins in molecular structure, 449–455
  potential energy curve comparisons, 453
  repulsive forces, 452–453
  water, special properties of, 457–458
Internal conversion A nonradiative transition between electrons states of the same spin, 986
Internal energy (***U***) The sum of the internal kinetic and potential energies of the particles composing a system, 526–527
  molecular contributions to, 537–542
Interstitial alloy An alloy in which atoms of one or more additional elements enter the interstitial sites of an iron crystal, making the material stronger and harder than pure iron, 1056
Interstitial site A space between atoms in a crystal lattice in which an additional atom can be introduced, 1046–1047, 1054
Interstitials Crystal defects in which atoms are inserted at points different than their usual locations, usually away from lattice sites, 1054
Intersystem crossing A nonradiative transition between electrons states of different spin, 986
Intrinsic properties The properties displayed by a substance in very high purity form, before dopants are added, 1093
Ion product constant for water The equilibrium constant for the dissociation of water, it is the product of the concentration of hydronium ions and hydroxide ions in liquid water, 677
Ion–dipole forces, 450–451
Ionic bond A bond formed through the Coulomb attraction of two ions of opposite charge; formed from atoms with significantly different electronegativities, 64, 94–98
Ionic character Partial charge separation which leads to a dipole and a polar bond, 89
Ionic compound Formed by ionic bonding between positive and negative ions, 94, 123–124
Ionic crystals, 1047–1048, 1058–1061
Ionic equilibria between solids and solutions, 737–740
Ionic solids, solubility of, 735–736, 737t
Ion–ion forces The Coulombic interactions among ions, 450
Ionization energy (***IE***) The minimum energy required to remove an electron from an atom, molecule, or ion that is in its ground state, 79–82, 155, 226–227
Ionization methods, 68
Ionizing radiation Radiation with wavelengths shorter than that of visible light; includes ultraviolet light, X-rays, and gamma rays, 144
Ions An atom or group of atoms that has lost or gained one or more electrons, thereby becoming electrically charged, 16
  complex ions and solubility, 746–751
  selective precipitation of, 751–754
  size of, 224–225
  spectator ions, 480
Ion-selective electrode An electrode the potential of which is determined by the concentration of a particular ion in solution, 787
Irreversible process A process that does not proceed through a series of equilibrium states, and cannot be reversed by an infinitesimal change in an external force, 523
Isentropic process A process occurring at constant entropy, 584
Isobaric coefficient of thermal expansion, 446
Isobaric process A process occurring at constant pressure, 551
Isobars Nuclides with the same mass number but different numbers of protons and neutrons, 895
Isochoric process A process occurring at constant volume, 551
Isolated system A thermodynamic system which is surrounded by walls that prevent it from exchanging energy or matter with its surroundings, 521
Isomerases, 872
Isomers Compounds that have the same molecular formula, but different molecular structure and therefore different properties, 67
Isosurfaces, 202
Isotactic form Polymer structure in which the side groups are arranged on the same side of the backbone chain, 1114
Isothermal compressibility, 445, 446f
Isothermal process A process occurring at constant temperature, 551–553, 582–584
Isotones Nuclides with the same number of neutrons but different numbers of protons, 895
Isotope One of two or more atoms with very nearly identical chemical properties but with different masses, 24, 895
Isotope effects in chemical kinetics, 866–867
Isotropic, isotropy A property that is the same regardless of direction, 1078
Iteration, A.21

Kelvin temperature scale The temperature scale on which the zero is the absolute zero of temperature and the unit of measure is equal to 1 K, 405
Ketone A compound containing the

functional group, 329–330
Kinetic energy The part of the energy of a body that is associated with its motion, defined as $mv^2/2$, 78f, A.14
Kinetic molecular theory of matter, 395, 556–558
Kinetic theory of gases A model for molecular motion that predicts the properties of gases, particularly the relationship between temperature and the distribution of molecular speeds, 410
  molecular speeds, distribution of, 413–417
  temperature, meaning of, 410–413

Koopmans's approximation The ionization energy of an electron is the negative of the energy of the orbital in which the electron is bound, 222, 266–267, 267f

Labile complex A complex in which the ligands undergo rapid substitution by other ligands, 360
Lamellar membranes Layered structures of membranes, 1119
Lanthanide contraction The general reduction in the radii of atoms of sixth-period elements that occurs during the filling of the 4*f* orbitals, 225, 348–349
Lanthanide element An element from La to Lu in the periodic table; also called a rare-earth element, 70
Lasers, 144f
  Einstein radiation relations and, 1018–1020
Lattice energy The work required to separate the atoms, molecules, or ions in a crystal to an infinite distance at the absolute zero of temperature, 1057–1061
Lattice point, 1038
Law of chemical combination, 10
Law of combining volumes The volumes of reacting gases at constant temperature and pressure stand in the ratio of simple integers, 14
Law of conservation of mass In a chemical change, an equal quantity of matter exists before and after the change, 10–11
Law of definite proportions The proportions by mass of the elements that compose a compound are fixed, independent of the origin of the compound or its mode of preparation, 11
Law of mass action The relationship between concentrations or partial pressures of reactants and products of a chemical reaction at equilibrium, 618–619
  gas-phase reactions, 619–620
  reactions in solution, 620–621
  reactions involving pure substances and multiple phases, 621–623
  for related and simultaneous equilibria, 630–632
Law of multiple proportions When two elements form a series of compounds, the masses of one element that combine with a fixed mass of the second stand in the ratio of small integers, 12–14
Le Châtelier's principle A system in equilibrium that is subjected to a stress will react in a way that counteracts the stress, 639, 642–646
Lead-acid battery An assembly of rechargeable cells that employ the reaction $Pb(s) + PbO_2(s) + 2\ (aq) + 4H_30^+\ (aq) \rightarrow 2\ PbSO_4(s) + 6\ H_2O(\ell)$ to generate a voltage, 803
Leclanché cell (zinc-carbon dry cell) A primary cell using the reaction $Zn(s) + 2\ MnO_2(s) + 2NH_4^+\ (aq) \rightarrow [Zn(NH_3)_2]^{2+}\ (aq) + Mn_2O_3(s) + H_2O(\ell)$ to generate a voltage, 801
Lennard–Jones potential An expression for the potential energy of interaction of two atoms of nonpolar molecules, 421–422
Leveling effect The observation that all acids (bases) stronger than the conjugate acid (base) of a solvent have the same effective strength in that solvent, 678
Lewis acid A species that accepts electron pairs from a Lewis base, 674–676, 676
Lewis base A species that donates an electron pair to an acceptor species, 674–676, 676
Lewis diagrams for molecules, 107–109
  covalent compounds, 107–108
  double bonds, 108
  drawing, 110–111
  formal charges, 109
  heteronuclear diatomic molecules, 109
  homonuclear diatomic molecules, 108
  lone pairs, 108
  octet rule, 107–108, 113–114
  resonance hybrid, 112
  triple bonds, 108
Lewis dot symbol A representation in which an atom is shown by its symbol surrounded by dots for its valence electrons, 85
Lewis electron dot diagram A pictorial representation of covalent bonding in a particular molecule; Lewis dot symbols for the participating atoms are juxtaposed and covalent bonds are represented by dots or lines positioned between the symbols, 64
Ligand A molecule or ion bound to a metal atom or ion through coordination of its lone electron pairs, 352, 746
  strong field ligands, 370
  weak field ligands, 370
Ligand field theory A theoretical model for the formation of coordination complexes that uses concepts of molecular orbitals to describe bonding and magnetic properties, 378
Ligand substitution reactions, 360–361
Ligand-to-metal (L → M) A model of bond formation in which electrons flow from a ligand to fill a σ molecular orbital with the metal, 380, 382, 385
Ligand-to-metal (L → M) π donation, 380
Ligand-to-metal (L → M) σ donation, 382
Light, 141–144
Limiting reactant The reactant that is used up first in a chemical reaction, 49–50
Linear combination of atomic orbitals (LCAO) Method for generating approximate molecular orbitals as linear combinations of atomic orbitals, 236, 247–249, 263–265
  heteronuclear diatomic molecules, 262–265
  homonuclear diatomic molecules
    first-period atoms, 251–253
    second-period atoms, 253–262, 268f
  hydrogen molecular ion, 248–251
  valence bond method
    compared, 290–293
    using with, 286–289
Linear low-density polyethylene, 1113–1114
Linear momentum (*p*) In linear motion, the product of the mass of the moving particle and its velocity; $p = mv$, 154
Linear triatomic nonhydrides, 287–288
Liquid crystal A liquid state of matter in which some orientational ordering of the molecules persists, 1117
  micelles and membranes, 1118–1119
  structure of, 1117–1118
Liquids
  bulk properties, 443–449
  compressibility, 445
  diffusion, 447–448
  fluidity, 446–447

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

hydrogen bonds, 456–457
intermolecular forces in, 455–458
molar volume, 444
nonpolar liquids, 456
phase diagrams, 462–465
phase equilibrium, 459–460
phase transitions, 460–462
polar liquids, 456
rigidity, 446–447
surface tension, 448–449
thermal expansion, 446
water, special properties of, 457–458
Lithium-ion batteries, 804
Logarithms
common, A.25
natural, A.26
and powers, A.24–A.26
London dispersion forces Attractive forces that arise between neutral, nonpolar atoms or molecules from interactions between fluctuating dipoles in the electron density distribution of the atoms, 452
Lone-pair electrons An unshared pair of valence electrons, 108
Low-density polyethylene, 1113
Low-spin complex A coordination complex in which the *d* electrons of the metal are paired in the lowest energy orbitals available, 369
Low-spin configuration Electron configurations with a small number of unpaired spins, 369–370
LUMO (lowest unoccupied molecular orbit) The lowest energy molecular orbital that is unoccupied by one or more electrons, 795, 974
Lyases, 872

Macroscopic masses and atomic masses, 36
Macroscopic methods, 5–9
Madelung constant (*M*) The constant of proportionality, dependent on crystal structure, that relates the lattice energy of an ionic crystal to the interatomic separation, 1059–1060
Magnesia, 1083
Magnesium and electrometallurgy, 813–814
Magnetic fields, 142
Magnetic properties of coordination compounds, 372–373
Magnetic quantum number (*m*) The quantum number for a one-electron atom that governs its behavior in a magnetic field; it may have positive or negative integral values ranging from ℓ to $+\ell$, including zero, 196
Magnetic susceptibility The tendency of a substance to be attracted or repelled by magnetic fields, 372–373
Mass density, 396
Mass (*m*)
composition, 41–42
law of conservation of mass, 10
relative mass measurements, 23–26
Mass number The integer nearest to the relative atomic mass of an isotope; the combined number of protons and neutrons in the nucleus of an atom, 28
Mass percentage The percentage by mass of a given substance in the solution, 474
Mass relationships in chemical reactions, 47–49
Mass resolution, 68–69
Mass spectrometry Method for inferring the structure of a molecule by measuring the mass-to-charge ratio of the various ionic fragments produced from bombarding the molecule with energetic electrons, 23–26, 68
Mass-energy relationships, 903–908
Maximum amplitude Either the height of a crest or the depth of a trough in a wave, quoted as an absolute value, 141
Maximum-boiling azeotrope, 503
Maxwell–Boltzmann speed distribution The probability distribution for the speeds of molecules in a gas at thermal equilibrium, 414
Mean (average) value, A.3
Mean free path (λ) The average distance traveled by a molecule between collisions with other molecules in a gas, 427
Mean-square speed The square of the speed of a molecule in a gas, averaged over all the molecules, 412
Mediators, 789
Medicine, radiation in, 913–917
Megaelectron volt or million electron volt (MeV), 897
Melting The phase transition in which a liquid forms from a solid, 462
Meniscus The interface between a liquid and a gas, 463
Mesosphere, 993
Metal A substance with a characteristic metallic luster, good ability to conduct electricity, and good malleability, 71, 1090
Metal sulfide solubility, 753–754
Metallic crystals, 1048–1049, 1049f, 1050f
Metalloid, 71, 1053. *See also* **Semimetal**
Metal-to-ligand ($M \rightarrow L$) π donation Transfer of electron density from occupied metal atomic orbitals to unoccupied ligand molecular orbitals, 382
Mica A class of layered aluminosilicates, 1073
Micelle Small, nearly spherical structure formed when molecules containing both hydrophilic and hydrophobic units dissolve in water, 1119
Michaelis constant K_m, 873
Michaelis–Menten equation An equation that relates the rate of an enzyme-catalyzed reaction to the concentrations of enzyme and substrate present; $d[P]/dt = k_2[ES] = k_2\,[E]_0[S]/([S] + K_m)$, 873
Microstate A microscopic state of a system, characterized by a particular distribution of molecules among the positions and momenta accessible to them, 578
Microstructure Structural aspects of a solid, on a length scale smaller than macroscopic but larger than nanoscopic or atomic. It includes sizes and shapes of crystalline grains, sizes and shapes of voids, and the presence of mechanical stresses, 1076
Millikan, Robert, 20–21
Million electron volt Energy unit equivalent to one million electron volts, 897
Minimum basis set, 252
Minimum-boiling azeotrope, 503
Mixed oxide ceramic A ceramic in which two or more metal oxides are present, 1083
Mixture A portion of matter that can be separated into two or more substances by physical means alone, 7

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Mobility (μ) Proportionality constant relating the drift speed of a charged particle to the magnitude of the applied electric field, 1089
Moderator A substance that effectively slows high-velocity neutrons, 918
Molality (m) The number of moles of solute present per kilogram of solvent, 475
Molar absorption coefficient A measure of the amount of light absorbed by a 1 M solution of a given compound (sometimes also called the molecular extinction coefficient), 975
Molar conductivity (L_m), 1088
Molar enthalpy of fusion The energy per mole for melting a solid at constant pressure, 545
Molar enthalpy of vaporization The energy per mole for vaporizing a liquid at constant pressure, 545
Molar heat capacity (c_p), 531
Molar mass (M) The mass of one mole of a substance, 37
Molar volume The volume occupied by one mole of a substance, 39, 444
Molarity (M) The number of moles of solute per liter of solution, 474
Mole fraction (X_A) The number of moles of a particular component in a mixture divided by the total number of moles of all components; $X_A = n_A/n_{tot}$, 409, 474
Mole (mol) The SI base unit giving the amount of any that contains as many elementary particles as there are in 0.012 kg of ^{12}C, 37–38
Molecular beams, 414, 867–868
Molecular crystals, 1051–1052, 1051f, 1057–1058
Molecular electrochemistry, 787–800
Molecular formula A chemical formula that specifies the actual number of atoms of each element in one molecule, 40–41, 43
Molecular orbital (MOs) A one-electron wave function that is distributed over all the atoms in a molecule, 236, 245, 378
  antibonding MOs, 252
  bonding MOs, 252
  linear combination of atomic orbitals method, 236, 247–248
    heteronuclear diatomic molecules, 262–265
    homonuclear diatomic molecules
      first-period atoms, 251–253
      second-period atoms, 253–262, 268f
    hydrogen molecular ion, 248–251
  photoelectron spectroscopy for molecules, 266–267, 267f
Molecular shapes/structures, 115–120
  and acid strength, 685–687
  and electrostatic forces, 284–286
  intermolecular forces, 449–455
  predicting, 281–286
  quantum mechanics and, 235–299
Molecular size, 38–40
Molecular spectroscopy, 102–103, 941–944
  experimental methods in, 947–948
  rotational spectroscopy, 102–103, 949–954, 962
  spectral transitions, intensities of, 944–946
  vibrational spectroscopy, 955–973
Molecules A group of two or more atoms bonded together by forces strong enough to maintain its existence for a reasonable period of time, 12, 65
  electronic spectroscopy of. *See* **Electronic spectroscopy of molecules**
  representations of, 65–70
  scanning tunneling microscope, 26–27, 27f
Momentum Velocity multiplied by mass, 411, A.12
Monomer unit A basic repeating unit in a long-chain polymer molecule, 1105
Monoprotic acid An acid capable of donating at most one hydrogen ion per molecule, 704
Monosaccharide A simple sugar containing only one ring, 1120
Morse potential energy function A model intramolecular potential energy function that accounts for the shapes of potential energy curves but also allows for analytic solutions of the Schrödinger equation for nuclear vibrational motion, 960–961, 961f
Mortar A mixture of portland cement with sand and water, 1081
Most probable speed The speed at which the Maxwell–Boltzmann distribution achieves its maximum value, at a particular temperature, 415
Motion of an object, A.12–A.14
Mulliken's electronegativity scale, 88–91
Multiple bonds, 271
  in organic carbon compounds, 278–280

Nanoscopic models, 5–6
Nanotubes, 323
Naphtha, 311
Natural logarithm Logarithms expressed in the base of e = 2.7182818..., A.26
Negative force An attractive force that tends to pull two charged particles together is negative by convention, 770, A.17
Nematic phase of liquid-crystal formation A liquid crystal in which the molecules show a preferred orientation but their centers are distributed at random, 1117
Nernst equation A relationship giving the potential difference developed by an electrochemical cell as a function of the temperature and the concentrations and partial pressures of reactants and products; $\Delta E = \Delta E° - (RT/nF) \ln Q$, 781–787
Nernst heat theorem The statement that the entropy change in any process approaches zero as the temperature approaches absolute zero, 590
Net ionic equation A chemical equation in which only those ions and molecules involved in the chemical change are represented; spectator ions are omitted, 480
Network solid, 1084
Neutralization reaction A reaction between an acid and a base, 484
Neutron diffraction, 926
Neutron emission Decay mechanism for nuclides with very small N/Z rations, involving loss of neutrons, 900
Neutron number (N), 894
Neutron scattering, 926
Newton The unit of force in the SI system, 76

Nicad batteries, 802
Nickel-cadmium cell, 802
Nitrate ions, 112
Noble gas An element of Group VIII of the periodic table, 72
Nodal line, 179
Node A region of no vibration (of zero amplitude) of a standing wave, 161, 168
Nonbonding atomic orbitals Atomic valence orbitals that do not participate in formation of the bond in a particular molecule, 263–265
Nonideal solution A solution in which the vapor pressures of the components deviate from the predictions of Raoult's law, 491–492
Nonlinear synthetic polymers, 1109–1110
Nonlinear triatomic molecules, 288–289
Nonmetal A substance lacking a metallic luster, having poor ability to conduct electricity, and lacking the malleability of metals, 71
Nonoxide ceramics, 1076, 1084–1086
Nonpolar Having no dipole moment, 120
Nonpolar liquids Liquids whose molecules are nonpolar, and in which only dispersion forces operate between molecules, 456–457
Nonpolar molecules, 120
Nonprimitive unit cells, 1039
Nonradiative transitions Transitions between quantum states of molecules that do not result in the absorption or emission of radiation, 985
Nonsilicate ceramics, 1082–1086
Nonstoichiometric compound A solid compound in which the proportions of the constituent elements are continuously variable over some range, 11, 1054–1056
Nonvolatile solutes, phase equilibrium in, 491–499
Normal alkanes, 309–311
Normal boiling point The temperature at which the vapor pressure of a liquid equals one atmosphere, 462
Normal hydrogen electrode (NHE), 773
Normal melting point The temperature at which the solid and liquid phases of a substance are in equilibrium at a pressure of one atmosphere, 462
Normalized A probability distribution in which the probability weight for each possible event, summed over all possible events, has the value 1, 171, A.32
***n*-type semiconductor** A semiconductor that conducts electric current through the motion of negatively charged particles (electrons) in its conduction band, 1093
Nuclear binding energies, 906–908
Nuclear chemistry, 891–892, 923
  alpha decay, 900
  beta decay, 900
  decay kinetics, 908–912
  decay process, 898–903
  electron capture, 902
  fission, 900, 917–922
  mass-energy relationships, 903–908
  neutron emission, 900
  nuclear fusion, 922–923
  nucleosynthesis, 923
  positron emission, 901–902
  proton emission, 900
  radiation in biology and medicine, 913–917
  radioactive dating, 911–913
  radioactivity, 892–894
  uranium enrichment, 428–429
Nuclear fission, 918
Nuclear fusion The exothermic union of two light nuclei to form a heavier nuclide, 922
Nuclear magnetic resonance spectroscopy, 966–973
Nuclear magneton A fundamental electromagnetic physical constant used to express nuclear magnetic moments, 967
Nuclear power reactor Controlled nuclear reactors that generate heat to drive electrical power generation plants, 920–922
Nuclear structure, 894–898
Nuclear wave function, 242
Nucleic acids, 1125–1128
Nucleons General name for protons and neutrons, the building blocks for nuclei, 894
Nucleosynthesis The production of heavier nuclides from lighter ones, especially in the interiors of stars, 923
Nucleotide A component of the genetic material DNA composed of a pyrimidine or purine base, a sugar, and a phosphate group, 1126–1128
Nucleus, 21–23
  shell model of, 925–932
  slow nuclei, 239–240
  structure of, 28–29
Nuclides Distinct atomic species characterized by atomic number *Z*, mass number *A*, and nuclear energy state, 894
Number density Number of molecules per unit volume, usually number cm^{-3}, 396, 444
Number of moles To group atoms or molecules in counting units of $N_A = 6.0221420 \times 10^{23}$ to measure the moles in a substance, 37

Octahedral geometries, 361–362, 363f
Octahedral site, 1046
Octane number A measure of the smoothness of combustion of gasoline in an automobile engine, 314
Octet rule Main-group elements lose, gain, or share electrons in chemical bonding in such a way as to attain a valence octet, 107–108, 113–114
Olivine A complex silicate of magnesium and iron used in refractories, 1071
Open system A thermodynamic system in which both matter and energy may be freely exchanged with the surroundings, 521
Optical displays, 1096–1097
Optical isomerism An isomer that is not superimposable on its own mirror image and therefore is capable of rotating the plane of polarization of a beam of planepolarized light passed through it or its solutions, 313–314
Optical properties of transition-metal complexes, 374–376
Orbital A wave function that is an allowed solution of the Schrödinger equation for an atom or molecule, 198
  d orbitals, 206–209, 208f
  H_2^+, 294–299

Hartree orbitals, 194, 210–211
shielding effects, 212–214, 215f, 215t
sizes and shapes, 211–212
hybridization for polyatomic molecules, 273–280
linear combination of atomic orbitals method. *See* **Linear combination of atomic orbitals (LCAO)**
molecular orbitals. *See* **Molecular orbital**
nonbonding atomic orbitals, 263–265
p orbitals, 204–206
s orbitals, 200–204
self-consistent field (SCF) orbital approximation method, 210
sizes and shapes, 199–209
Hartree orbitals, 211–212
sp hybrid atomic orbitals, 273–274
sp^2 hybrid atomic orbitals, 274–275, 276f
sp^3 hybrid atomic orbitals, 276–277, 278
Orbital approximation for atoms The use of a one-electron wave function for each electron in a many-electron atom, 211
Orbital approximation for molecules, 248
Order The power to which the concentration of a species is raised in the rate law for a reaction is the order of the reaction with respect to that species, 840
Organic acids and bases, 710–712
electronegativity, 712–713
resonance, 713–714
steric hindrance, 713
Organic carbon compounds, 278–280
Organic chemistry The study of the compounds of carbon, 308–309
Organic molecule bonding, 339–340
alkanes. *See* **Alkanes**
alkenes, 314–319
alkynes, 314–319
aromatic hydrocarbons, 319–321, 322f
fullerenes, 322–323
functional group. *See* **Functional group**
hydrocarbons, 308–309
petroleum refining, 308–309
Organic molecules with delocalized electrons, 289
Orthosilicate, 1071
Osmotic pressure (π) The pressure that must be applied to a solution to prevent the net diffusion of pure solvent through a semipermeable membrane into the solution, 498–499
Outcomes, A.30
Outer coordination sphere Nondirectional arrangement of ligands coordinated to metal atoms, 355
Overall reaction order The sum of the exponents of the species appearing in the rate expression for a reaction, 841
Oxidation number A number assigned to an atom in a molecule that reflects its state of oxidation, 120–122
Oxidation reduction reaction (redox reaction) A reaction in which electrons are transferred; a reaction in which the oxidation number of at least one element changes, 485–489
Oxidation states of transition-metal elements, 351–352
Oxide ceramics A class of ceramics in which silicon is a minor or nonexistent component, 1075, 1082–1083
Oxides of manganese, 122f
Oxidized Having lost electrons in a chemical reaction, 485
Oxidizing agent A substance that causes the oxidation of another substance, while it itself is reduced, 776
Oxidoreductases, 872
Oxoacid An acid containing a hydrogen ion in combination with an oxoanion, 685
Ozone depletion, 1003–1009

***p* orbital** A set of three degenerate atomic orbitals with angular momentum quantum number $\ell = 1$, 204–206
PANs Abbreviation for polyacylnitrates, a class of nitrogen-containing molecules that are associated with photochemical smog, 996
Paramagnetic substance The property of being attracted into an inhomogeneous magnetic field, 217
Parameter, 242
Partial pressure (P_A) That part of the total pressure of a gas mixture due to one particular component, 408
Particle-in-a-box models, 172, 175f
one-dimensional boxes, 172–176
three-dimensional boxes, 176–178
two-dimensional boxes, 176–178
wave functions for particles in cubic boxes, 180–182
wave functions for particles in square boxes, 178–180
Partition coefficient (K) The equilibrium constant describing the distribution of a solute species between two immiscible solvents, 650
Pascal (Pa) The SI unit of pressure; equal to 1 N m^{-2}, 399
Passivation The phenomenon in which an active metal is protected from further oxidation by the formation of a thin oxide layer at its surface, 810
Pauli exclusion principle The statement that no two electrons in an atom may have the same set of quantum numbers; more generally, two electrons with the same spin may not occupy the same point in space at the same time, 215
Pauling's principle of electroneutrality, 88–91
***p*-block element** An element that arises with the filling of a *p* orbital in the building up of the periodic table, 217
Peptide linkage The linkage formed by the reaction of the carboxyl group of one amino acid with the amine group of a second, with elimination of water, 1122
Percentage composition and empirical formula, 41
Percentage yield The actual yield of a reaction divided by the theoretical yield (and multiplied by 100%), 64
Period A row in the periodic table, 70
Periodic law The chemical and physical properties of the elements are periodic properties of their atomic numbers, 70
Periodic properties, 224–227
Periodic table A table that organizes the elements by atomic number and chemical properties into groups and periods, 64, 70–73, 71f
shells and, 220–223
Periodic trends in ionizing energies, 226–227
Permittivity of the vacuum (I_0), 73
Perovskite, 1083
Pesticides, 335–336
Petroleum refining, 308–309
pH A measure of the hydronium ion concentration in a solution; pH = $-\log [H_3O^+]$, 679–680
effect on solubility, 744–746

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

pH meter A galvanic cell in which the voltage is a linear function of the pH of the solution in the cell, 679–681, 785–787
Pharmaceuticals, 337–340
Phase A sample of matter that is uniform throughout, both in its chemical constitution and in its physical state, 459
Phase diagram For a one-component system, a plot of temperature against pressure, showing the state or states of matter that are stable under each set of conditions, 462–465
Phase equilibrium Equilibrium state in which two or more different phases coexist, for example, solid and liquid, 459–460, 474
  nonvolatile solutes, 491–499
  volatile solutes, 499–504
Phase transition A change in the physical state of a substance, 460–462
  entropy, 583–584
  and Gibbs free energy, 594–595
Phenol An organic compound which has an —OH substituted on an aromatic ring, 327
Phlogiston, 10
Phosphor A doped semiconductor capable of emitting light when excited, 1096–1097
Phosphorescence, 986
Phosphoryl chloride, 111
Photocathode, 158
Photochemical processes Chemical reactions initiated by the absorption of electromagnetic radiation, almost always visible or ultraviolet radiation, 984
Photocurrent, 158
Photoelectric effect The ejection of electrons from the surface of a substance by light; the energy of the electrons depends upon the wavelength of the light, not the intensity, 157–161
Photoelectrochemistry, 795–797
Photoelectron spectroscopy A type of spectroscopy in which the kinetic energies of electrons ejected by photons from an atom, molecule, or solid are measured; allows orbital energies to be determined, 220–223, 266–267, 267f
Photoelectrons, 158
Photographic emulsion, 893
Photon A packet of electromagnetic radiation; the "particle" of light, 159
Photophysical processes Physical processes initiated by the absorption of electromagnetic radiation, almost always visible or ultraviolet radiation, 984
Photosynthesis, 1009–1014
  artificial, 798
Physics overview, A.12–A.19
Pi (π) bonds, 271
π acceptors Alternate name for strong field ligands, 385
π donors A bond resulting from the occupancy of p molecular orbitals by electrons, 385
Pigments, 1096–1097
Pitch, 1118
Planck's constant (h) The proportionality constant between the energy and the frequency of a photon; equal to 6.62608×10^{-34} J s, 148
Planck's hypothesis, 146–149
Planetary model of atom, 153
Plastics A polymeric material that is molded when hot and that hardens upon cooling, 1113
Point mass, 1113–1115
p–n junctions, 1094–1095
Point mass, A.12
Polar Having a dipole moment, 120
Polar covalent bond A bond intermediate in character between covalent and ionic, 64, 105
Polar liquids Liquids whose molecules have permanent dipole moments, 456
Polar molecules, 120
Polarizability A measure of the extent to which electrons in atoms or molecules are displaced by electric fields, most often the electric fields of electromagnetic radiation, leading to induced dipole moments, 451, 952
Polarization The distortion of the charge distribution of an atom or ion due to a nearby charge, 98
Polyatomic molecules, 271–273
  dipole moments of, 118–120
  orbital hybridization, 273–280
  rotational spectroscopy, 962
  vibrational spectroscopy, 962–966
  wave function for electron-air bonds, 271–273
Polyene, 318
Polymer A compound of high molar mass comprised of repeating subunits, 1105
  amino acids, 1122–1126
  carbohydrates, 1120–1122, 1121f
  electrically conducting polymers, 1116–1117
  natural polymers, 1119–1128
  nucleic acids, 1126–1128
  nucleotides, 1126–1128
  polysaccharides, 1120–1122, 1121f
  proteins, 1122–1126
  synthetic. *See* **Synthetic polymers**
Polymerization reactions for synthetic polymers, 1106–1110
Polypeptide A polymer of amino acid monomer units, 1122
Polyprotic acid An acid capable of donating more than one hydrogen ion per molecule to base acceptors, 704
  pH on solution composition, effect of, 706–707
  titration of, 718–719
  weak polyprotic acids, 704–706
Polysaccharide A polymer formed by linking simple sugars together in long chains, 1120–1122, 1121f
Polyunsaturated oil, 331
Portland cement A building material made by a high-temperature reaction of lime with clay to form a calcium aluminum silicate; when mixed with water, sand, and aggregate, it makes a concrete that can be poured in place and allowed to harden to give a strong solid, 1080
Positive charges, A.17
Positron A positively charged fundamental particle; the antiparticle of the electron, 895
Positron emission A mode of radioactive decay in which a nuclide emits a positron and a neutrino as one of its protons transforms into a neutron, 901–902
Positron Emission Tomography, 914–915
Postulates, 9
Potential difference, 767

Potential energy curves Representation of the potential energy of an object as a function of its position relative to a selected reference point, 420
force, stability and, A.16–A.17
representing energy conversion by, A.15, A.15f
Potential energy (E_p) The energy that a particle has by virtue of being attracted to (or repelled by) other particles, A.14–A.15
in atoms, 73–78
comparison of curves, 453
Coulomb potential energy, A.18
in molecules, 91–94
Potential energy function, 73–74
Pottery, 1077–1078
Powers and logarithms, A.24–A.26
Precipitation
selective precipitation of ions, 751–754
and solubility product, 740–744
Precipitation reaction The formation of a solid from solution; the reverse of dissolution, 480
Precision, A.3
Prefixes Greek prefixes used in the SI system of units to indicate orders of magnitudes, A.10
Pressure (*P*) The force exerted by a gas or other material per unit area on the walls of its container, 398–401
Gibbs free energy of a gas, dependence on, 624
heat transfer at constant pressure, 532–533
vapor pressure, 459–460
Pressure-volume work, 525
Primary alcohol, 327
Primary amine, 334
Primary cells A battery (galvanic cell) that must be discarded when its energy has been transferred and its voltage gone to zero, 801
Primary kinetic isotope effects, 866
Primitive unit cell A unit cell containing one lattice point, 1038
Principle quantum number (n), 195–196
Probability, 170, A.30
random variables, A.30–A.31
average values of, A.32
continuous, and probability functions, A.32–A.33
theoretical, experimental tests of, A.33
Probability density function A continuous function that describes the probability of finding the value of a dependent variable within an infinitesimally small region around each value of the independent variable, A.33
Probability function (*P*[*X*]) A function, which may be discrete or continuous, that describes the probability of finding the value of a dependent variable at or near each value of the independent variable, A.31–A.32
continuous random variables and, A.32–A.33
Probable value X_{mp}, A.31
Product, 643–644
Product constant for water, 677
Promotion A concept introduced by Linus Pauling to account for the filling of nearly degenerate hybrid orbitals, 273
Propagation The second stage in a chain reaction, 855
Proportional counters A class of radiation counters that measures both the energy and the intensity of ionizing radiation, 894
Proteins A naturally occurring longchain polymer composed of amino acid subunits, 332–333, 1122–1126
heme, 364–365
Proton emission A rare event in which a proton is emitted from a nucleus to bring the neutron/proton ratio closer to the line of stability, 900
Proton (p), 28–29
***p*-type semiconductor** A semiconductor that conducts electricity through the apparent motion of positively charged particles (holes) in its valence band, 1093
Pure substance A sample of matter that cannot be separated into different components by a physical process, 8
Pyrometallurgy The recovery of elemental metals from their ores through high-temperature chemical reactions, 810–811

Quanta, 147
Quantum electrodynamics A relativistic quantum theory that accounts for the interactions between matter and radiation, 169–170
Quantum mechanics The fundamental branch of physics that describes the properties, interactions, and motions of atomic and subatomic particles, 64, 139–141
Bohr model, 153–157
bonds. *See* **Bond(s)**
discrete energy levels, predicting, 153–157
electromagnetic radiation, 142–145
energy quantization in atoms. *See* **Energy quantization in atoms**
light, 141–144
and molecular structure, 235–299
particle-in-a-box models. *See* **Particle-in-a-box models**
Schrödinger equation, 167–171
wave motion, 141–144
wave-particle duality. *See* **Wave-particle duality**
Quantum numbers, 195–197, 210
Quantum state Any state of a quantum system characterized by a unique set of quantum numbers, 196
Quantum yield The fraction of events that leads to a particular outcome divided by the total number of possible outcomes, 988
Quarks, 897
Quaternary compounds, 8
Quotient of integers, 12

rad, 913
Radial charge density distribution function $p(r)$, 212
Radial node A sphere about the nucleus on which ψ and ψ^- are zero, 204
Radial probability density The probability per unit volume of finding a particle (such as an electron) at a distance r away, 202
Radiation in biology and medicine, 913–917
Radiative transitions Transitions between quantum states of molecules that result in the absorption or emission of radiation, 985
Radical A species in which one or more valence electrons are unpaired; radicals are often but not always highly reactive; often occurs as an intermediate in reactions, 314
Radioactive dating, 911–913

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Radioactivity, 892–894
Radiotracers A radioactive element, or a compound that contains a radioactive element, that is used to follow the course of chemical reactions or to follow the movement of substances, primarily in living organisms, 901, 914, 915
Raman scattering A form of inelastic light scattering in which part of the energy of an incident photon is transferred to an atom or molecule resulting in a scattered photon with lower energy, 942
Random copolymer A polymer made from two or more types of monomer units, arranged at random along the chain, 1109
Random variables, A.30–A.31
  average values of, A.32
  continuous, and probability functions, A.32–A.33
Raoult's law A relationship between the vapor pressure P_1 of component 1 of an ideal solution, its mole fraction X_1, and the vapor pressure $P°$ of the pure substance: $P_1 = X_1$, 491
Rate constant (***k***) The proportionality constant between the rate of a reaction and the concentrations of the species that appear in the rate law, raised to the appropriate powers, 839
Rate expression or rate law An equation relating the rate of a reaction to the concentrations of species present in the reaction mixture, 839
Rate-determining step, 850
Reactant, 643–644
Reaction coordinate, 858–859
Reaction dynamics That branch of chemistry concerned with understanding the microscopic details of reactive encounters as they relate to chemical kinetics, 859
Reaction enthalpy The energy change in a chemical reaction carried out at constant pressure, 542–546
Reaction intermediate A chemical species that is formed and consumed in the course of a reaction and does not appear in the chemical equation representing the reaction, 848
Reaction mechanism A series of elementary reactions, together with their rates, that describe the detailed steps by which a reaction proceeds, 836, 846–855
Reaction path The route followed as reactant molecules, atoms, or ions interact to give products, 858
Reaction quotient (***Q***) A positive number in which the ratio of concentrations or partial pressures of products raised to powers corresponding to their stoichiometric coefficients are divided by concentrations or partial pressures of reactants similarly raised to powers, 639, 647
Reaction stoichiometry
  acid–base titrations, 481–484
  oxidation-reduction titrations, 485–489
Reactions, 835–836, 878
  activated complex, 858–859, 865
  activity, 628–630
  catalysis, 869–873
  chain reactions, 855
  collision theory, 859–864
  diffusion-controlled reactions, 868
  direction of change in
    empirical description, 639, 642–646
    thermodynamic explanation, 646–650
  elementary reactions, 847
  endothermic reactions, 543, 645
  equilibrium reactions for gas-phase and heterogeneous reactions, 638
  exothermic reactions, 543, 645
  first order reactions, 840, 843–844
  gas-phase reaction rate constants, 856–858
  and Gibbs free energy, 595–597
  ideal gases and equilibrium, thermodynamic description of, 624–627
  ideal solutions and equilibrium, thermodynamic description of, 627–628
  integrated rate laws, 843–846
  isotope effects in, 866–867
  kinetics and chemical equilibrium, 849–850
  law of mass action for reactions in solutions, 620–621
  law of mass action for reactions involving pure substances and multiple phases, 621–623
  mass relationships in, 47–49
  measuring rates, 837–839
  mechanisms, 846–850, 850–855
  order of, 839–842
  polymerization reactions for synthetic polymers, 1106–1110
  precipitation reaction, 480
  involving pure solids and liquids and multiple phases, 628–630
  radioactive decay, 908–912
  rate laws, 839–845
  rates of, 836–839, 850–859
  reaction coordinate, 858–859
  second order reactions, 840, 844–846
  in solution, 868–869
  steady-state approximation, 853–854
  temperature, effect of on rates, 856–859
  transition state theory, 864–865
  zeroth order reactions, 840
Reactive cross section The cross sectional area of a molecule that is effective as a target for collision and reaction, 860
Rechargeable batteries, 802–805
Recrystallization Powerful method of the purification of substances by dissolution and subsequent precipitation, 734
Rectification The conversion of alternating current into direct current, 1094
Redox reactions, 485–489
Redox titration, 490–491
Reducing agent A substance that causes the reduction of another substance, while it itself is oxidized, 776
Reduction potential diagram A convenient diagram that summarizes the potentials for oxidations and reductions of a chemical species and for determining its propensity to disproportionate, 777–778
Reforming reaction, 326
Reforming reaction [1] Generation of aromatic hydrocarbons from straight-chain alkanes, 320–321
Reforming reaction [2] Generation of hydrogen and carbon monoxide by the high-temperature reaction of methane (or another hydrocarbon) with water, 327, 619
Refractory A ceramic material that withstands a temperature of more than 1500°C without melting, 1083

Relative atomic mass The dimensionless mass of an atom, measured on a relative scale with the mass of a ^{12}C atom equal to 12, 13, 15
Relative molecular mass The sum of the relative atomic masses of the elements contained in the molecule, each one multiplied by the number of atoms of that element in the molecule, 25
rem, 913
Representative element An element of Groups I through VIII of the periodic table; a main-group element, 70
Repulsive charges A force between two particles that pushes them apart, A.17
Repulsive forces Forces that correspond to negative slope of the potential energy curve, 452–453
Resistance (*R*) Property of a system that measures the difficulty of passing electrical current through that system; depends on geometry and composition of the system, 1087
Resistivity (*ρ*) Property of a substance or material that measures the difficulty of passing electrical current through it, regardless of geometry, 1087
Resonance and organic acids and bases, 713–714
Resonance hybrid The "true" Lewis structure represented by the combination of two or more resonance structures, 112
Reverse micelles, 1119
Reverse osmosis The nonspontaneous movement of a solvent through a semipermeable membrane driven by an external force, 499
Reversible process A process that proceeds through a series of equilibrium states, and can be reversed by an infinitesimal change in an external force, 523
Rigid walls Walls that do not deform when arbitrarily large external forces are applied, 521
Rigidity Tendency to maintain shape under stress, 446–447
Rock-salt structure of ionic crystals, 1047 *See also* **Sodium chloride structure**
Root-mean-square speed A measure of the typical speed of molecules at thermal equilibrium; equal to the square root of the average of the squares of the speeds of the molecules, 413
Rotational spectroscopy
  bond angles and lengths, 102–103
  diatomic molecules, 949–954
  polyatomic molecules, 962
Rounded off, A.6
Rubber, 1115–1116
Rutherford, Ernest, 22–23
Rydberg (Ry) A unit of energy used in atomic spectroscopy; equal to 2.18×10^{-18} J, 155

***s* orbital** Nondegenerate atomic orbitals with angular momentum quantum number ℓ, 200–204
Sacrificial anode A piece of an active metal (such as magnesium) placed in electrical contact with a metal (such as iron) that is to be protected from oxidation, 810
Salt bridge A tube containing a salt solution that is used to connect two half-cells in an electrochemical cell; allows the passage of ions, but prevents mixing of the half-cell electrolytes, 765
Salt solubility, 746
Salts of bases, solubility of, 746
Saturated A carbon atom bonded to four other atoms, the maximum number allowed by its valence, 314, 331
Saturated calomel electrode A standard electrode that consists of a platinum wire in contact with a paste of liquid mercury, calomel (Hg_2Cl_2), and a saturated solution of Hg_2Cl_2, 778
Saturated hydrocarbon, 314, 734
Saturated solutions A solution in equilibrium with a solid solute, 734
Saturated triglycerides, 331
s-block element, 217
Scanning tunneling microscopy of atoms, 26–27
  at single molecule level, 26–27, 27f
Schottky defect A vacant site in a crystal where the pattern indicates an atom should be found, 1054
Schrödinger equation The fundamental equation of quantum mechanics that relates the wave function of one or more particles to their masses and potential energies, 167–171
Scientific law, 4
Scientific notation, A.2
Scientific revolution, 139
Scintillation counter An instrument for the detection of radioactive decay based on the counting of light pulses produced by radiation when it enters a crystal, 893
Second law of thermodynamics, 580–581
Second order reaction A reaction that has a total order of 2, as determined by the sum of the exponents of the concentration terms in the rate law; if a reaction is second order in a single species A, the concentration of A changes with time according to $1/[A] = 2kt + 1/[A]_0$, 840, 844–846
Secondary Refers to batteries that cannot be recharged in electrochemistry or to isotope effects at atoms adjacent to the reactive site in kinetics, 801, 866
Secondary alcohol, 327
Secondary amine, 334
Secondary battery, 802
Secondary cell, 801
Secondary kinetic isotope effects, 866
Selection rule A rule that governs the probability of a particular transition between quantum states, 950
Self-consistent field (SCF) orbital approximation method Generating approximate one-electron wave functions for each electron in a many-electron atom or molecule by estimating the effective field set up by all the other electrons and obtaining the wave function for that effective field; the process is repeated iteratively until the effective field and approximate wave function no longer change upon further iterations, 210
Semiconductor A substance having electrical conductivity that is small but still greater than that of an electrical insulator and that increases with temperature, 72, 1053, 1092, 1093–1095, 1096f
Semimetal A material intermediate in character between a metal and a nonmetal, 71, 1053
Semipermeable Allowing passage of small molecules but not of large molecules, 498
Separation of variables, 176
Sequester To coordinate a species so strongly that it is prevented from taking part in its ordinary reactions, 367

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Shear viscosity The measure of the resistance of a substance to flow, 446
Shell A group of subshells in the electron configuration of an atom that have similar energies, 212
Shell model for atomic structure A model of the atom in which the electrons are envisaged as occupying a series of concentric shells centered around the nucleus, 82
Shell models
of the atom, 82–85
for many-electron atoms, 210–214, 215f, 215t
of the nucleus, 925–932
and the periodic table, 220–223
Shift reaction, 619
SI units, A.9–A.11
Sialon An alloy of silicon, aluminum, oxygen, and nitrogen, 1085
Side-centered unit cell A unit cell having lattice points at the center of one pair of parallel cell faces as well as at the eight corners, 1039
Sigma (σ) bond A bond resulting from the occupancy of s molecular orbitals by electrons, 271
Sigma (σ) donor Alternate name for intermediate field ligands, 385
Significant figures, A.5–A.7
Silicate A compound containing silicon and oxygen and formed from the linking together of structural units, 1070–1072
Silicate ceramics Ceramics made from aluminosilicate clay minerals, 1075, 1077–1081
Silicon bonding, 1090–1093
Silicon carbide, 1086
Silicon nitride, 1084
Simple cubic lattice A crystal lattice in which the unit cell comprises a simple cube, with one atom located at each vertex, 1042
Simultaneous algebraic equations, 632
Single bond, 268–271
Sintering The partial merging of grains in a solid by diffusion at a temperature less than the melting point, 1077
Slope of line, A.21
Slow nuclei, 239–240
Smectic phase of liquid-crystal formation A liquid crystal in which molecules show a preferred orientation and a layered structure, 1117
Smelting The melting and reduction of metals from their ores, 811
Soda-lime glass Common glass of approximate composition $Na_2O \cdot CaO \cdot (SiO_2)_6$, 1079
Sodium chloride structure of ionic crystals An ionic crystal structure that consists of two interpenetrating face-centered cubic lattices of cations and anions, 1047
Soft acids, 354
Solar energy conversion, 798–799
Solids, 1035–1036
alloys, 1056
amorphous solids, 1056
bulk properties, 443–449
compressibility, 445
crystals. *See* **Crystal**
diffusion, 447–448
fluidity, 446–447
glasses, 1056
ionic equilibria between solids and solutions, 737–740
ionic solids, solubility of, 735–736, 737t
molar volume, 444
phase diagrams, 462–465
phase equilibrium, 459–460
phase transitions, 460–462
rigidity, 446–447
surface tension, 448–449
thermal expansion, 446
Solubility The amount of a solute that dissolves in a fixed volume of a particular solvent at a given temperature, 479, 735
complex ions and, 746–751
of hydroxides, 744–745
ionic solids, 735–736, 737t
and K_{sp}, 738–740
of metal sulfides, 753–754
of salts of bases, 746
Solubility equilibria, 733–734, 750
complex ions and solubility, 746–751
features of, 734–735
ionic equilibria between solids and solutions, 737–740
ions, selective precipitation of, 751–754
pH on, effects of, 744–746
precipitation and solubility product, 740–744
Solubility product The amount of a solute that dissolves in a fixed volume of a particular solvent at a given temperature, 738, 740–744
Solute One of the minor components in a solution, 473, 491–499
Solution A homogeneous system that contains two or more substances, 473–474, 508
acid and base properties in aqueous solutions, 677–680
aqueous solutions of ionic species, 479–481
aqueous solutions of molecular species, 478–479
boiling-point elevation, 492–495
colloidal suspensions, 504–505
composition of, 474–478
dissolved species, natures of, 478–481
distillation, 501–504
freezing-point depression, 495–497
Henry's law, 500
ideal solutions and equilibrium, thermodynamic description of, 627–628
ionic equilibria between solids and solutions, 737–740
law of mass action for reactions in, 620–621
nonvolatile solutes, 491–499
osmotic pressure, 498–499
oxidation-reduction titrations, 485–489
pH on solution composition, effect of, 706–707
phase equilibrium in
nonvolatile solutes, 491–499
volatile solutes, 499–504
precipitation from, 741–742
preparation of, 476–478

reaction stoichiometry
acid–base titrations, 481–484
oxidation-reduction titrations, 485–489
saturated solutions, 734
supersaturated solutions, 735
unsaturated solutions, 734
vapor-pressure lowering, 492
volatile solutes, 499–504
Solvate The process of surrounding solute molecules with solvent molecules, 734
Solvation, 734
Solvation shell The shell of solvent molecules that surrounds a solute molecule, 479
Solvent The major component in a solution, 473
sp hybrid atomic orbitals A pair of hybrid orbitals constructed from one *s* and one *p* orbital oriented 180° with respect to one another, 273–274
sp^2 hybrid atomic orbitals A set of three hybrid orbitals constructed from one *s* and two *p* orbitals oriented 120° with respect to each another, 274–275, 276f
sp^3 hybrid atomic orbitals A set of four hybrid orbitals constructed from one *s* and three *p* orbitals oriented 109.5° with respect to each another, 276–277, 278
Specific heat capacity (c_s) The amount of heat required to raise the temperature of one gram of a substance by one kelvin at constant pressure, 527, 531
Spectator ion An ion that does not take part directly in a chemical reaction but is present in the reaction system, 480
Spectrochemical series An ordering of ligands according to their ability to cause crystal field splittings, 375
Spectrograph An instrument used to record the wavelengths of light emitted by atoms or molecules, 149–150, 150f, 151f
Spectrophotometers, 828
Spectroscopy
electronic spectroscopy. *See* **Electronic spectroscopy of molecules**
molecular. *See* **Molecular spectroscopy**
nuclear magnetic resonance spectroscopy, 966–973
Spectrum, 149–150
Speed (***u* or *s***) The rate at which a molecule is moving, in meters per second, 410
average speed, 415, A.12
Sphalerite structure, 1048
Spherical harmonics A set of functions used to describe angular momenta in atoms, 197
Spin quantum number (m_s) A quantum number that describes the magnetic properties of a particle; takes on the values $\pm\frac{1}{2}$ for an electron, 210
Spin-spin coupling The presence of nuclear spins on atoms adjacent to the atom to which a nucleus of interest is bonded affects the local magnetic field at that nucleus, leading to characteristic patterns used to identify functional groups in NMR spectroscopy, 971
Spin-spin splitting, 969
Spontaneous processes, 571–572
entropy. *See* **Entropy** (***S***)
Gibbs free energy. *See* **Gibbs free energy**
nature of, 572–575
nature of spontaneous processes at fixed *T* and *P,* 592–593
Square-planar complexes, 370–372
Square-planar geometries, 362, 363f, 366
Stable equilibrium That state of a system in which the net force acting is zero, A.17
Standard atmosphere (**atm**) A unit of pressure; equal to 101,325 Pa; the daily pressure at sea level varies in the vicinity of one standard atmosphere, 399
Standard cell potential The potential of an electrochemical potential when all of its components exist under standard conditions, as defined thermodynamically, 772
Standard cell voltage (ΔE°), 772
Standard deviation A measure of the uncertainty in the average value of a property described by a Gaussian distribution, A.4
Standard enthalpy (ΔH°) The enthalpy change for the reaction that produces products in their standard states from the reactants, also in their standard states, 547
Standard enthalpy of formation (ΔH_f°) The enthalpy change for the reaction that produces one mole of a compound in its standard state from its elements, also in their standard states, 547
Standard hydrogen electrode (**SHE**) A standard reference electrode constructed from inert platinum metal, H_2 gas, and an acidic solution, with the latter two components at unit activity, 773
Standard molar entropy (S°) The entropy of one mole of a substance, 590–591
Standard molar Gibbs free energy of formation ΔG_f° The Gibbs free energy of formation of one mole of a substance from the most stable forms of its elements in their standard states at a specified temperature, 595
Standard reduction potentials, 773–776, A.43–A.44
Standard state, 546
Standard-state enthalpies, 546–549
Standard-state entropies, 590–592
Standing wave A wave that vibrates in a fixed region, 161
State function A property of a system that is uniquely determined by the present state of a system and not at all by its history, 523, 574
Stationary state A standing wave that exists indefinitely, 170
Statistical mechanics The branch of science that studies the relation between the structure of molecules and macroscopic observations, 395
Statistical thermodynamics The study of the relation between the statistical properties of a large number of particles and macroscopic observations, 575
Steady state concentration of O_3, 999
Steady states, 617
Steady-state approximation The approximation that the concentrations of reactive intermediates remain approximately constant during the course of a reaction, 853–854
Steric factor A factor (less than unity) in the Arrhenius equation that accounts for the fact that reactants must have a particular range of relative orientations in order to react, 864
Steric hindrance Physical blocking of a reactive site by a bulky component, 713

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Steric number (*SN*) The number of atoms bonded to a central atom plus the number of lone pairs on the central atom, 116, 118f, 119t
Steric strain, 312
Steroids Naturally occurring compounds that derive formally from cholesterol, 339–340
Stoichiometry The study of mass relationships in chemical reactions, 43
Straight-chain alkanes A type of hydrocarbon consisting of chains of carbon atoms bonded to one another by single bonds, with enough hydrogen atoms on each carbon atom to bring it to the maximum bonding capacity of four, 309–311
Strain energy, 311
Stratosphere, 993
Stratospheric chemistry, 998–1003
Strong acid An acid that has a K_a greater than 1, 678–679
Strong base A base that has a K_a greater than 1, 678–679
Strong field configuration Alternate for low-spin configurations, used because they occur at large values of the crystal field, 370
Strong field ligand A ligand that induces a large crystal field splitting in a transition-metal complex, 370
Strong force The force between nucleons that binds them together in the nucleus, 897
Structural clay products, 1077–1078
Sublimation A phase transition in which gas forms directly from a solid, 464
Subshell A group of orbitals in an atom with the same energy, 212
Substance A material that cannot be separated by physical means into two or more materials with different properties, 8
Substitutional alloy An alloy in which some of the metal atoms in a crystal lattice are replaced by other atoms, 1056
Substrate A reactant molecule that is capable of binding to the active site of an enzyme, 872
Sugar Small carbohydrate rings with the empirical formula CH_2O, 1120
Superconductor A material offering zero resistance to the passage of an electric current, 1083–1084
Supercooling A process by which materials reach kinetically metastable states at temperatures below their equilibrium melting points, 462
Supercritical fluid Term applied to a substance held at a temperature and pressure that exceed its critical pressure and temperature; at these conditions the distinction between liquid and gas no longer exists, 463
Superheating The phenomenon in which a liquid temporarily attains a temperature exceeding its boiling point without boiling, 462
Superposition, 144
Supersaturated solution A solution that temporarily contains more of a solute than the equilibrium quantity, 735
Supersaturated solutions, 735
Surface tension The resistance of the surface of a liquid to an increase in its area, 448–449
Surroundings The part of the universe that lies outside a system, 521
Symmetry In a molecule or crystal, the set of rotations, reflections, and other changes that, when applied to the structure, give a structure indistinguishable from the original, 1036
Syndiotactic form Polymer structure in which side groups alternate in regular position between sides along the backbone chain, 1114
Synthesis, 6
Synthesis gas A mixture of hydrogen and carbon monoxide, produced by the reaction of water vapor and a hydrocarbon (or coke) that is used as the starting point in the synthesis of methanol and other chemicals, 326
Synthetic metals, 1116–1117
Synthetic polymers
  fibers, 1111–1112
  nonlinear synthetic polymers, 1109–1110
  plastics, 1113–1115
  polymerization reactions for, 1106–1110
  rubber, 1115–1116
System A real or imagined portion of the universe that is confined by boundaries or mathematical constraints, 521

Tangent line, A.27
Temperature (***T* or *t***) The degree of hotness or coldness of an object as measured on some defined scale, 402–405
  effects of, on ΔG, 596–597
  effects of changing on equilibrium, 645
  entropy and, 584–585
  equilibrium constant, dependence of, 648
  kinetic theory of gases, 410–413
  reaction rates, effect on, 856–859
  vapor pressure, dependence of in equilibrium, 649–650
Termination The final stage in a chain reaction, 855
Termolecular An elementary reaction that involves the simultaneous collision of three reactants, 847
Ternary compounds, 8
Tertiary alcohol, 327
Tertiary amine, 334
Tesla (**T**) The SI unit for magnetic field strength, 967
Tetrahedral complexes, 370–372
Tetrahedral geometries, 362, 363f, 366
Tetrahedral site, 1046
Theoretical probability A prediction of the outcome(s) of an experiment based upon a theoretical model, A.33
Theoretical yield The amount of a product of a reaction predicted from stoichiometry assuming that the reaction proceeds without loss or side-reaction, 50–51
Thermal cracking The breaking down of long-chain hydrocarbon molecules in petroleum through heat, 319
Thermal energy, 520, 527–528. *See also* **Heat** (*q*)
Thermal equilibrium A macroscopic condition of a system characterized by the constancy of its pressure and temperature, 417
Thermal expansion, 446
Thermal shock The failure of a ceramic due to large, localized thermal expansion, 1075
Thermochemistry The study of heat effects in chemical reactions, 503
  adiabatic processes, 542, 551, 553–556, 576
  bond enthalpies, 549–550
  isothermal process, 551–553

reaction enthalpies, 542–546
reversible processes in ideal gases, 551–556
standard-state enthalpies, 546–549
Thermodynamic efficiency (ϵ) The ideal efficiency an engine would have if it could be operated in a purely reversible fashion, 581, 600
Thermodynamic equilibrium constant, 619, 625–626
Thermodynamic equilibrium state, 614
Thermodynamic process A process that leads to a change in the thermodynamic state of a system, 522
Thermodynamic properties, A.35–A.42
Thermodynamic state A macroscopic, time-independent condition of a system at thermal and mechanical equilibrium characterized by a well-defined temperature and pressure, 522
Thermodynamic universe The system and the surroundings for a process, 521, 574
Thermodynamics, 519–520
bomb calorimeters, 532
direction of change in chemical reactions, 646–650
enthalpy, 532–533
equilibrium, thermodynamic description of, 623–630
first law of, 529–530
heat and work for ideal gases, 536
heat capacities for ideal gases, 534–536
heat, 527–528, 536
heat capacity, 530–531, 534–536
heat transfer at constant pressure, 532–533
heat transfer at constant volume, 532
internal energy, 526–527
processes, 521–523
second law of, 580–581
states, 521–523
statistical thermodynamics, 576
systems, 521–523, 524f
thermochemistry. *See* **Thermochemistry**
third law of, 590–591
work, 524–526, 536
Thermolecular reaction, 847, 922–923
Thermosphere, 993
Third law of thermodynamics The entropy of any pure substance in its equilibrium state approaches zero at the absolute zero of temperature, 590–591
Thompson, J.J., 17–19
Titration A process in which a measured volume of solution of known concentration of one reactant is added to a second solution containing the other reactants; an indicator is added to signal the point at which the reaction is complete, 482–483
of polyprotic acids, 718–719
redox titration, 490–491
strong acid with strong base, 699–701
weak acid with strong base, 701–703
Titration curve A plot of the pH of a solution as a function of the amount of acid or base added to a base or acid, 699
Total energy, 78f
Transferases, 872
Transistor Solid state amplifiers in which the current that pass through the device is controlled by a voltage, much like the flow through a faucet is controlled by the position of the valve, 1095
Transition state The location of the highest energy configuration of a reacting system on a potential energy diagram, 858
Transition state theory, 864–865
Transition-metal element An element in the 10 middle groups of the third, fourth, and fifth periods of the periodic table, 70, 71f, 348, 385–386
coordination chemistry. *See* **Coordination chemistry/complexes**
crystal field theory. *See* **Crystal field theory**
optical properties, 374–376
oxidation states of, 351–352
physical properties of, 348–352
spectrochemical series, 374–376
Transitions between energy states, 149–151, 150f
Transuranic element Man-made elements with atomic numbers greater than that of uranium, 923
Traveling wave A wave that propagates through space, 161
Triatomic nonhydrides, 286
linear, 287–288
nonlinear, 288–289
Triglyceride An ester formed from glycerol by reacting all three of its hydroxy groups with fatty acids, 331
Triple bond Three pairs of electrons shared between two atoms, 108
Triple point The condition of temperature and pressure in which three phases of a substance coexist in equilibrium, 463
Triplet state An atomic or molecular quantum state that contains two electrons with parallel spins, a total spin of 1 and a degeneracy $g = 3$, 983
Troposphere, 993
Tropospheric chemistry, 994–998
Trouton's rule, 584
Tunneling current, 27
Turning point, 76
Turnover number k_{cat} The number of substrate molecules that react per enzyme molecule per second, 874

Unbound motion, 77, 78f
Uncertainty principle, 167
Unimolecular reaction An elementary reaction in which a single reactant molecule decomposes, 847
Unit cell The repeating motif or building unit from which a crystal could be constructed by simple stacking operations, 1038–1039
Unit conversions, A.9–A.11
Units, A.9
Unsaturated hydrocarbon A compound of hydrogen and carbon that contains double or triple carbon–carbon bonds, 314–315
Unsaturated solution, 734

Upfield Protons in compounds with resonances shifted to stronger magnetic fields than other compounds, towards tetramethylsilane (TMS), the standard NMR reference compound, 970
Uranium enrichment, 428–429

Vacancy, 1054
Valence Refers to the outermost electrons in an atom, 64
Valence band (VB) A band of occupied electron energy states responsible for bonding in a semiconductor, 795, 1091
Valence bond A method for describing bonding in molecules that focuses on the central role of the two-electron, two-center bond, a local picture, 1091–1092
and LCAO methods, 286–293
Valence bond (VB) theory Bonding theory in which electrons are viewed as localized either between particular pairs of atoms or as lone pairs on atoms, 236, 268
coordination complex bonding, 376–383
linear combination of atomic orbitals method compared, 286–293
orbital hybridization, 273–280
single bonds, 268–271
wave function for electron-pair bonds
multiple bonds, 271
polyatomic molecules, 271–273
Valence electron An electron (in the valence shell of an atom) that can take part in chemical bonding, 64, 84–85
Valence shell The outermost unfilled shell of electrons surrounding the nucleus of an atom, 84–85
Valence shell electron-pair repulsion theory, 64, 115–120, 281
Valence shell expansion The participation of more than eight electrons in the bonding of a molecule or molecule-ion, 113–114
van der Waals equation of state An equation of state used to express the physical behavior of a real gas: $(P + an^2/V^2)(V - nb) = nRT$, 418–420
van der Waals forces, 452
van der Waals radius The effective size of an atom or molecule; equal to the maximum distance at which nonbonded interaction with other atoms or molecules causes repulsion, 453
van't Hoff equation An equation relating the temperature dependence of the equilibrium constant to the enthalpy change in the reaction; $(K_2/K_1)\ (\Delta H°/R)\ [(1/T_1) - (1/T_2)]$, 648–649
Vapor pressure (P_{vap}) The pressure of the vapor coexisting with a confined liquid or solid at any specified temperature, 459–460, 649–650
Vapor-pressure lowering The vapor pressure of a solvent decreases when a nonvolatile solute is added, 492
Variational principle A principle in quantum mechanics that states that the energy of a molecule calculated using an approximate wavefunction will always be higher than the true energy, 291
Velocity A vector that specifies both the speed and direction of motion, 410
average velocity, A.12
Vibrational energy distribution, 557–558
Vibrational fine structure Peaks appearing in electronic absorption, emission, or photoelectron spectroscopy that are attributable to the excitation of vibrational transitions, 980
Vibrational spectroscopy
diatomic molecules, 955–962
polyatomic molecules, 962–966
Vibronic bands Transitions that correspond to simultaneous electronic and vibrational transitions between quantum states, 988
Virial theorem States that the average kinetic and the average potential energy of a system of particles interacting only through electrostatic forces are related as follows: $\overline{\mathcal{T}} = -\frac{1}{2}\overline{V}$, 93–94
Visible light, 1096
Volatile solutes, phase equilibrium in, 500
Voltmeter An instrument used to measure electrical potential differences, 767
Volume
effects of changing on equilibrium, 644–645
equivalent volume, 700
heat transfer at constant volume, 532
law of combining volumes, 14
Volumetric flask A flask that contains an accurately known volume of liquid when filled exactly to a calibration mark at a specified temperature, 476
VSEPR theory, 64, 115–120, 281
Vulcanization The process of treating crude or synthetic rubber or similar plastic material chemically to give it useful properties, 1115

Water
autoionization of, 677–678
electrolysis of, 816–818
special properties of, 457–458
structure of, 118f
Water gas shift reaction The reaction between carbon monoxide and water that is the dominant method for the commercial production of hydrogen gas, 619
Wave function (ψ) A function that describes the properties of a particle; its square (ψ^2) is proportional to the probability of finding the particle at a particular point in space, 168
electronic wave function, 242
for electron-pair bonds
multiple bonds, 271
polyatomic molecules, 271–273
single bonds, 268–271
for H_2^+ orbitals, 294–295, 296f–297f
hydrogen atom, 197–198
nuclear wave function, 242
for particles in cubic boxes, 180–182
for particles in square boxes, 178–180
in Schrödinger equation, 170–171
Wave motion, 141–144
Wavelength (λ) The distance between two successive crests or two successive troughs in a wave, 141
Wave-particle duality The result that light and small particles such as electrons behave as waves in some experiments and as particles in others, 157

de Broglie waves, 161–162
electron diffraction, 162–165
Heisenberg indeterminacy principle, 165–167
indeterminacy and uncertainty, 165–167
photoelectric effect, 157–161
Weak acid An acid that has a K_a smaller than 1, 681, 689–692
Weak base A base that has a K_b smaller than 1, 687, 689, 691–692
Weak electrolyte An electrolyte that dissociates only to a negligible extent in solution, 681
Weak field configurations High-spin configurations that result from small crystal field splittings, 370
Weak field ligand A ligand that induces only a small crystal field splitting in a transition-metal complex, 370
Work function The energy required to ionize an electron from a bulk solid, analogous to the ionization energy for gas-phase atoms and molecules, 160
Work (*w*) The product of the external force *F* acting on a body and its displacement *d;* when work is done on a system, the system's energy increases; when work is done by a system, the system's energy decreases, 524–526, 536
Writing balanced chemical equations, 43–45
X-ray scattering by crystals, 1039–1042

Zeolite An aluminosilicate having significant amounts of open space in its interior structure, 1074–1075
Zero-point energy The quantized energy associated with zero-point motion; $E_\nu = (1/2)h\nu$, 175, 237
Zero-point motion Nuclear motion that occurs even at absolute zero (0 K), 957
Zeroth order reaction A reaction that has a total order of 0; that is, one that proceeds at a rate that is independent of the concentrations of the species present in the reaction mixture, 840
Zinc blende structure of ionic crystals, 1048
Zinc-mercuric oxide cell A primary cell using the reaction $Zn(s) + HgO(s) + H_2O(\ell) \rightarrow Zn(OH)_2(s) + Hg(\ell)$ to generate a voltage, 802

Physical Constants

Avogadro's number	$N_A = 6.02214179 \times 10^{23}\ \text{mol}^{-1}$
Bohr radius	$a_0 = 0.52917720859\ \text{Å} = 5.2917720859 \times 10^{-11}\ \text{m}$
Boltzmann's constant	$k_B = 1.3806504 \times 10^{-23}\ \text{J K}^{-1}$
Electron charge	$e = 1.602176487 \times 10^{-19}\ \text{C}$
Faraday constant	$F = 96{,}485.3399\ \text{C mol}^{-1}$
Masses of fundamental particles:	
Electron	$m_e = 9.10938215 \times 10^{-31}\ \text{kg}$
Proton	$m_p = 1.672621637 \times 10^{-27}\ \text{kg}$
Neutron	$m_n = 1.674927211 \times 10^{-27}\ \text{kg}$
Permittivity of vacuum	$\epsilon_0 = 8.854187817 \times 10^{-12}\ \text{C}^{-2}\ \text{J}^{-1}\ \text{m}^{-1}$
Planck's constant	$h = 6.62606896 \times 10^{-34}\ \text{J s}$
Ratio of proton mass to electron mass	$m_p/m_e = 1836.15267247$
Speed of light in a vacuum	$c = 2.99792458 \times 10^{8}\ \text{m s}^{-1}$ (exactly)
Standard acceleration of terrestrial gravity	$g = 9.80665\ \text{m s}^{-2}$ (exactly)
Universal gas constant	$R = 8.314472\ \text{J mol}^{-1}\ \text{K}^{-1}$
	$= 0.0820574\ \text{L atm mol}^{-1}\ \text{K}^{-1}$

Values are taken from the 2006 CODATA recommended values, as listed by the National Institute of Standards and Technology.

Conversion Factors

Ångström 1	$\text{Å} = 10^{-10}\ \text{m}$
Atomic mass unit	$1\ \text{u} = 1.660538782 \times 10^{-27}\ \text{kg}$
	$1\ \text{u} = 1.492417830 \times 10^{-10}\ \text{J} = 931.494028\ \text{MeV}$ (energy equivalent from $E = mc^2$)
Calorie	$1\ \text{cal} = 4.184\ \text{J}$ (exactly)
Electron volt	$1\ \text{eV} = 1.602177 \times 10^{-19}\ \text{J}$
	$= 96.485335\ \text{kJ mol}$
Foot	$1\ \text{ft} = 12\ \text{in} = 0.3048\ \text{m}$ (exactly)
Gallon (U.S.)	$1\ \text{gallon} = 4\ \text{quarts} = 3.785412\ \text{L}$ (exactly)
Liter	$1\ \text{L} = 10^{-3}\ \text{m}^{-3} = 10^{3}\ \text{cm}^{3}$ (exactly)
Liter-atmosphere	$1\ \text{L atm} = 101.325\ \text{J}$ (exactly)
Metric ton	$1\ \text{t} = 1000\ \text{kg}$ (exactly)
Pound	$1\ \text{lb} = 16\ \text{oz}\ 0.4539237\ \text{kg}$ (exactly)
Rydberg	$1\ \text{Ry} = 2.17987197 \times 10^{-18}\ \text{J}$
	$= 1312.7136\ \text{kJ mol}$
	$= 13.60569193\ \text{eV}$
Standard atmosphere	$1\ \text{atm} = 1.01325 \times 10^{5}\ \text{Pa}$
	$= 1.01325 \times 10^{5}\ \text{kg m}^{-1}\ \text{s}^{-2}$ (exactly)
Torr	$1\ \text{torr} = 133.3224\ \text{Pa}$
